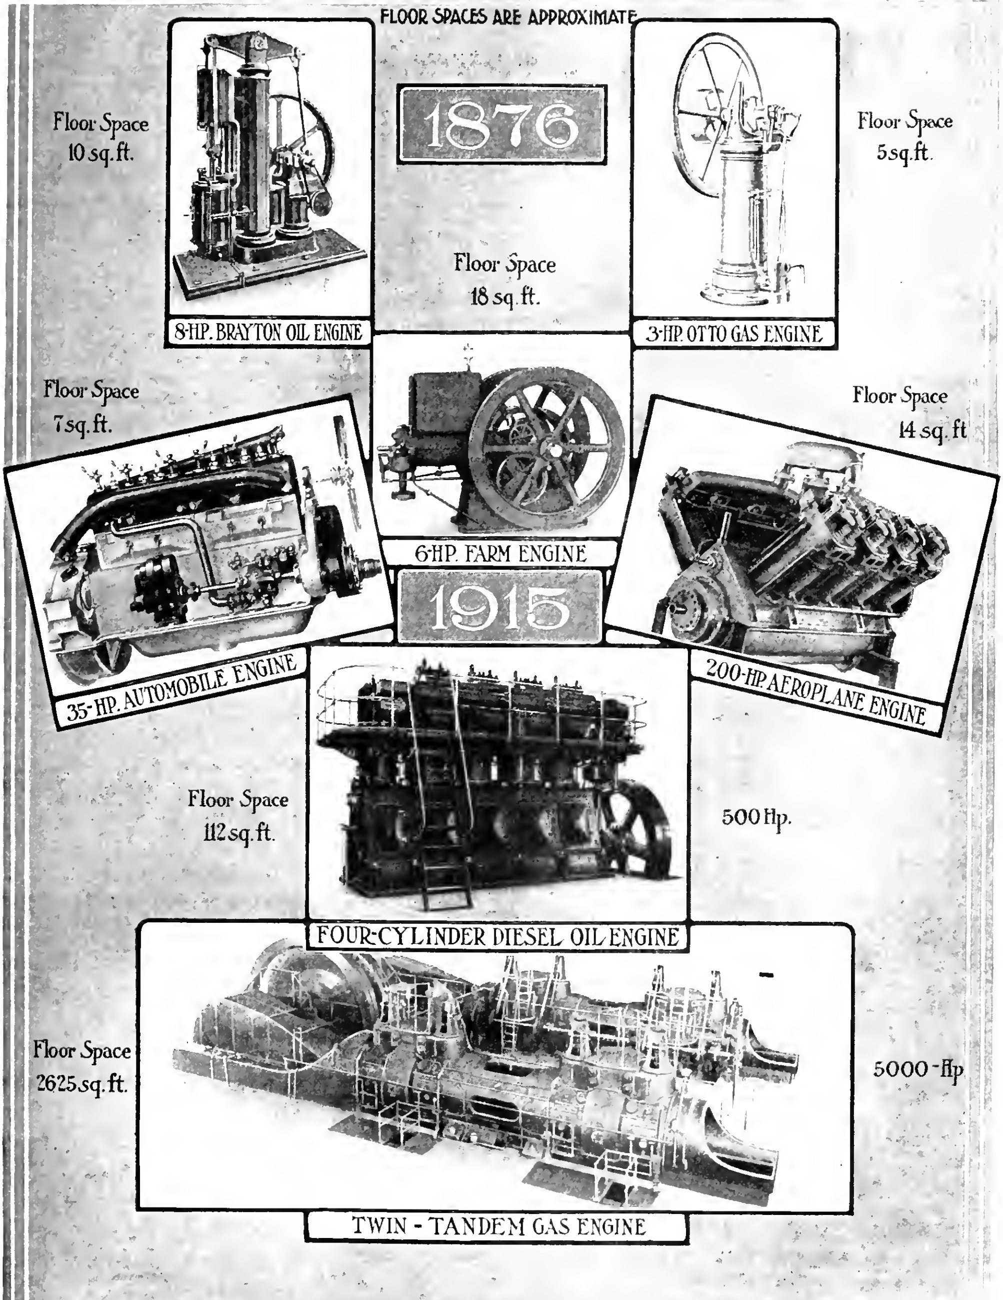
Otto	Single, single-acting, 9 in. x 5 ft. 10 in.	3			28 cu.ft. coal gas per hp.-hr.
Brayton	Double, tandem, vertical, 6x9-in.	8			About 2 lb. per hp.-hr.; oil of 0.85 sp.gr.
Automobile	6-cycle, 3½x5-in.	35 hp. at 1800 r.p.m.	500 lb.	14.5 lb.	
Aeroplane	8-cyl., 5x7-in.	200 hp. at 1700 r.p.m.	650 lb.	3¼ lb.	0.1 gal. per hp.-hr.
Farm	Single	6 hp. at 350 r.p.m.	1550 lb.	258 lb.	
Blast-furnace gas	Twin-tandem, 44x60 in.	5000 hp. at 83⅓ r.p.m.	1,900,000 lb.	380 lb.	
Diesel	4-cyl., 19x24½-in.	500 hp. at 200 r.p.m.	181,000 lb.	362 lb.	0.408 lb. per hp.-hr.

The automobile has been responsible for the development of the gasoline engine to a high state of perfection during the past ten years, the motor shown representing one of the standard makes. In accordance with the latest practice, this is a long-stroke, high-speed type with cylinders cast *en bloc,* and weighs only 14½ lb. per horsepower.

Since the practical application of the aëroplane followed closely that of the automobile, the experience with the latter was invaluable in the design of a motor for the former. The departures were essentially in the reduction of weight, increase of power and provision for continued operation at maximum load. The engine shown represents one of the most successful American designs, in which the weight has been reduced to 3¼ lb. per horsepower and the fuel consumption to 0.1 gal. per horsepower-hour—another vital point in aëroplane work.

The farm engine, on the other hand, had been developed with a view to ruggedness and foolproof operation, with fair economy and little attention to weight. The

EVOLUTION of the INTERNAL-COMBUSTION ENGINE



6-hp. engine shown, which is representative, weighs two and one-half times that of the 200-hp. aëroplane motor and three times that of the 35-hp. automobile motor.

The 5000-hp. gas engine is one of a number of similar units operating on blast-furnace gas and driving generators and blowers at the Gary plant of the U. S. Steel Corporation, and represents one of the largest of its kind now in operation in this country. Owing to the size of the cylinders, 44x60 in., and the pressures involved, the construction is necessarily heavy, and it is probable that 5000 hp. will be about the limit for engines of this type.

Just as the Otto engine was the pioneer in the gas-engine field, so was the Brayton in the oil-engine field. It needed, however, the genius of Dr. Diesel and the untiring efforts of the manufacturers who took up his patents to produce what is today the most highly efficient heat engine in existence. To obtain this economy extremely high working pressures are required—500 to 600 lb. per square inch as compared with 50 lb. in the Otto and slightly more in the Brayton. This necessitates heavy construction, the engine shown, which is one of American make that is being exhibited at the Panama-Pacific Exposition, weighing 362 lb. per horsepower.

Firing Low-Grade Fuel and Wastes

By Sterling H. Bunnell

Much has been done toward operating steam-boiler furnaces on wastes of various plants, in utilizing slack and culm or coal-mine wastes and in developing power from city garbage. The question of economy is of first importance in deciding whether or not a low-grade fuel should be used. There are three elements to be considered; namely, the quantity of heat which can be produced per pound of fuel, the efficiency with which this heat can be transmitted to the boiler, and the cost of the fuel put into the furnace. Coal at $3 per ton delivered at the fire room and having a heat value of 10,000 B.t.u. per pound and fired in a furnace under conditions which give 70 per cent. boiler efficiency, must be fired at the rate of 10,000 divided by 0.70, or 14,300 B.t.u. of coal to put 10,000 B.t.u. under the boiler; and as 2000 times 10,000 B.t.u. cost 300c., the cost of 14,300 is 0.214c. Assuming that it costs 30c. to fire a ton of this coal, the cost of the coal in the furnace should be increased by $\frac{30}{300}$, or $\frac{1}{10}$, making 0.235c. to put 10,000 B.t.u. into the boiler.

In comparison with this coal, suppose a fuel to be obtainable at 50c. per ton, giving only 4000 B.t.u. heat value per pound and capable of being fired with a boiler efficiency of 50 per cent. The computation shows 20,000 B.t.u. required to put 10,000 B.t.u. into the boiler; so, as 8,000,000 B.t.u. cost 50c., 20,000 will cost $\frac{1}{8}$c. If this fuel costs 50c. per ton to fire, it will be necessary to add $\frac{50}{50}$, or 100 per cent. to obtain the cost of 10,000 B.t.u., making the amount 0.25c. There is no money in firing this fuel under these conditions, as the cost is slightly more than the cost of good coal. It would, however, be desirable to use the low-grade fuel if it were a waste accumulating like sawdust and wood refuse in wood-working factories, in which case it would cost less to burn it than to cart it away. If the value of the fuel were 6000 B.t.u. per pound instead of 4000, it would figure $\frac{1}{12}$c. for fuel and the same for firing, making 0.166c. for 10,000 heat units delivered to the boiler as compared to 0.235c. for the coal at $3 per ton.

In every case it is important to consider all the conditions in connection with the various fuels which can be obtained, not forgetting that good coal can be fired by average firemen, while low-grade waste requires special skill to handle it successfully.

The mechanical difficulties in burning low-grade fuel are important and must be met by special construction and firing methods. Fine coal and dust tend to fall through the grates, no matter how small the openings are made. These fuels also tend to pack together, making a strong draft necessary to force air through the fire. Agricultural wastes, like spent tan bark, often contain a weight of water equal to or greater than the combustible. It costs as much to evaporate water in the fuel as in the boiler.

The draft for burning most kinds of low-grade fuel should be strong. The worst and wettest garbage is successfully burned in furnaces supplied with forced ashpit draft under pressures of 2 in. and more of water. If means can be provided to heat the air before entering the ashpit, by using waste heat from the flue gases, the combustion in the furnace is improved. The moisture content of the fuel should be reduced as much as possible. Sometimes this advantage can be gained by a change in the mechanical operation producing the waste. If not, it is usually necessary to fire the fuel as it comes, regardless of the quantity of water it may contain, as fuel-drying operations on a large scale are practically impossible. One instance to the contrary, however, is the burning of sewage sludge, which is first dried by passing it through a rotary drier in which hot flue gases circulate. Sewage sludge, however, has no heat value, and is burned merely to dispose of it without nuisance.

With most materials containing much moisture the drying must take place in the furnace and this requires careful watching and stoking. Sometimes a drying hearth can be provided on which the wet fuel can be first charged and allowed to dry in the direct heat of the fire. It is important to observe that the fuel must not be burned faster than it can be dried, or the fire will soon be blocked and extinguished by wet material. The fireman must, therefore, manage to keep a brightly burning fire of dried fuel and to supply wet fuel so that most of the moisture will dry off before the fresh material is charged on to the burning surface.

A common difficulty with low-grade fuel, particularly coal waste and the rubbish from cities, is the presence of mineral matter which forms clinker. With good coal the proportion of noncombustible substance amounts to only a small percentage, not enough to form very bad clinker. Factory ashes from well handled fires contain only a small fraction of unburned carbon and are finely divided into small particles. From the average house furnace, however, the ash contains one-half or more of combustible carbon. Such ash, fired in a suitable furnace with forced draft, would be of commercial value. As the combustible portions of low-grade fuel burn away, the areas of worthless ash and clinker remaining become larger. The melting clinker tends to inclose particles of unburned coal and prevent air from reaching it. With all low-grade fuels, therefore, the fire must be carefully watched, and the free passage of air through it must be maintained by stoking, and breaking up areas where combustion is giving out from lack of accessible fuel.

Editorials

Flywheel Explosions

In the power plant the boiler is commonly regarded as the most dangerous part of the entire equipment. Probably nine out of every ten engineers are of this opinion, and it is not surprising, as the number of boiler explosions in this country is excessive, the casualty list is large and the value of property destroyed is greater by far than in other lands, where rules for safety are more rigidly and uniformly enforced. From people who should know, however—men dealing every day in power-plant accidents—comes the surprising information that the flywheel is more dangerous than the boiler. In other words, the ratio of flywheel explosions to the number of flywheels installed is greater by one-third than that for boilers. This does not refer to totals, as boiler explosions would then have the lead by a large margin, owing to the greater number of boilers installed.

Viewing power-plant safety from this standpoint, it is evident that more attention is due the flywheel. Every boiler has its safety valve, and if statistics are of any value every flywheel should have at least equivalent protection.

The potential energy stored in the flywheel is tremendous, although, owing to the swift and even turning, appearances are to the contrary. There is no indication of danger, and as a result, proper precautions are not often taken. The rim velocity of an average flywheel is close to a mile a minute and it is seldom that a wheel explodes at a velocity lower than three miles per minute, or 264 ft. per second. The damage that might ensue from the heavy pieces of disrupted wheel moving at this terrific velocity may, perhaps, be imagined. Numerous articles in the past have recounted the actual results.

Property damage, however, is only a minor consideration when compared to the safety of employees. For every flywheel explosion the average is one man killed or injured, and the toll for the year is so heavy as to warrant every precaution which will tend to prevent these accidents.

The function of the governor is to control the speed of the engine and with it the flywheel. Usually, there is also included a safety provision to guard against emergencies, but this is a secondary consideration in the design, and there are certain contingencies which it will not take care of. With this single protection against accident, derangement of the valve gear or failure in the governor's own mechanism may result in disaster. An independent device is needed to make safety doubly sure, and this device is the safety stop.

When the engine reaches a predetermined speed, the stop automatically shuts off the steam and relieves the engineer of the dangerous task of trying to close the throttle under emergency conditions. If the governor fails to work, the stop is on guard to prevent destruction. In military circles the secret of success lies in a strong reserve to supplement and reinforce the first line. In the engine room the stop occupies the same position. It is ready to come to the rescue of the governor, and if kept in good working condition it will reduce the number of accidents and afford added protection to the engineer.

Neglecting the damage to property and the interruption of service usually resulting from a flywheel explosion, the device is warranted from the standpoint of safety. At best, power-plant work is dangerous and there are few places in which the "safety-first" slogan is more urgent. The life of at least one engineer every week is surely worth saving, and if the installation of safety stops will effect even a small reduction in the fatalities, there is not a power plant in the country which should not have one. It is due the engineer, and incidentally, the reduction of property loss may be worth while to the owner.

Compulsory Boiler Inspection

In most of these United States a man may buy any old kind of a boiler that he wants to, new or second-hand, have it set up by the local plumber, hire the hunk to run it who will do it for the least money, and put any amount of pressure upon it that he sees fit.

It may be said that ordinary business prudence and fear of damage to himself and his own people and property would preclude a man from taking too long chances; but any government or insurance inspector can tell of numbers of death traps set by the cupidity or, in justice be it said, more often by the ignorance of the boiler user.

Last year the inspectors of the Hartford Steam Boiler Inspection & Insurance Co. condemned outright 756 boilers as unsafe to use, and pointed out 23,012 defects involving the safety of the boiler.

In the same time the inspectors of the Fidelity & Casualty Co., of New York, condemned outright 340 boilers and pointed out 11,130 serious defects.

This, after the boilers had been prepared for inspection by the agents of their owners. These are only two, but the largest two, of a number of companies carrying boiler insurance. There are nine such companies doing business in Massachusetts.

Is it not reasonable to suppose that, if these boilers had not been inspected by specialists, there would have been a considerable addition to the loss of life and property by boiler explosions?

It is true that boilers which have been insured and inspected have exploded. Inspectors are human and fallible. They may overlook obvious faults, and there are hidden cracks in lap seams and flanges which the best of them could not detect; but this is no reason for condemning the whole system and renouncing the good which they are doing.

If the inspection incidental to insurance has revealed this number of serious defects, why would not an equally thorough and efficient inspection of uninsured boilers reveal an equally large proportion of defects and obviate an equally large proportion of explosions?

Are the boilers whose owners take a chance apt to be better selected, installed and operated than those whose owners take the precaution to insure them?

In Massachusetts 17.969 boilers are inspected by the insurance companies. The state inspects the rest of them, 6723, itself. This is what all the states ought to do. Public safety ought not to be left to the "ordinary business prudence" of any man in the matter of boilers more than in storing and using gasoline or explosives.

A boiler full of hot water under pressure is just as dangerous under a sidewalk or a building as a keg of gunpowder.

The necessity of governmental regulation seems too obvious to question. Everybody does it but us.

Safety-Valve Capacity

One of the hardest nuts which the American Society of Mechanical Engineers' committee, while preparing the standard boiler code, had to crack was the question of safety-valve capacity. Previous to the last annual meeting the manufacturers of safety valves got together and said: "Now, let us go at this thing scientifically. What has a safety valve to discharge?"

"Steam."

"How much steam?"

"As much as the boiler can make—and then some."

"How much can the boiler make?"

"Ah! that depends upon the boiler, and the furnace, and the fuel, and the air supply, etc. But if we take the heat value per pound of the fuel and multiply that by the number of pounds which can be burned under the boiler per hour, multiply that again by the combined efficiency of the boiler, furnace and grate, and divide the product by the difference between the total heat per pound of steam as made and the heat per pound in the feed water, we shall find the amount of steam made per hour. Then we can give them a table of the discharge capacities of our valves of different sizes, and they can tell right away how many valves, of what size, it will take to discharge this amount of steam."

But the discharge capacity of a valve depends upon its lift, and there are makers who believe in high lifts and those who do not. After long discussion the valve manufacturers agreed unanimously upon the table of capacities which appeared in the third and fourth reprintings of the tentative report of the committee.

The proposed method evoked storms of protest. The conception of the country pipe fitter struggling with the B.t.u. per pound of fuel, the heat of the liquid and of evaporation, and the possible effect of draft on rate of combustion, was a little too much. The government and insurance inspectors vowed that it would take longer to inspect the safety valve than it would the boiler.

The question was therefore turned back at the safety-valve men, and they, unable again to meet upon a common ground as to a standard rate of discharge for safety valves, have presented a table giving the discharge in pounds per hour at minimum, intermediate and maximum lifts. The three-inch valve of no manufacturer shall lift less than five-hundredths nor more than one-tenth of an inch at one hundred pounds gage, and it is guaranteed to discharge certain amounts per hour at each of these lifts and the average of them.

At its rated capacity a boiler is expected to evaporate about three pounds of water per square foot of heating surface. In some of the large stations they are evaporating ten or more. If it be assumed that any boiler may possibly be subjected to this rate of evaporation some time in its life, and the amount of steam to be provided for by the safety valve be assumed at ten times the number of square feet of heating surface, the calculation would become an extremely simple one. A boiler having one hundred square feet of heating surface might possibly be subjected to conditions under which it would evaporate ten thousand pounds of steam per hour, and to discharge this would, by the table submitted, require one four-and-one-half-inch or two three-inch valves, at one hundred and fifty pounds gage pressure.

This gives somewhat more valve area than is common in ordinary practice, and ordinary practice seems to be good enough, for we never knew of a boiler which exploded for want of safety-valve capacity when the safety valve was operative at all. The modern high rate of combustion is provoked and intentional, and can be attained only purposely by well managed fires urged by artificial draft. A boiler even in the heart of a conflagration would not accidentally do as much. A smaller though somewhat less convenient factor than ten would doubtless have to be used, but it would seem that the heating surface is the logical measure of the safety-valve capacity. The grate area may be changed from time to time, oil or gas may be used, the boiler may simmer under a natural draft or fume under the action of a blower, the fuel may vary from wet tanbark to oil or natural gas, but the number of square feet of heating surface is always the same, and if the boiler is provided with safety-valve area to take care of all the steam which that heating surface can generate, it will make no difference who gets the boiler or what he does with it, as far as this phase of the question is concerned.

Committee work in engineering organizations is usually hard, tedious and trying, but the fellow who never did any is the one who most loudly proclaims that it's a sinecure.

Beats all how some engineers can go through most of their lives telling themselves they do not need to keep studying the progress of their calling, and then suddenly become most enthusiastic over engineering educational work. In nine cases out of ten you will find that the change of front is due to the central station making a strong bid for their jobs.

Several inquiries have come to us regarding the decision of the American Manufacturing Company, of Greenpoint, L. I., to discontinue running its power plant and to purchase power from the Brooklyn Edison Company. It would seem that the amount of power here used could be generated on the spot more cheaply than a public service company could furnish it, and we sought an interview with the officials of the company for the purpose of learning, if possible, the facts which led to the decision. The only statement which was forthcoming was that it had been made to the advantage of the American Manufacturing Company to purchase its current from the Brooklyn Edison Company and that there was nothing to discuss regarding comparative costs. The mere cost of production is not always the controlling factor in the interrelations of Big Business.

Correspondence

Transformer Connections

After reading Mr. Fox's article on transformer connections in the issue of Jan. 12, I feel that although his process of testing the polarity of transformers and grouping them to obtain various results is instructive, it could be somewhat improved by adding a simplified method for remembering the various connections and ways for determining when the devices are connected properly.

The opinion seems to exist among practical electricians with a limited knowledge of electrical theory, that there is one particular kind of parallel and series connections for batteries and some other kind for transformers or other devices; but this is not true, as there is one hard and fast rule that applies to all. When batteries are connected in parallel all positive terminals are connected together, likewise all negative terminals, and then a positive and a negative lead are brought out from the group as indicated in Fig. 1. What is true for this is also true for any other electrical device, from which the rule for parallel connection may be obtained, namely, connect like poles to like poles and bring out two unlike leads.

In connecting batteries in series a positive terminal is connected to a negative terminal until all are connected except one negative and one positive; these two are connected to the device to be operated. This is indicated in Fig. 2 and is true for any device, from which the law for series connections is obtained, namely, connect unlike poles until but two remain unconnected; bring these two out to the load.

When transformers are connected in parallel or series it is first necessary to determine which are like poles. After the transformers have been set symmetrically, consider all right-hand terminals of one polarity, say positive, and all left-hand terminals of the opposite polarity; then proceed as though connecting batteries, as indicated in Fig. 3, which shows two transformers connected in parallel. By comparison with Fig. 1 it will be seen that the grouping is similar. There is always a chance of the leads being brought out of the transformers to give the wrong polarity, and to guard against a short-circuit, connect a piece of two- or three-ampere fuse-wire in the low-voltage side as shown at *f*, Fig. 3. Then close the primary circuit with the secondary disconnected from the load, and if the connections are correct the fuse will not blow.

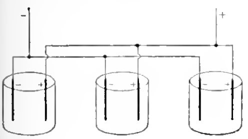


FIG. 1.

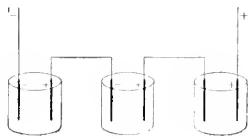

FIG. 2.

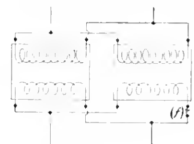

FIG. 3.

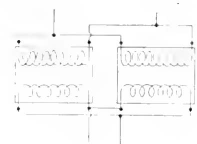

FIG 4

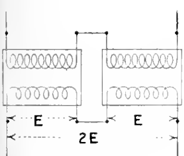

FIG. 5.

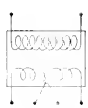

FIG 6.

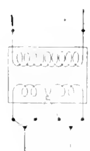

FIG. 7.

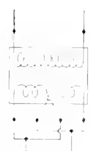

FIG. 8.

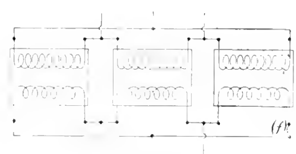

FIG. 9.

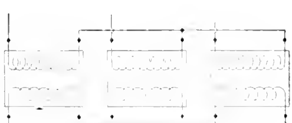

FIG. 10.

CONNECTIONS OF TRANSFORMERS

If the fuse blows, cross either the primary or the secondary leads of one transformer as in Fig. 4; this will correct the defect, irrespective of which transformer had the wrong polarity. A test lamp or voltmeter may be used in place of the fuse. If the connections are correct the lamp should not light nor the voltmeter read. The fuse, however, is not only the most likely to be at hand, but is also the most reliable, as there is always a chance of a defective lamp or instrument.

When transformers are connected in series the same rule is followed as in batteries, and by comparing Fig. 5 with Fig. 2 it will be seen that the same relation of connections is maintained in both cases. However, if the leads are brought out of one transformer to give the wrong polarity, the proper voltage relation will not be obtained on the secondary side, which should be as indicated, and instead of the voltage being 2E between the two outside terminals, it will be zero. This can be remedied by crossing the secondary or primary leads on one of the transformers.

There are usually four leads brought out on the low-voltage side of all small commercial transformers; the two center leads being brought out crossed as in Fig. 6. This brings the like terminals of each coil adjacent to each other and eliminates crossing them on the outside when the coils are connected in parallel as shown in Fig.

7. Care should be taken not to connect the two terminals of each coil together as in Fig. 8, for this would be a dead short-circuit.

It may be easy for those familiar with the laws of graphics and alternating currents to depend upon connecting transformers so that they form an angle of 60 or 120 electrical degrees to each other to obtain a delta or star-connection on a three-phase circuit; but for the man that does not possess this knowledge, the fact that the delta connection, as far as the grouping is concerned, is nothing more than a short-circuited series connection should greatly simplify the matter, as will be understood by referring to Fig. 9. The three transformers are connected in series as are the batteries in Fig. 2, but instead of bringing out the two outside terminals to the load as in the battery connections, they are connected together to form a complete loop with a lead brought out from each junction point. To make sure that the connections have been made properly and the transformers are all the same polarity connect a piece of fuse wire as at *f*; if the fuse does not blow the connections are correct and the transformers are of the proper polarity.

The making of a star connection may be greatly simplified if it is remembered that like terminals of the transformers are connected together (it may be either the right-hand or the left-hand terminal) and the other three terminals are brought out to the line as in Fig. 10, which shows the three right-hand terminals connected, with the three left-hand ones brought out to the line.

Boiler Explosion at Menlo, Iowa

A disastrous boiler explosion occurred at the electric-light plant at Menlo, Iowa, shortly after 6 p.m., Feb. 14, killing three men instantly and completely demolishing the power house.

The boiler was of the return-tubular type, of 60-hp.

Fig. 1. Wreckage after Boiler Explosion

capacity. The safety valve was set at 95 lb. The rupture occurred in the rear sheet, which ripped entirely around where it joined the middle sheet, and was thrown a distance of about 300 ft., breaking a number of telegraph lines in its descent. The rear flue sheet was thrown a distance of 600 ft., and fell through the roof of a dwelling shown in Fig. 2 and landed in the kitchen. A heavy stop valve fell in the yard of the same residence. As the explosion occurred at the supper hour, the occupants of the house were seated at the table in an adjoining room and no one was injured.

The power house stood some distance from other buildings and being constructed of heavy concrete, the injury to the surrounding property was slight, consisting of some damage to roofs due to falling pipes, brick, etc. The heavy concrete walls, together with the fact that the boiler was set below the ground line, undoubtedly prevented much damage to the adjoining property.

No definite cause is known for the explosion, as all those who might know were killed. The boiler was about 18 years old and fairly clean and free from scale. The men were evidently sitting directly in front of the boiler, judging from the position in which the bodies were found.

Fig. 2. The Tube Sheet. Fig. 3. The Rear Circular Sheet Near Railway Track. Fig. 4. Close View of Pitted Sheet

Had the accident occurred a few minutes later it is likely the loss of life would have been much greater, as it was the custom of a number of the employees and others to spend some time at the plant after the supper hour.

S. Kirlin.

Stuart, Iowa.

[Figs. 2, 3 and 4 were received later from J. C. Bruff, Atlantic, Iowa, without additional information as to the probable cause of the explosion.—Editor.]

Some Reasons for Different Rates

There appears to be a prevalent idea that central stations sell power below cost to large consumers and make up the loss by charging the small ones high rates. It doesn't seem to occur to some of these people, however, that if this were true it would be a wise policy to cut out the large consumer and make a still larger profit.

The average power company has a scale of many different rates to cover different conditions, and the writer will attempt to explain the reason for some of them. To make the explanation more simple, he will compare the product and sale of electricity to ice. Let the square figure represent a pond with a crop of ice. Jones, the iceman, builds up a trade from house to house to sell in lots of 50 to 100 lb. daily from his wagon and will cut the area marked *A*. He also looks over the grocery and provision markets that will take 200 to 500 lb. daily and estimates that the area marked *B* will supply them. There is likewise a large demand from the ice-cream factories and soda fountains, each of which will require 1000 to 2000 lb. per day, and he secures that business, requiring him to cut area marked *C*.

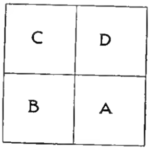

Diagram Representing Pond

In the town where Jones does business Smith and Brown have small icehouses which are badly in need of repair, and it occurs to them that Jones can harvest the balance, or area marked *D*, cheaper than they could harvest their own, so they arrange to take that amount from Jones. To harvest ice marked *A*.

Cost of labor per ton	$1.00
Cost of machinery, house and other equipment per ton	1.50
Total cost per ton	$2.50

To harvest *B*, in addition, will require another story on the icehouse and the labor will be more efficient, making

Cost of labor per ton	$0.85
Cost of machinery, house and other equipment per ton	0.85
Total cost per ton	$1.70

To harvest *C*, in addition, will require another story on the icehouse and the labor will continue to become still more efficient, making

Cost of labor per ton	$0.75
Cost of machinery, house and other equipment per ton	0.60
Total cost per ton	$1.35

To harvest *D* will require another story on the icehouse, still using the same machinery as at first, and there will be a slight improvement in labor, making

Cost of labor per ton	$0.70
Cost of machinery, house and other equipment per ton	0.45
Total cost per ton	$1.15

Leave out the shrinkage and other losses before summer and consider the delivery.

A two-horse team is worth $5 per day and two men will cost about $5 more, making $10. These will make two trips per day, delivering one ton per trip to householders taking 50 to 100 lb. of ice. The usual rate to consumers of small quantities is about $8 per ton, so it is easy to figure the profits:

Two tons at $8 per ton		$16.00
Cost of two tons at $1.15	$2.30	
Cost of team	5.00	
Cost of two men	5.00	
		12.30
Gross profit		$3.70

The rate to markets which take 200 to 500 lb. may be $6 per ton, and a similar team would make three trips per day, or deliver three tons, the profit working out as follows:

Three tons at $6 per ton		$18.00
Cost of three tons at $1.15	$3.45	
Cost of team	5.00	
Cost of two men	5.00	
		13.45
Gross profit		$4.55

The rate to ice-cream factories and soda fountains, which take 1000 to 2000 lb. at a time, and allowing the team to make five trips daily, may be $4 per ton, working out as follows:

Five tons at $4 per ton		$20.00
Cost of five tons at $1.15	$5.75	
Cost of team	5.00	
Cost of two men	5.00	
		15.75
Gross profit		$4.25

Now Smith and Brown have arranged to take their own ice from the house, using about ten tons each per day, and Jones made them the ridiculous price of $2 per ton; but the profit comes out as follows:

10 tons of ice at $2	$20.00
Cost of 10 tons at $1.15	11.50
Gross profit	$8.50

It is evident that Jones cut down his cost by harvesting the whole field, and if he had stopped at *A* he would have had to charge at least $10 per ton to householders, to make a reasonable profit.

On the other hand, he could not charge the markets, ice-cream factories and Smith and Brown (whose business caused the whole lot to be cheaper) the same price as the householder for two good reasons—he couldn't get the business, and if he did the profits would be unreasonable.

If Jones found it necessary to give up part of his business and had his choice, which part would he drop?

CHARLES R. SEED.

Worcester, Mass.

Oil-Engine Tendencies

In the Feb. 9 issue, under the heading "Oil Engine Tendencies," Mr. Ward makes a number of statements to which I wish to take vigorous exception, based on many years of work on this subject.

Oil-Fuel Situation

Mr. Ward states that, since petroleum is composed of 15 per cent. gasoline, 15 per cent. kerosene, 10 per cent. high-grade distillate above 39 deg. Baumé, 10 per cent. low-grade distillate below 39 deg. Baumé, 15 per cent. lubricating oils and a remainder of 5 per cent. "slop," not over 10 per cent. is of such a nature as to require a crude-oil engine to utilize it. In Mexico, for instance, there is much oil which is of an asphaltic base and so low in volatile or refinable products as to be practically valueless for refining. The oil to which Mr. Ward referred was evidently of a paraffin base, which constitutes less than half the oil supply. If I am correct, over 60 per cent. of the raw product as drawn from the wells is available only for use in the heavy-oil engine, for generating steam, etc.

Semi-Diesel Type

It is further stated in the article that by changing from 500 to 300 lb. compression, the fuel does not burn immediately upon entering the combustion space, as the heat of compression is insufficient to ignite it. I have demonstrated that for a running engine 150 lb. is sufficient to ignite the fuel,* the hot plate being needed only for starting in the engine which I have developed. Mr. Ward says that the semi-Diesel type should be built as heavy as the regular Diesel; further, that the maximum pressure in the semi-Diesel is 500 lb. The Diesel must have a relief valve set at from 750 to 800 lb., indicating that the pressure frequently runs to 800 lb., whereas the semi-Diesel pressures do not run over 500 lb. According to this the semi-Diesel need be built only five-eighths as strong as the Diesel. The writer's experiments would tend to indicate that an oil engine can be built which need be but little heavier or stronger than the conventional gas engine.

Two-Stroke-Cycle Type, Fuel Injection and Hot Bulb

Of these points I have little to say, except to voice the opinion that the two-stroke-cycle type can be beaten on every point by the four-stroke-cycle type. The fuel injection is still very crude and is only slightly developed from what Brayton disclosed in 1890. It seems possible to greatly improve upon the present arrangements, but my experiments along this line as yet are incomplete. Hot bulbs seem to be uncalled for and are not very practical for large sizes.

Water Injection

This is the weakest point in the semi-Diesel type. Mr. Ward says that a pressure of 300 lb. is not sufficient to ignite the fuel, and yet he mentions the use of water injection in order to keep the temperature of compression within bounds. The use of water from a thermodynamic point is as wise as it would be to propose to govern an engine by an automatic brake that would absorb the unneeded power and in this way regulate the speed of the engine. Provided the engine can first be started, the Brayton fuel injection can be used on the semi-Diesel type and the waste from the water injection can thus be avoided.

Lubrication

The writer fails to see any problem in the lubrication of the oil engine not met in the gas engine. The jacket should be used to keep the temperature at a point which is reasonably below the safe line. To go below this point is wasteful; to go above it is dangerous.

The writer got into a controversy with an engineer in the employ of the original Diesel Engine Co. of America in 1904. The point was the maximum temperature in the engine, which at that time was taken to be the temperature of compression. Temperature calculations were made from a Diesel diagram and submitted to the company. The answer was that the engine worked and that was all that the firm was interested in. The writer was interested, however, and as a result of this lack of interest on the part of the oil-engine men concerning their engine, has been able to be the first applicant in the U. S. Patent Office on many lines of development of the oil engine. There is a thermodynamics of the steam engine. In the gas engine one is limited by premature explosion, in the amount of compression carried. In the Diesel, owing to starting troubles, one is limited in the minimum compression on account of lack of ignition. The oil engine, once it is started or warmed up, can be operated on any pressure from, say 125 lb. up. The best method for getting the oil engine into a condition to avail itself of this low pressure of compression depends upon the use of the engine. For large engines there can be no better method in the opinion of the writer than to follow the practice of the steam engineers, namely, that of warming up their engines by the introduction of steam into the jackets.

John F. Wentworth.

Quincy, Mass.

*See paper by the writer presented before the last meeting of the Society of Naval Architects; also abstract of same in "Power," Jan. 26, 1915

Driving Boilers and Bursting Tubes

Referring to the discussion of the above subject which was started by the picture and story of a burst boiler tube given in the Dec. 8, 1914, issue, page 805, the editorial comment on page 95, Jan. 19, 1915, is correct in stating that increasing the furnace heat increases the evaporation. However, Mr. Kent is right in saying that there may be times when the heat will be greater, as when the steam gets low and it becomes necessary to regain the pressure; the heat must be increased and also the evaporation, but the average evaporation remains the same.

The temperature of the water in the tube has nothing to do with overheating the tube, for the water, either hot or cold, will take up all of the heat that can be forced through the insulation of oil or scale in the tube.

The pressure has a great deal to do with the bursting of the tube, as it will require more overheating to burst the tube at low pressure than it will at high pressure.

Spokane, Wash.

Trouble with Oil Separator

Referring to the query by H. G. Goodwin in the issue of Feb. 9, page 207, I would suggest that for a possible source of trouble he should examine his sewer connections. Referring to his sketch, we find that, as nearly as can be estimated, there is a difference of ten to twelve feet head in the two connections leading to the sewer. If the sewer connection is not adequate and is connected to other sources, it is possible that water backs up in the pipe leading to the oil separator in the basement until conditions allow the oil and exhaust steam to pass over into the heating system. This oil would naturally be carried into the heating system through the lower oil separator on account of the difference in head between the pipes leading from the two oil separators.

If such a condition existed the remedy would be to disconnect the exhaust from the 25-hp. engine in the basement and connect it with the same piping which leads from the 100-hp. engine on the first floor. This would remedy the trouble if the oil were passing into the heating system from the basement floor only. If oil then passed over and if the rain-leader connections from the building led into the same sewer, the remedy would be to run independent sewer connections from the oil separators and from the heating system.

Washington, D. C.

Inquiries of General Interest

Chatter of Reducing Valve—What will cause a reducing valve to chatter?

E. H

A reducing valve is likely to chatter if the valve is large in proportion to the use of steam at the reduced pressure. In most cases the remedy for chattering is to throttle the supply or to throttle the valve which admits low-pressure steam to the diaphragm.

Advantages of Mechanical Stokers Burning Cheap Fuel—Why are mechanical stokers better adapted for burning the cheaper grades of fuel than hand firing?

G. M.

A mechanical stoker can usually handle a lower grade of fuel because it carries a cleaner fire, the coal is fed more uniformly and the air required for combustion can be supplied at a more uniform rate.

Percentage of Output for Excitation—What percentage of output of an alternating-current generator is required for excitation?

L. H.

The excitation of a generator will vary according to the load and the voltage, but, under normal conditions and rated load, will amount to from 1 to 2 per cent. of the generator output in large machines and slightly more in smaller machines.

Weight of Cast Iron, Wrought Iron and Steel—What is the weight per cubic inch of cast iron, wrought iron and steel?

G. L.

The weight of each varies with the texture and method of manufacture. The approximate mean values used in calculations are 0.2604 lb. for the weight per cubic inch of cast iron; 0.2779 lb. for wrought iron, and 0.2834 lb. for steel, but more commonly 0.26 lb. for cast iron and 0.28 lb. for both wrought iron and steel.

Heating of Conduits Containing Wires of Polyphase Circuit—When the wires of a polyphase circuit are put in separate conduits, instead of all in one conduit as is usually done, why is it that the conduits heat?

E. D.

The greater the distance between conductors of a polyphase circuit, the greater the induction set up between these conductors, hence, the greater the heating effect thus produced. Putting the conductors in the same conduit lessens the distance between them, thereby cutting down the induction and the heating effect.

Required R.p.m. to Develop 1000 Hp.—How many revolutions per minute would be required for development of 1000 hp. by a pair of hoisting engines having cylinders 30x60 in. and a mean effective pressure of 90 lb. per sq.in.?

W. C. R.

As 1000 hp. would represent a development of

$$33{,}000 \times 1000 = 33{,}000{,}000 \text{ ft.-lb.}$$

of work per minute and as one revolution of the engine would develop

$$90 \times (30 \times 30 \times 0.7854) \times {}^{60}/_{12} \times 4 = 1{,}272{,}348 \text{ ft.-lb.}$$

then for the development of 1000 hp. the engine would have to make

$$33{,}000{,}000 \div 1{,}272{,}348 = 25.93 \text{ r.p.m.}$$

Working Pressure for Old Boiler—Is resistance of a hydrostatic test pressure 50 per cent. in excess of the working pressure proposed for an old boiler sufficient for determining the safety of the boiler operated at the proposed working pressure?

A. B.

A hydrostatic test pressure would only determine whether the boiler would probably be tight for the proposed working pressure. The working pressure should be decided from computation of the safe working strength of parts, based upon internal and external inspection before and after the hydrostatic test, with due consideration of the condition of the material and previous kind and length of service of the boiler.

Higher Efficiency with Oil than with Coal Burning—Why are higher boiler efficiencies obtainable with oil burning than with coal burning?

W. E. C.

Oil burning can be conducted with admission of but little more air than that which is required for furnishing the oxygen actually necessary, the furnace doors need not be opened while the boiler is under steam, and the boiler surfaces are not so quickly fouled with soot. In coal burning, to obtain distribution of an adequate amount of oxygen for the perfect combustion of each atom of carbon in the coal, it is necessary to introduce sufficient air to contain about double the quantity of oxygen actually required by the combustion. Therefore, in oil burning there is less loss from excessive air supply and, consequently, higher efficiency.

Difference of Water Pressure from Difference of Temperature—What would be the difference in pressure per square inch of a column of water 4 ft. high at a temperature of 40 deg. F. and at 100 deg. F.?

G. W. L.

The weight of a cubic foot of water at 40 deg. F. is 62.42 and the pressure per square inch exerted by a column 4 ft. high would be

$$\frac{62.42}{144} \times 4 = 1.733 \text{ lb. per sq.in.}$$

and as the weight of a cubic foot at 100 deg. F. is 62.02 lb the pressure exerted by a 4-ft. column at the latter temperature would be

$$\frac{62.02}{144} \times 4 = 1.722 \text{ lb. per sq.in.}$$

and the difference of pressure would be

$$1.733 - 1.722 = 0.011 \text{ lb. per sq.in.}$$

Discharge of Steam to Vat—What will be the rate of discharge of steam at 100-lb. gage pressure from the open end of a 1-in. pipe into water contained in an open vat with the end of the pipe submerged about one foot?

W. E. P.

The rate of discharge can be approximately determined by the Napier formula for discharge of steam through an orifice into a pressure which is less than 58 per cent. of the initial absolute pressure, viz.:

$$W = \frac{A \cdot P}{70}$$

in which

W = Weight of steam discharged, pounds per second;
A = Area of orifice in square inches;
P = Absolute initial pressure,

according to which the discharge would be about

$$\frac{0.7854 \times (100 + 15)}{70} = 1.29 \text{ lb. of steam per second.}$$

Clattering Exhaust Valves—How can I stop the clattering noise of the exhaust valves of a noncondensing Corliss engine, which usually occurs when the engine is running light?

B. N.

The noise is probably due to the valves becoming unseated from expanding the steam below atmosphere, in which case the remedy would be to run the engine with lower initial pressure, obtained by carrying lower boiler pressure or by throttling, and thus secure higher terminal pressure. If it is not practicable to reduce the initial pressure, expansion below atmosphere can be prevented at small cost of economy by joining together the indicator connections of opposite ends of the cylinder and, having them throttled sufficiently to prevent bypassing of more steam than found barely necessary to prevent the clattering of the exhaust valves, by admission of only enough pressure from one end of the cylinder to the other to prevent expansion below atmosphere.

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Commission Orders Reduction in Edison Rates

Following so closely upon Governor Whitman's investigation of the New York Public Service Commission as to imply a belated attempt to make good, the commission, after nearly four years of investigation and protracted hearings, has announced a decision in the Stadtlander case. By this the New York Edison Co. is ordered to reduce its maximum price of electricity from 10 to 8c. per kilowatt-hour. This reduction, if put in effect, will mean a saving of perhaps two million dollars annually to the large number of small consumers.

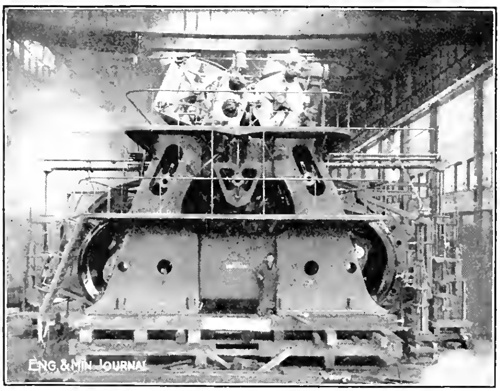
Commissioner Maltbie, who conducted the hearings, offered a resolution to reduce the price from 10 to 6½c. per kilowatt-hour, allowing the company to charge for the meters. This was voted down, 4 to 1, and Commissioner Williams' resolution for a reduction from 10 to 8c. was substituted. The former would have meant a greater saving to the large retail consumer, such as the storekeeper, but would hardly have favored the average householder as much as the recommendation adopted.

Just what action the Edison company will take in complying with the order is not known.

Large Compound Condensing Hoist

The largest compound condensing hoisting engine in the world was recently ordered by the Homestake Mining Co., and built by the Nordberg Manufacturing Co. It is of the duplex inclined cross-compound type, as shown by the side view. The two high-pressure cylinders are 28 in. in diameter and the two low-pressure 52 in., all with a common stroke of 42 in.

The hoist is built with two reels, each on a separate crankshaft. The reels are driven by axial plate clutches



NORDBERG COMPOUND CONDENSING HOISTING ENGINE

and equipped with gravity post brakes, air-operated. The hoist lifts 12,000 lb. net of ore per trip from a depth of 3200 ft. in a vertical shaft. The rope is ⅝x7¾ in., and the total rope pull is 41,900 lb.

The initial steam pressure is 150 lb. gage. All cylinders are steam-jacketed, and the exhaust pressure is maintained at 26-in. vacuum by a special design of counter-current jet condenser developed by Mr. Nordberg for hoisting-engine work. The circulating and dry-air pumps are direct-connected and driven by a simple Corliss engine.

The arrangement of this engine, having two main crankshafts connected with side rods and a reel mounted on each shaft, was necessary, owing to the topography of the ground around the shaft where this hoist is being installed. The only desirable location for the engine house bore such a relation to the shaft that the two ropes from the head sheaves to the hoist stand 12 in. center to center. With two ropes, each 7¾ in. wide and their centers 12 in. apart, it is obvious that it would be impossible to mount two reels on one shaft, as is commonly done.

The inclined cylinders and the relative position of the cranks are such as to give practically a uniform turning effort.

On small compound condensing hoisting engines working from depths of less than 1000 ft., the Nordberg company has obtained economies of less than 30 lb. of steam per shaft horsepower-hour, including the steam used by the condenser, and it is expected that the Homestake hoist will break all records for low cost of hoisting as soon as it is put in operation.—"Engineering & Mining Journal."

Unused Water Rights

What may well be helpful legislation is proposed by the Washington Water-Code Commission in a bill for the distribution of unused water rights in that state, and empowering the commonwealth to proceed by power of eminent domain to ascertain existing and proposed rights. The proposed law aims at more widespread use of the abundant waters and creates a new department under the direction of a hydraulic engineer who shall hold office for six years at an annual salary of $6000. Under the provisions of the bill an individual may exercise the power of eminent domain in the acquisition of water rights by petitioning the state which prosecutes the action in court and determines the rights of the parties.

It is urged in support of the bill that existing water titles are hazardous and that much of the water of the state is withdrawn from necessary use by the mixed condition of affairs. It is held that the state has enough unharnessed water power to furnish all the heat and power now generated by coal. Capital, it is urged, declines to develop water rights when titles are in the present precarious condition.

Extensive Water-Power Project at Millinocket, Maine

A dam fifty feet high that will flow the west branch of the Penobscot River back twenty-four miles and merge three lakes in one, is to be built this spring by the Great Northern Paper Co.

Before anything could be done toward the construction of this dam it was necessary to build a highway through the wilderness from the shore of Moosehead Lake to the gorge of Ripogenus, as in no other way could the cement and other materials be transported to the site. Two years have been occupied in building this road.

It is estimated that 40,000 to 60,000 horsepower can be developed at the gorge, but the dam is to be constructed primarily for the purpose of increasing the water-storage capacity of the west branch. The present storage capacity, estimated at 16,000,000,000 cu.ft., will be increased by the new dam to 21,000,000,000 cu.ft., while at Twin Lakes, some distance below, there has been created a storage of 15,000,000,000 cu.ft. Together, these storage basins will furnish a uniform flow throughout the year sufficient for the operation of the great pulp and paper mills at Millinocket and East Millinocket, where 1200 to 1500 men are employed and two thriving villages have grown up.

Connors Creek Plant of Detroit Edison

Before the Cleveland Engineering Society on Feb. 9, Prof. C. F. Hirshfeld gave an interesting talk on the new station now being erected by the Edison Illuminating Co., of Detroit. A brief abstract of the address follows:

A study of conditions indicated that a new plant would have to be installed and that economy and safety of distribution dictated a location about as far east of the business district as the older Delray plant is to the west of that district, with its heavy and concentrated loads. The Connors Creek site was finally selected as meeting this requirement as well as offering proper facilities for the receipt of coal and an adequate supply of circulating water.

One-third of the contemplated first plant on this site is now completed. The finished plant is designed to contain six 25,000-kv.-a. turbo-alternators and twelve 2365-hp. boilers similar to those now in use at Delray. It is probable that the turbo-alternators later installed may have greater capacity than those first contemplated.

Surface condensers, arranged for 35,000 sq.ft. of cooling surface, have been used. These condensers are so arranged that half of the tubes, with which the steam first comes in contact, contain cold circulating water. The circulating pumps are motor driven, and the air is withdrawn from the condenser by means of a motor-driven rotative dry vacuum pump arranged for two stages in one cylinder.

All auxiliaries, with the exception of the boiler-feed pumps, are electrically operated, the power being preferably taken from 1000-kw. turbo-alternators installed for that purpose. These small units and the boiler-feed pump turbines exhaust into heater condensers, the condensate from the main units being used as the circulating water for these condensers. The mixture of circulating water and condensed auxiliary steam serves as boiler feed. It is hoped that this arrangement will make possible the attainment of all of the advantages of electrically driven auxiliaries, together with the advantages accruing from the use of steam-driven auxiliaries.

Throughout the plant many innovations of a minor character have been introduced for the purpose of obtaining greater thermal and operative efficiency.

U. S. Geological Survey at the Panama Exposition

The exhibit of the United States Geological Survey at San Francisco occupies 62x78 ft. in the Palace of Mines and Metallurgy, flanked on one side by the display of the Bureau of Mines and on another by the Alaskan exhibit. The central feature is a booth, containing stage-like settings of a scene, partly modeled and partly painted. The first represents an undeveloped district in the arid West being studied by the Survey. Topographers, geologists and a stream gager are at work. The second scene shows the same district after development. The results of the stream gaging have been utilized in planning a power plant which shows in the distance and an irrigation project which covers the valley floor. A coal bed is being mined on one side; an oil field is under development elsewhere; a sandstone bed is being quarried in the foreground; mining and milling are in progress in the mountains; a town has been built, and roads, railroads and other evidences of civilization abound.

On recessed screens are shown pictures illustrating the different kinds of Survey work and the part they play in the development of the country. At one end of the space is shown the per capita production of minerals in the United States in 1880, about the time of the Centennial Exposition and of the organization of the Survey, and in 1913. A series of cases illustrate what our common things are made of, what the raw material looks like, and where it occurs in the United States; as examples, an aluminum saucepan, an electric-bulb filament and a fountain-pen point.

At the west end of the space is an exhibit of the power and fuel resources of the United States, including maps showing the distribution of the black shale from which oil is derived and the apparatus used in the field in determining the shales that are worth studying. In the portion of the exhibit relating to water resources is a display of automatic gages being run by clockwork and recording the fluctuating height of water in a tank.

Stereoscopic pictures will be arranged in boxes of fifty each, on a table at which one may sit and study various features of Survey work. There are also shown four series of pictures of the Grand Cañon and Rocky Mountain region, taken in the early days of the Geological Survey by the famous photographers, Jackson and Hillers. Other cases show the gem minerals, the rare mineral ores, etc.

Heating and Ventilation at the University of Illinois

The Department of Mechanical Engineering of the University of Illinois has been developing work along the lines of heating and ventilation, under the direction of Prof. A. C. Willard. A considerable amount of equipment for the experimental study of heating and ventilating problems has been installed within the last few months.

A recent addition consists of an air washer and humidifier specially arranged for experimental purposes. Complete control of the volume and temperature of the water circulation and of the air passing can be maintained. The washer is equipped with a double bank of spray nozzles which, by means of a finely divided mist, wash the air passing and also cool and humidify it. After passing the nozzles any entrained water in the air is removed as the air passes through a double row of V-shaped eliminators. The washer has a capacity of 3150 cu.ft. of air per minute at a velocity of 450 ft. per minute through the spray chamber. The spray water is circulated by a motor-driven centrifugal pump with a capacity of 30 gal. of water per minute at a discharge pressure of 25 lb. per sq.in.

When humidification is desired, it is necessary to saturate the air leaving the washer, and for this purpose a steam and water mixer of the injector type is installed in the tank below the spray chamber. The operation of this mixer is made to depend upon the temperature of the entrained spray water leaving the eliminator plates. A water-temperature regulator is placed in the path of the discharge from the eliminators, and this automatically operates a pneumatic diaphragm valve in the steam line leading to the mixer. Since the temperature of the saturated outgoing air and of the entrained spray water will be the same as they leave the eliminators, the regulator maintains a definite temperature of outgoing air of known humidity (100 per cent.).

The temperature of the outgoing air is also under the control of a duct thermostat which operates the pneumatic diaphragm valve supplying steam to a tempering coil placed in the inlet to the air washer. This coil makes it possible to preheat the air and determine the cooling effect or "humidifying efficiency" of the washer over a wide range of entering air temperatures. As an air washer or cleanser this apparatus is guaranteed to remove 98 per cent. of all solid matter contained in the entering air. The flow of air through the washer is induced by a multi-bladed fan with a 24-in. diameter rotor. This fan is driven through a transmission dynamometer by a variable-speed motor.

Reduction in Lighting Rates

In support of a bill to reduce residence-lighting rates from 6c. to 5c. per kilowatt hour, a schedule has been filed with the city council of Seattle of the earnings and profits of the municipal light and power plant, after having made reductions to 6c. per kilowatt hour, and a partial report of the net profits of the plant for the year 1914.

Since the beginning of 1911 the council has made four reductions in the residence-lighting schedule. About the middle of 1911 the rate was cut from 8½c. to 7c. and the minimum charge from $1 to 75c. per month, and in 1912 the rate was cut to 6c. and the minimum charge to 50c. per month.

Public Service Decisions

After careful examination by its engineers and accountants the New York Public Service Commission, Second District, has approved a method for the utilization of a large water power at Minetto, owned by the Columbia Mills, Inc., and to be leased to the Niagara, Lockport & Ontario Power Co. for use on its Syracuse and near-by lines, through the creation of a new company to develop the power. The stock of the new company, called the Northern New York Power Corporation, is to be taken by the Columbia Mills in part payment for its power. The bonds, interest and principal are also to be guaranteed by the Columbia Mills.

Though the Columbia Mills is a corporation organized under the business law, the Commission holds that, as it already sells a small amount of electricity to employees and other neighbors, it comes within the definition of an electrical corporation in the Public Service Commissions law, and as such its ownership of the stock of the other electric corporation must be approved by the Commission.

The Northern New York Power Corporation is authorized to issue $900,000 of its 6 per cent. first mortgage bonds at not less than 97 to net $873,000. Of this sum $350,000 is to be paid in cash to the Columbia Mills for its water rights, property, etc., and $455,000 is to go for the completion of the hydro-electric development. In addition, the power corporation is to issue $500,000 capital stock. This, at 125, is to be turned over to the Columbia Mills, in payment of the balance on the property transferred. The Commission further approves the lease of the new company's thus acquired and developed hydro-electric property to the Niagara, Lockport & Ontario Co.

The Commission has also approved a new link in the chain of power transmission lines in the northern part of the state, by approving franchises of the St. Lawrence Transmission Co. to extend its lines from Norfolk to Hannawa Falls, there to connect with the line of the Northern Power Co., and from Massena north to the Canadian border, where connection is made with the lines of the Cedar Rapids Transmission Co. of Canada, connecting the Cedar Rapids power with that at Hannawa Falls and elsewhere through the territory.

The Commission limits the use of these lines to transmission purposes only, through the villages of Norwood, Massena and Potsdam, and the towns of Pierrepont, Potsdam, Norfolk, Stockholm and Massena, for which the company holds franchises, but in which other local companies, such as the Norwood Electric Light & Power Co., are already doing a distributing business with the approval of the Commission.

OBITUARY

CHARLES A. SCHIEREN

Hon. Charles A. Schieren, millionaire philanthropist and once mayor of Brooklyn, died Mar. 10, of pneumonia. Mrs. Schieren, having contracted the same disease, died on the following day. Born in Rhenish Prussia in 1842, Mr. Schieren came to this country at the age of 14 with his parents, who settled in Brooklyn, N. Y. At first a cigar maker, in 1864 he went to work in the leather-belting factory of Philip F. Pasquay, in New York City. When his employer died in 1865, Mr. Schieren assumed the management of the concern and continued with the successors of the old firm until 1868, when he founded the firm of Charles A. Schieren & Co. The business grew steadily and numerous agencies were established in Europe, as well as in this country and Canada. In 1908 the Charles A. Schieren Co. was incorporated, and is today

CHARLES A. SCHIEREN

one of the greatest leather-belting concerns in the world, with factories at Ferry and Cliff St., New York City, and tanneries at Bristol, Tenn.

Mr. Schieren was chief organizer and vice-president of the Hide and Leather National Bank, president of the Germania Savings Bank and a director in the Nassau National Bank, Brooklyn Trust Co. and the Germania Life Insurance Co. He was a member of many clubs and was the chief organizer of the Brooklyn Academy of Music. During the Spanish-American War he was treasurer of the American Red Cross Society. In 1893 he was elected mayor of Brooklyn on the Republican ticket. He refused a renomination.

Mr. Schieren married Louise, daughter of George W. Bramm, in 1865. They had eight children, four of whom died. The living ones are Charles A., Jr., G. Arthur, Harry V. Schieren and Mrs. Albert H. Mathews.

PERSONALS

Prof. G. A. Goodenough, of the Department of Mechanical Engineering of the University of Illinois, recently gave a lecture on "The Development of the Steam Turbine" before the College of Engineering of the University of Wisconsin.

L. B. Marks and J. E. Woodwell, consulting engineers, 103 Park Ave., New York City, will dissolve partnership on May 1, 1915. Mr. Woodwell will locate at 8 West Fortieth St., where he will continue the general practice of consulting engineering, and Mr. Marks will remain at 103 Park Ave. and specialize, as heretofore, in illuminating engineering.

B. H. Bryant, civil engineer, has returned from Guatemala, Salvador and Honduras, where he had been locating railroad lines as chief locating engineer of the International Railways of America, and is taking a much needed vacation in Washington, D. C. Mr. Bryant, who has acted in the capacity of division engineer, chief engineer, construction engineer and general superintendent of steam railroads in the United States, Canada, Mexico, Brazil and South American countries for many years, is well known among railroad men. He expects to return to active work in the spring.

ENGINEERING AFFAIRS

National Association of Master Steam and Hot Water Fitters—The twenty-seventh annual convention of this association will be held at Milwaukee, Wis., June 21-24. It is suggested that those who contemplate going to the San Francisco Exposition can very nicely arrange to attend this convention and continue on their way to California, while those who expect to attend the convention of the National Association of Master Plumbers can leave at the close of this convention and reach San Francisco in time for the other.

NEW PUBLICATIONS

SANITARY REFRIGERATION AND ICE MAKING. By J. J. Cosgrove. Technical Book Publishing Co., Philadelphia, Penn., 1915. Size, 8½x6 in.; 331 pages, 45 tables; cloth. Price, $3.50.

The author has aimed to make the treatment graphical rather than mathematical and theoretical. To persons seeking an introduction to refrigeration and ice-making this book is one of the best that has come to our attention. It will also be a good book for many operating refrigerating engineers for it is well adapted to giving them the ground-work in theory that so many need. The first fifty pages are devoted to a simple treatment of heat. We cannot recommend the book to consulting refrigeration engineers, for, obviously, if it is adapted to the needs of the operating man it cannot be well suited to the consulting engineer. For the most part the book is descriptive of the systems of refrigeration, their applications, accessories and of ice-making systems.

GRAPHIC METHODS FOR PRESENTING FACTS. By Willard C. Brinton. Published by the Engineering Magazine Co., New York, 1914. Cloth, 7x10 in.; 371 pages. Price, $4.

The engineer has a well defined and a standardized method of representing objects. The blueprint "language" has a literature satisfying the simplest as well as the most complicated needs. But very little information is available regarding the best means of showing the relations between data by the difference in the length, size and direction of lines, areas and curves. Mr. Brinton's book, which is designed to serve as a handbook in the preparing of charts and the plotting of curves, is said to be the first dealing with methods of graphical presentation. That a great deal of the subject matter appeals primarily to nontechnical readers in itself makes the book valuable to the engineer illuminating data for a non-technical audience.

Some of the methods covered are the use of vertical and horizontal bars, the comparisons of objects by their size or number, map presentations, and organization and routing diagrams. The treatment of curves, described in six of the seventeen chapters, includes their general arrangement, the advantages of comparative, cumulative and frequency curves, and suggestions for executive and financial curves.

At the end of the book are given a checking list and a set of rules for graphic presentation, the two forming practically a summary of the entire contents. The list is a set of questions with which a curve can be checked to see whether it comes up to the standard. The rules are suggested as a basis for the standardizing of graphical presentations. The chapters are logically arranged, but the headings given under the chapter numbers in the list of contents could well have been repeated in the text, thus definitely locating the particular heading.

The book will prove a useful aid to the many who hitherto, in preparing charts and curves, have depended mainly on their own ingenuity to satisfy the needs of executives as to the information in and the arrangement of the graphical reports rendered.

Don't Be a Nagger

> **Results are what count, and as long as an engineer gets them quickly and efficiently, how he gets them is his own concern.**
>
> * * * * * * * * * * *
>
> **Nothing on earth demoralizes an organization and takes the heart out of an engineer like a manager who is constantly changing his mind.**

IF A MAN IS HIRED to fill a certain position, give him credit for having horse sense enough to run his own job, at least until he proves the contrary to be true.

By this is not meant that a manager is never to check up the work that his engineer is doing, but *results are what count, and as long as an engineer gets them quickly and efficiently, how he gets them is his own concern.*

No two humans were ever created exactly alike. Such being the case, it is seldom that any two will tackle a given proposition in the same way—and right there is the rub.

Give a man credit for a personality and ideas of his own, and don't tell him he is blundering the instant he deviates from a plan you had in mind. Forget the details. The chances are ten to one he knows more about them than you do, and anyway, your engineer is being paid for the express purpose of looking after them and relieving your shoulders of that burden.

Don't make an errand boy of him, or reduce him to such a state of indecision that he will come and ask if it will be all right to have a couple of men out Sunday to wash the boilers. Such tactics kill all the initiative an engineer possesses.

When you give instructions make them clear and concise and give them to the chief and not to some man under him, if you wish him to maintain any discipline and have the respect of his helpers; and before you give instructions settle in your own mind first, just what result you wish to attain and then stick to it.

Nothing on earth demoralizes an organization and takes the heart out of an engineer like a manager who is constantly changing his mind.

A man gets so he will exert no effort whatever to "make things hum," because he knows that as soon as he gets a piece of work nicely started, in will come the boss, change his mind and then a "patched up," "made over" job will be the result.

In other words, be consistent. Treat your chief engineer as if he were a man who knows his business, and don't nag him until his head is so busy thinking up new words to describe your special brand of ivory that he has no time to think of his plant, as the former kind of "thinks" don't help the coal pile.

Addition to the Westport Power Plant

By Warren O. Rogers

SYNOPSIS—Owing to increased business the Westport power plant, the original capacity of which was 22,500 kw., has recently been enlarged by putting in a 15,000-kw. turbine and six water-tube boilers, each with a heating surface of 10,470 sq.ft. The boiler furnaces are each equipped with an 11-retort underfeed stoker. A special design of jet condenser, so far as known, the largest built, is used with the new turbine, and is designed to take care of 200,000 lb. of steam per hour with a vacuum of 28.5 inches. The brick chimney is supported by steel girders and columns. The base of the chimney is level with the top of the boiler-room roof, 65 ft. above the ground level.

The electric and gas business in Baltimore, Md., is controlled by the Consolidated Gas, Electric Light & Power Co., and until three years ago nearly all of the electrical energy was generated at the company's steam plant at Westport, on the west bank of the Middle Branch of the Patapsco River. Prior to the addition the plant had a rated capacity of 30,000 hp.; a small steam plant of 8000-hp. capacity on Gould St. and a small water-power plant at Ilchester are also operated by the company.

Although the Westport plant, Fig. 1, is tied in with the McCalls Ferry* hydro-electric plant of the Pennsylvania Water & Power Co., this company is separate and distinct

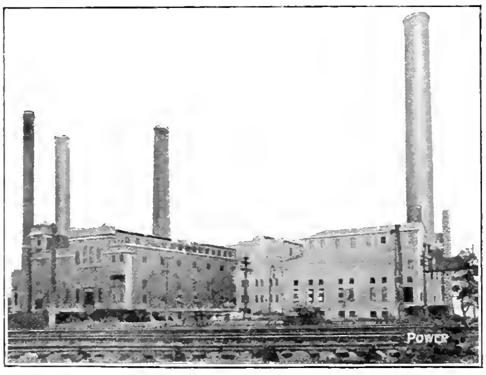

Fig. 1. Showing Addition to Westport Power House

as an organization, from the Consolidated Gas, Electric Light & Power Co. The former company, however, has a contract with the latter calling for the capacity of the latter's plant in case of failure to the hydro-electric station apparatus or transmission lines. This arrangement also applies to the United Railways Co., which has a steam plant of 26,000-hp. rating that is operated in an auxiliary capacity during the peak-load hours.

Since the contract was made with the Pennsylvania company the electric business of the Consolidated company has increased 150 per cent., being now 2½ times as great as three years ago. As a matter of prudence the Westport plant has been enlarged sufficiently to take care of its business in case of a breakdown of the water-power plant. The former equipment consisted of four 2500-kw., one 5000-kw. reciprocating units, as shown in

Fig. 2. View of the Old Engine Room, Westport Power House

Fig. 2, and a 7500-kw. turbine, or a total continuous capacity of 22,500 kw. The new 15,000-kw. turbine thus gives a station capacity of 37,500 kw. The old plant has a total in boiler heating surface of 120,000 square feet.

Turbine Room

The turbine room, which contains two horizontal turbines, adjoins the engine room shown in Fig. 2. The smaller turbine is a 7500-kw., 13,200-volt, three-phase, 25-cycle unit running at 1500 r.p.m. It occupies the space formerly taken up by a vertical turbine, recently discarded. The condensing apparatus of the original turbine is used with the newer unit and consists of two jet condensers, two 13x14-in. engine-driven 20-in. volute pumps for injection water, and two 8&10x24x24-in. dry-vacuum pumps, the steam ends of which are equipped with Corliss valve-gear. One of the condensers is shown in Fig. 3.

The 15,000-Kw. Unit and Condenser

The new 15,000-kw. unit is shown in the foreground of Fig. 4. It is a 13,200-volt, three-phase, 25-cycle, 1500-r.p.m. machine. The condenser for this unit is, as far as

*Described in the May 13, 1913, issue of "Power."

known, the largest jet condenser ever built. A partial view of one end is shown in Fig. 5 and a side view in Fig. 6. It is designed to take care of 200,000 lb. of steam per hour, at an absolute pressure of 1.5 in. with 70 deg. F. injection water, using 25,000 gal. per minute.

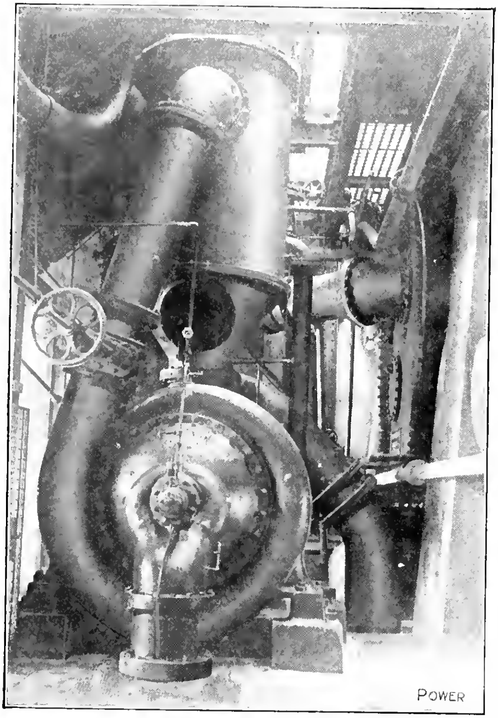

FIG. 3. ONE OF THE CONDENSERS USED WITH THE 7500-KW. TURBINE

The floor space available for the condenser and air pumps under the turbine and between the turbine foundation walls was 11x15 ft. This necessitated several departures from the usual design of jet condensers and demanded highly efficient apparatus.

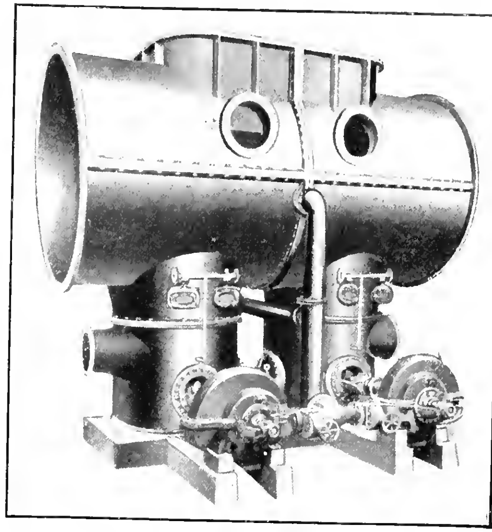

FIG. 6. LARGEST KNOWN JET CONDENSER, CAPACITY 200,000 LB. OF STEAM PER HOUR

The condenser consists of a horizontal cylinder 10 ft. in diameter and 20 ft. long, with a 7-ft. 6-in. by 10-ft. 9-in. rectangular flanged exhaust opening at the top and two 6-ft. diameter wells on 8-ft. centers at the bottom. These wells are bolted to a base plate with the condenser. The pumps are driven by two turbines mounted on independent base plates and are located below the generator and connected through extended shafts with flexible couplings. These turbines at their rated speed of 1050 r.p.m. develop 300 hp. each under full-load conditions.

To effect a balanced condition and uniform distribution, the injection water is taken in at each end of the condenser through two 24-in. pipes running through the condenser shell and bolted to each head. These pipes are fitted with brass nozzles which direct the water against spray plates; the water is further broken up by staggered trays with serrated edges, placed under the injection pipes. The air and noncondensable vapors are removed from the condenser at each side. This arrange-

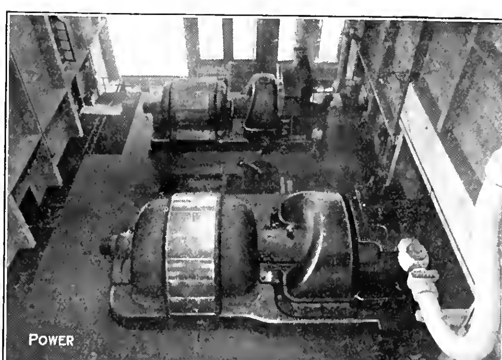

FIG. 4. GENERAL VIEW OF THE TURBINE ROOM FROM THE TRAVELING CRANE

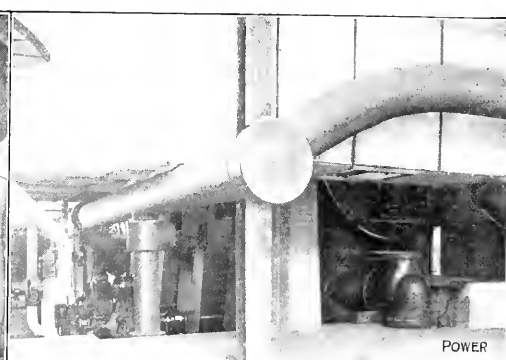

FIG. 5. ONE END OF THE LARGE JET CONDENSER AND THE PUMP TURBINES

Fig. 7. View at Rear of the Boilers

ment of water distribution and spray, combining the features of parallel-flow and counter-current types of jet condensers, makes it possible to effect close terminal differences between the vacuum temperature and the temperature of the discharge water at light and at full loads. Due to the arrangement of the air and removal pumps, it is possible to operate the condenser with but one set of pumps if at any time the turbine is carrying half-load.

Boiler House

The boiler room is laid out at right angles to the turbine room and contains at present six boilers each of 10,470 sq.ft. of heating surface, forming a unit designed to furnish steam for one 15,000-kw. turbo-generator or 1.13 kw. capacity per sq.ft. of boiler heating surface. Additional units of six boilers each will be added for each 15,000-kw. generator installed. The present stack serving the six boilers is of sufficient capacity to serve another unit of six.

Two walls of the boiler house are temporary, being made of asbestos-covered corrugated iron, which can be readily removed for extension. The asbestos color corresponds closely with the color of the concrete in the permanent building walls, and the general appearance of the structure is not marred by the temporary walls.

The boilers are set singly to allow access to both sides of the furnace, and they are supported from the building steel. The aisle between the rear ends of the two rows of boilers is unusually wide, giving ample space for operating blowoff valves and for repair work (Fig. 7). The space in front of the boilers is wide and well lighted, providing ample operating space for stokers, etc. (Fig. 8).

The building is provided with modern sanitary features consisting of a lavatory, toilets and shower baths. Ample light is admitted by numerous and large windows, rolled-steel sash and wire glass being used, with ventilating sections. A large storeroom is provided for in the basement, for repair materials and supplies.

Boilers and Stokers

The water-tube boilers are three-pass, of the water-leg type, and are designed to operate at 200 lb. pressure. Each boiler is provided with a superheater of 1425 sq.ft. of heating surface, to give 100 deg. of superheat under all conditions of load. The ratio of superheater surface to the boiler heating surface is 1 to 7.34 sq.ft.

A balanced draft is maintained in the combustion chamber by means of apparatus which controls the flue damper of the boilers and also the forced-draft damper of the stoker, so that a constant draft or negative pressure is maintained. Each boiler has four blowoff valves and an 8-in. steam delivery pipe.

Each boiler is equipped with an 11-retort underfeed mechanical stoker with a grate area of 156 sq.ft., this being the area of the combustion chamber in a horizontal plane. This gives 67 sq.ft. of boiler heating surface to 1 sq.ft. of grate area. These stokers are guaranteed to maintain twice the boiler rating continuously or three times the boiler rating for a period of two hours. Forced draft is provided by four paddle-wheel blowers directly connected to horizontal engines; they deliver air at a maximum pressure equivalent to 6 in. of water.

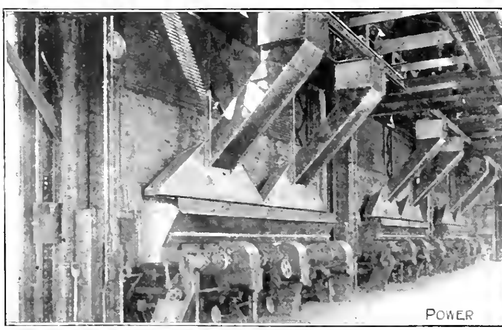

Fig. 8. Stoker Side of the Boilers

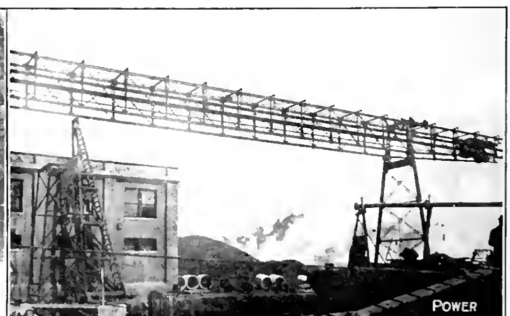

Fig. 9. Trolley Bridge and Grab Bucket

The stack has an internal diameter of 20 ft. 3 in. and is built of radial brick. It is supported on six heavy steel columns and 72-in. girders, the base of the stack being 65 ft. above the foundation on which the steel is carried. The height of the stack is 215 ft. above the steel supports and 250 ft. above the boiler grates. The foundation for the stack is a monolith 35x10, 8 ft. deep, resting on 198 piles driven to an average depth of 25 ft. Grillages of steel beams are placed in this foundation, distributing the weight evenly from the columns to all of the piles. The weight of the stack is 1224 tons. The cross-section is 320 sq.ft. or 2.92 sq.ft. of grate area to 1 sq.ft. of stack area. When the additional six boilers are installed there will be 5.8 sq.ft. of grate area to 1 sq.ft. of stack area.

The steel breechings connect the flues at the tops of the boilers and extend in a straight line to the bottom of the stack, which they enter by making a quarter turn upward. The dimensions of the breeching are gradually increased by a tapering construction to give proper cross-section for the several boilers connected. The arrangement at the base of the stack gives minimum friction or interference of gases in entering.

The new boiler house is designed to receive coal by cable cars over a bridge from a high-speed coaling tower to be constructed on the bulkhead line. At present coal is transferred from the system supplying the boiler house serving the reciprocating engines.

The coal is brought to the plant in barges, from which it is lifted by a grab bucket and transferred by a trolley over a bridge into the old house (Fig. 9). Coal is deposited in a movable crusher which, after crushing, delivers it to the bunkers. From one of these bunkers it flows by gravity into a 2-ton skip hoist which lifts it to a hopper above the roof, from which it is discharged to a 3-ton electrically operated car. This car transfers coal over a bridge on the roof of the power house to the new boiler house and dumps it into hoppers. From these hoppers it is delivered into hand-push cars which distribute it to the bunkers above the new boilers. The bunker above three of the boilers has a capacity of 400 tons and that above the other three has a capacity of 600 tons to provide for an additional row of boilers to be installed in the future.

From these bunkers the coal passes to automatic weighing scales, two for each boiler. Each scale discharges into

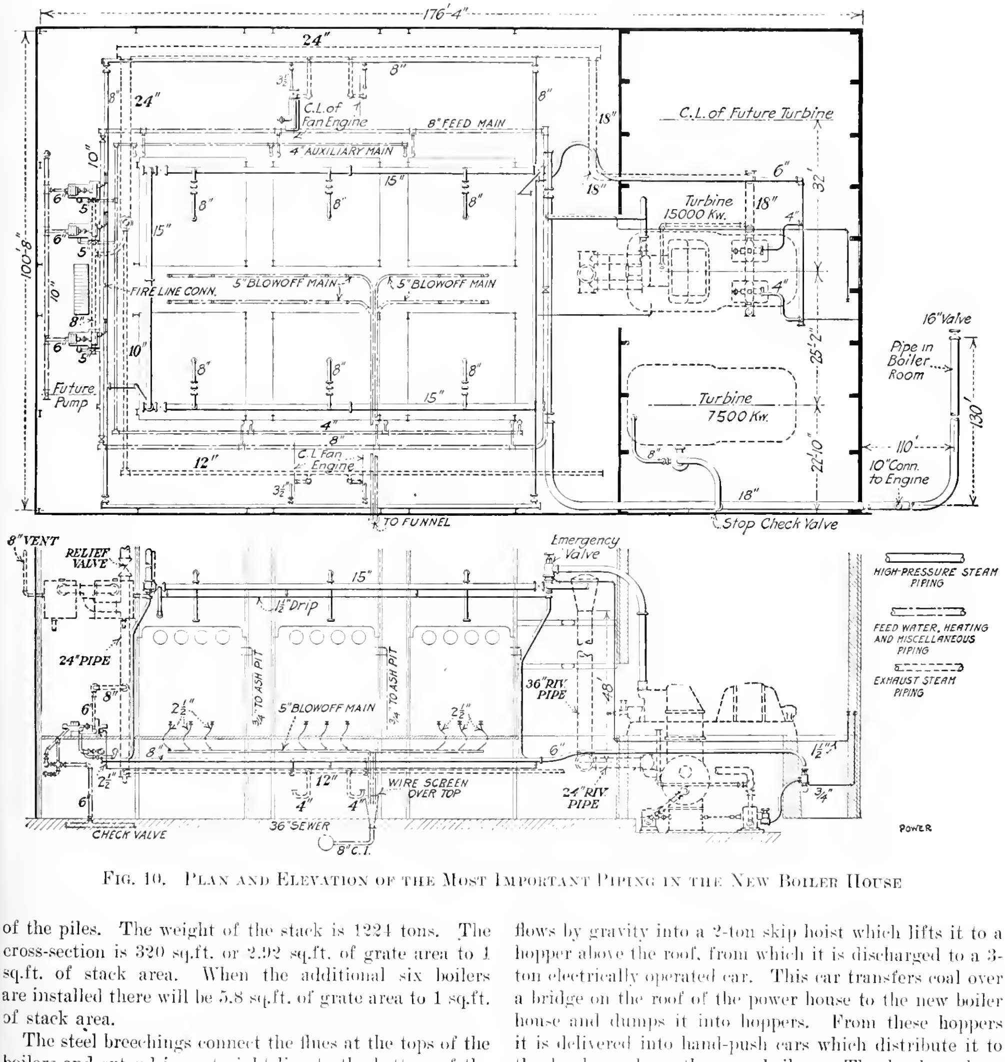

FIG. 10. PLAN AND ELEVATION OF THE MOST IMPORTANT PIPING IN THE NEW BOILER HOUSE

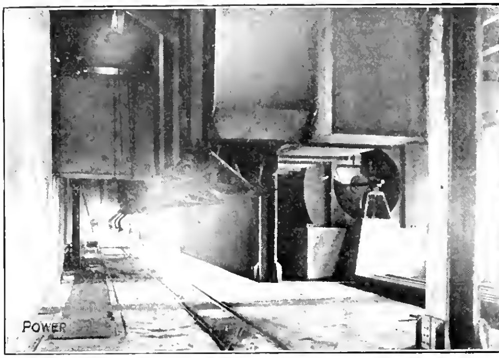

Fig. 11. Ash Outlets from Ash Pits

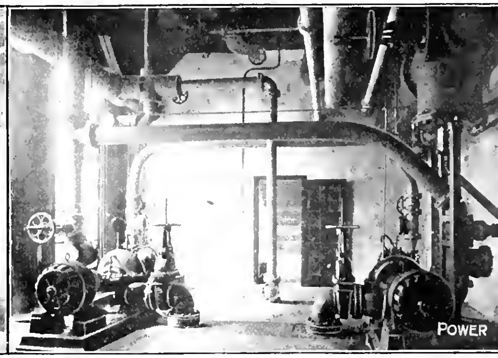

Fig. 12. Service and Heater Pumps

a chute equipped with a distributor which feeds the stoker hoppers, shown in Fig. 8.

Ashes from the stokers drop into ash hoppers in the basement. At the bottoms of these hoppers are 24x36-in. cast-iron gates. Ash cars run on tracks below these hoppers (Fig. 11) and are loaded by opening the gates mentioned. The ashes are used to reclaim land adjacent to the boiler house.

Piping

Fig. 10 gives a plan and section of the more important piping in the new boiler house and turbine room. The main high-pressure piping in the boiler house consists of a loop of 15-in. pipe. Each of the boilers connects with this header through a long 8-in. bend. The 15,000-kw. turbine is served by a 14-in. connection. The new boiler house is connected with the old one by an 18-in. pipe line and the 7000-kw. turbine is supplied from this pipe, the arrangement of valves being such that steam can be taken from either the old or the new house.

The high-pressure steam for auxiliaries in the basement of the turbine and boiler rooms is supplied by another loop header located in the basement. This header receives steam from the main boiler-room header through either of two 8-in. connections and supplies the four blower engines in the basement, the steam-driven pumps and turbine auxiliaries.

Van Stone joints and welded nozzles were used on all high-pressure piping. Steel valves with monel-metal seats were used and 1914 drilling for all flanges. Remote-control valves are installed on the principal units and main connections so that some may be closed from a control point in emergency.

The exhaust piping is located in the basement, the connections from each of the auxiliaries leading to a main 24-in. exhaust line which rises to the two feed-water heaters. Just above the connection to the feed-water heaters a 24-in. relief valve is placed to force the steam through the heaters and to relieve the exhaust above a predetermined pressure.

All steam piping is covered with 85 per cent. magnesia of ample thickness to conserve heat, and the various classes are painted with colors that indicate their functions. The high-pressure steam piping is white, exhaust steam buff, fresh cold water blue, salt water green, and blowoff and drain connections black.

Two 10,000-hp. open heaters receive the exhaust steam and deliver the hot water to a V-notch recording meter and tank. An 8-in. vent with exhaust head is provided for each of the heaters, to pass air and excess steam.

All of the pumps for the new boiler house are located in the space under the stack on both the basement and the boiler-room floor levels, this location being central for present and future boilers.

Three boiler-feed pumps (Fig. 13) are provided, each of 500-gal. capacity per min. against 240 lb. per sq.in. They are driven by 110-hp. noncondensing, three-stage turbines at 2500 r.p.m., the pump having an efficiency of 65 per cent.

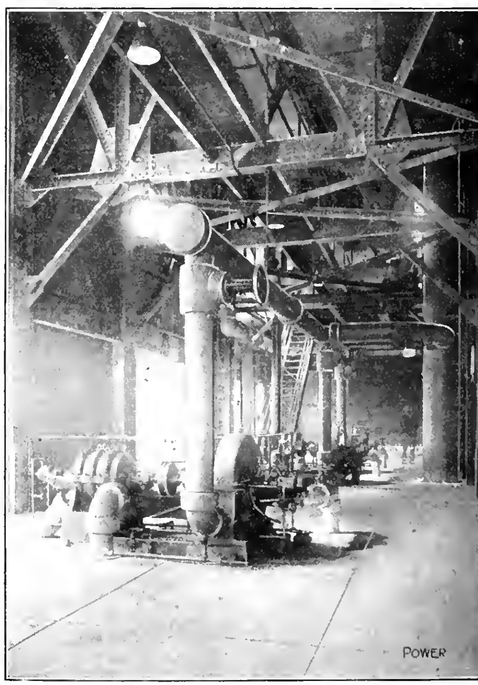

Fig. 13. Boiler-Feed Pumps

PRINCIPAL EQUIPMENT OF THE NEW EXTENSION TO THE WESTPORT POWER PLANT

No. Equipment	Kind	Size	Use	Operating Conditions	Maker
1 Turbine	Horizontal Curtis	7500-kw.	Main unit	175 lb. steam, 100 deg. sup., 1500 r.p.m.	General Electric Co.
1 Turbine	Horizontal Curtis	15,000-kw	Main unit	175 lb. steam, 100 deg. sup., 1500 r.p.m.	General Electric Co.
2 Condensers	Jet	72,000 lb. steam per hr	With 7500-kw. turbine	28½-in. vacuum	Alberger Pump & Condenser Co.
2 Engines	Fleming	12x14-in	Driving circ. pumps	250 r.p.m	Harrisburg Foundry & Machine Works
2 Pumps	Volute discharge	20-in	With small condensers	Engine-driven	Alberger Pump & Condenser Co
1 Condenser	Jet	25,000 gal. per min	With 15,000-kw. turbine	28.5-in. vacuum	C. H. Wheeler Mfg. Co.
2 Turbines	Single-stage	300-hp.	Driving condenser pumps	1050 r.p.m	Terry Steam Turbine Co.
2 Pumps	Thissen	No. 20	With large jet condenser	1050 r.p.m	C. H. Wheeler Mfg. Co.
6 Boilers	Edge Moor	10,470 sq. ft. heating surface	Steam generators.	200 lb. steam, 100 deg. superheat	Edge Moor Iron Co.
6 Superheaters	Foster		With boilers	100 deg. superheat	Power Specialty Co.
6 Stokers	Taylor	8 ft., 3½ in. x 19 ft., 6 in.	Boiler furnaces	Automatic	American Engineering Co.
6 Meters	Steam-flow		On main boilers	Continuous	General Electric Co.
12 Scales	Automatic		Weighing hopper coal	Intermittent	Richardson Scale Co
1 Crane	Gantry	7500-lb. capacity	Unloading coal	Motor-operated	Morgan Eng. Co
4 Engines	Fleming	9½x12-in	Driving Sirocco fans	Variable-speed	Harrisburg Foundry & Machine Works
4 Fans	Sirocco	9 ft. dia. wheels, 3 ft., 3½ in. wide	Forced draft	Engine-driven, variable-speed	American Blower Co.
6 Regulators	Draft-control		Air control to furnaces	Maintaining balanced draft	Blaisdell-Canady Co.
2 Pumps	Volute	2½-in	Service	Motor-driven, 1420 r.p.m	Alberger Pump & Condenser Co
2 Motors	Induction	7½-hp	Driving service pumps	440 volts, three-phase, 1420 r.p.m.	Westinghouse Electric & Mfg. Co.
2 Motors	Induction	20-hp	Driving heater pumps.	440 volts, three-phase, 1430 r.p.m.	Westinghouse Electric & Mfg. Co
2 Pumps	Volute	8-in	Supplying heaters	28-lb. head, 1430 r.p.m	Alberger Pump & Condenser Co
2 Heaters	Cochrane	300,000-gal. cap.	Feed water	Exhaust steam from aux. turbines	Harrison Safety Boiler Works
1 Meter	V-notch		Measuring feed water	Continuous	Harrison Safety Boiler Works
3 Pumps	Turbine	5-in	Boiler feed	2400 r.p.m., turbine-driven	Alberger Pump & Condenser Co
3 Turbines	Three-stage		Driving boiler-feed pumps	2400 r.p.m., 185-lb. steam	Alberger Pump & Condenser Co.
2 Pumps	Recip. 2-stage	24x24-in	Dry vac. for 7500-kw. turbine	Engine-driven	Alberger Pump & Condenser Co
2 Engines	Corliss, horizontal	8x24-in	For dry vac. pumps	Variable-speed	Alberger Puoip & Condenser Co
2 Pumps	Injection volute	16-in.	7500 turbine condensers	Engine-driven	Alberger Pump & Condenser Co

Two service pumps, each 150-gal. capacity per min. against a 90-ft. head, are driven by 7½-hp. induction motors at 1440 r.p.m. The efficiency of these pumps is 55 per cent.

These pumps supply water to two 25,000-gal. service tanks on the roof of the boiler house, one located on each side of the stack and supported by the same steel structure that carries the stack. This water is used for cooling and miscellaneous purposes.

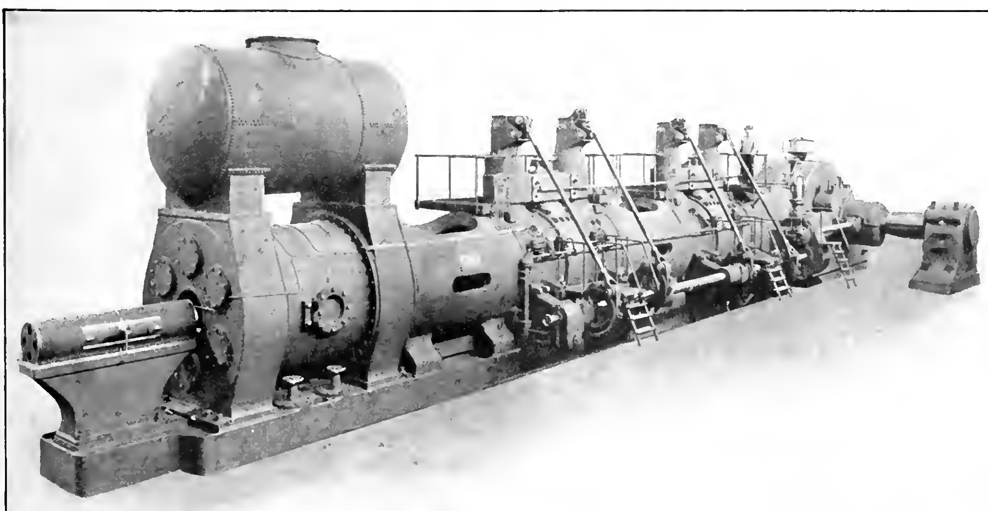
Two heater pumps, each of 1000-gal. per min. capacity against a 50-ft. head, are driven by 20-hp. induction motors. Each pump has an efficiency of 65 per cent.

Condensing water is supplied through a reinforced-concrete tunnel 10x12 ft. inside dimensions and the discharge water is carried away by another tunnel of the same construction and dimensions, under the basement floor, but located at a somewhat higher elevation. From the boiler room to the bulkhead line, a distance of 267 ft., the water is carried through two lines of reinforced-concrete pipe, 9 ft. inside diameter with a 9-in. wall. These pipes were molded in sections 15 ft. long, each section weighing 28 tons.

Large Blowing Engine

The photograph shows the largest single-tandem, gas blowing engine constructed to date in this country. It is one of two units built by the Mesta Machine Co. for the Pennsylvania Steel Co.'s plant at Steelton, Penn., and has gas cylinders 46 in. in diameter, air cylinders 84 in., and a stroke of 60 in. The speed will range from 45 to 85 r.p.m., depending upon the operating conditions.

The air end is equipped with automatic plate valves (Iversen patent) that require no valve-gear, which makes possible the placing of the air cylinder directly back of the gas cylinders, so that the air-cylinder piston can be driven directly through an extension of the gas-cylinder piston rod. The engine is of the center-crank type.



Largest Single-Tandem Blowing Engine

Recent Development in the Construction of the Uniflow Engine

By Prof. J. Stumpf*

Since the first uniflow engine was erected in the shop of the Erste Bruenner Maschinenfabrik, engines aggregating more than 600,000 hp. have been put in operation. This figure proves better than words can do the value of the uniflow principle and the success is the more gratifying to the pioneer, because in the beginning he had to back the new idea against almost everybody.

Much credit must be given to the German licensees such as Gebruder Sulzer, Maschinenfabrik Augsburg-Nuernberg, Elsaessische Maschinenfabrik, Ehrhardt & Sehmer, Maschinenfabrik Esslingen, A. G. der Goerlitzer Maschinenfabrik and Maschinenfabrik Badenia, which last developed the uniflow locomobile engine. Professor Stumpf praises especially Sulzer Brothers, whose uniflow engines show the same high-grade design and workmanship as everything manufactured by this company. The largest engine which they have built is one of 2000 hp. installed in a cotton mill. Still larger engines have been made by Ehrhardt & Sehmer for driving rolling mills, among which are a 6000 and a 7000 hp., probably the largest output for single-cylinder engines ever made.

The standard Sulzer engines have no tail rod. It required much experimental work to find the mixture of cast iron suitable for piston and cylinder, and a large self-supporting piston needs careful lubrication to insure reliable operation. Other builders, like Ehrhardt & Sehmer, use tail rods with their big engines. Taking up the weight of the piston on a bearing surface outside of the cylinder facilitates lubrication, the bearing surface being small and having low temperature; the friction in the cylinder is reduced to that of the piston rings only, insuring long life of this part of the engine. Cylinders for big uniflow engines have to be bored in such a way as to make the bore uniform under working temperatures.

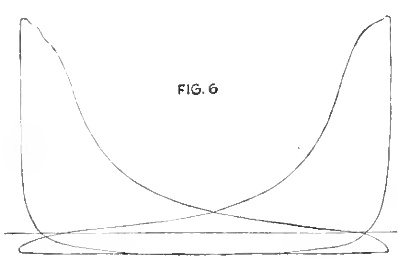

FIG. 6

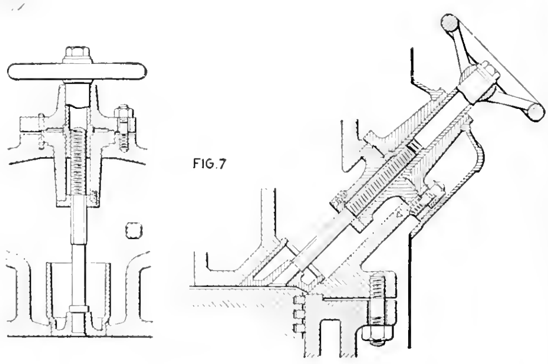

FIG. 7

engine; this engine having a tail rod only because the order called for it.

The driving parts, even those for driving the condenser air pump, are entirely inclosed. Forced-feed lubrication is used, the oil being supplied under a pressure of about 15 lb. by a small gear pump on the layshaft. The pump draws the oil from a reservoir in the basement and forces it into the main bearings, the discharge from the oil is collected in the crank pit and runs through a filter back to the reservoir to be used over and over again. Cylinder, stuffing-box and valve stems are lubricated from a separate oil pump, which is also driven by the layshaft; every feeder has its own plunger and the quantity of oil pumped is easily adjustable. The cylinder-oil consumption of a single-cylinder uniflow engine is of course considerably less than that of two- or three-cylinder compound engines.

All the larger engines are now built with layshaft and layshaft governor. The Sulzer engines have the governor close to the head-end bearing to prevent unnecessary deflection of the shaft. The governor acts by changing the stroke and the angle of advance of the eccentrics. Valve motions for uniflow engines have to be adjusted with small lead, and since the range of cutoff is short—only 25 per cent. maximum cutoff being required—it is possible to keep the variation of the lead within one-half of one per cent. or less.

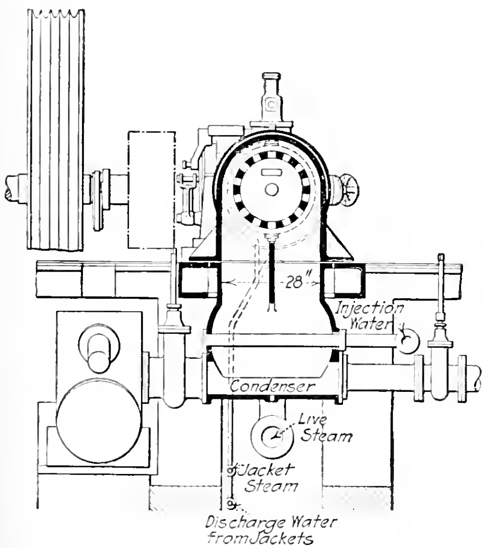

Fig. 8.

Double-beat poppet valves of the type used in compound engines have not proven successful with uniflow engines, where steam tightness of the valves is imperative. This can be insured only by making the valves as short as possible, by making one seat resilient and by balancing only to a certain amount, which has to be calculated. Fig. 2 shows valves of different types, suitable for uniflow engines. Such valves can be comparatively small. The cutoff is short and the gain in economy by reducing the clearance space outweighs the loss due to throttling. A good example of this is the cylinder of a pumping engine shown in Fig. 3, in which the clearance was reduced from 4 to 1.3 per cent. by using smaller valves, resulting in a reduction in steam consumption of more than one pound per horsepower-hour.

The elevation and plan of the 2000-hp. Sulzer engine as installed are shown in Fig. 4. All the piping is beneath the floor level, the steam pipe at one side of the engine, the exhaust pipe and air pump at the other. The condenser is connected to the exhaust belt through a wide opening so the pressure can equalize immediately.

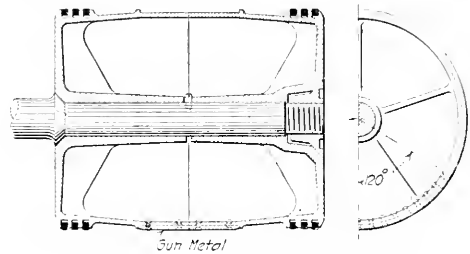

Fig. 9. Piston of Uniflow Engine

The air pump is driven from the main shaft by means of a crank and bell crank.

Belts are used for transmission, one for every story of the factory. The governing of the engine fulfills all the requirements of spinning machinery, with a comparatively light flywheel, because the governor of a uniflow engine controls more directly than in the compound engine where the influence of the governor is limited to the high-pressure cylinder. The steam consumption of this engine is better than that of a triple-expansion of the same size. Indicator diagrams are shown in Fig. 6; noteworthy is the shape of the compression line, which is almost adiabatic.

An 18x24-in., 150-r.p.m. side-crank engine, designed some time ago, is shown in Figs. 5 and 8. Cylinder and cylinder heads are jacketed, the steam for the cylinder jackets being taken from the steam main before the stop valve so the engine may be warmed up before starting it.

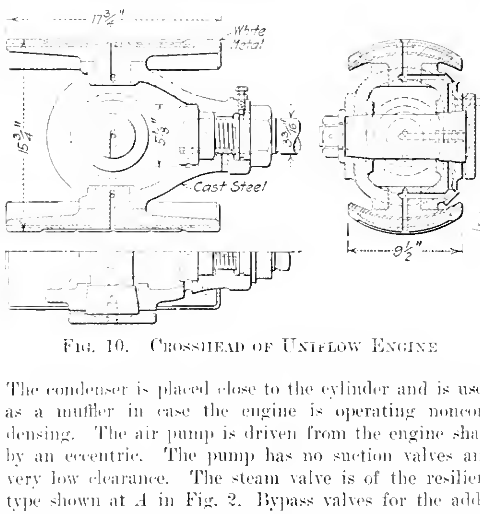

Fig. 10. Crosshead of Uniflow Engine

The condenser is placed close to the cylinder and is used as a muffler in case the engine is operating noncondensing. The air pump is driven from the engine shaft by an eccentric. The pump has no suction valves and very low clearance. The steam valve is of the resilient type shown at A in Fig. 2. Bypass valves for the additional clearance space, Fig. 7, are of a new type to give the smallest clearance when operating condensing. For relief valves the steam valves are relied on. The clearance space of this engine does not exceed 1.25 per cent. when operating condensing. The piston, Fig. 9, which is extremely light, is made in two parts of cast steel, fitted with three rings at each end. No tail rod is used, but the piston has a brass-mounted bearing surface in the middle and covering one-third of the circumference. The piston itself has ample clearance all around. The details of the crosshead are shown in Fig. 10.

It is wrong in principle to build uniflow engines for condensing service with auxiliary exhaust valves. The short compression is wrong and just as wrong is the increase of clearance space and surface connected with these valves. Even for noncondensing service, with steam pressures as used in modern power plants, auxiliary exhaust valves show no gain.

Professor Naegel, of the Technische Hochschule, Dresden, who conducted elaborate temperature measurements on a uniflow cylinder, says in his report: ". . . . The uniflow engine of the Stumpf type is able to utilize the steam in single-stage expansion in a more perfect way than it was possible to do before with the best multiple-expansion engines. The reason for this is the elimination of the initial condensation and the reduction of heat transmission through the walls, accomplished by the particular flow of steam through head jacket, steam valve, cylinder and exhaust ports, which constitutes the "Unaflow Principle."

Bayer Feed-Water Purifier

The effect of scale on the operating efficiency of a boiler and the difficulty and cost of its removal are factors which have led to the design of various types of apparatus for removing the suspended matter and scale-forming ingredients before the water enters the boiler. It will be generally conceded that this is the proper method to follow and that the solution of the problem rests in securing a device that will do the work efficiently and at a low cost. Quite recently, the Bayer Steam Soot Blower Co., of St. Louis, has given some attention to this question and is putting on the market the purifier illustrated herewith. It is licensed under Ray patents and is made for return-tubular and the various types of water-tube boilers.

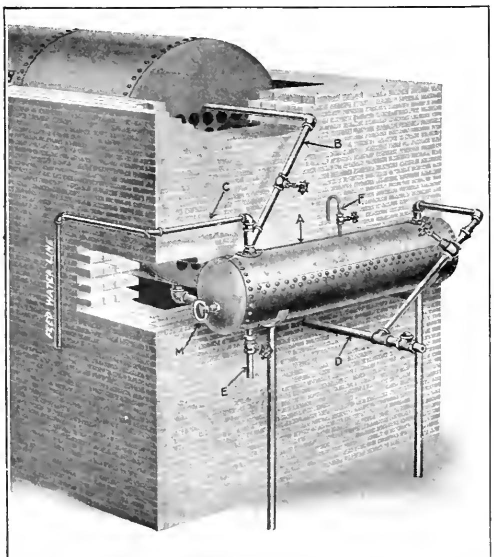

Fig. 1. Bayer Purifier Attached to Return-Tubular Boiler

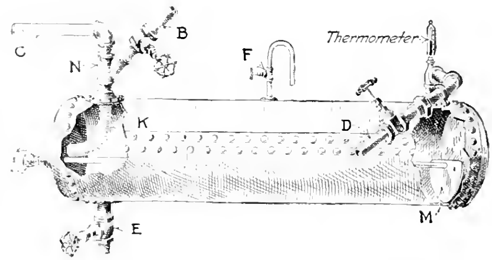

Fig. 2. Separating Tank in Part Section

Fig. 1 shows the purifier applied to a return-tubular boiler and Fig. 2 shows the tank in part section. The device consists of a cylindrical tank varying in size from 16x60 in. for a 100-hp. boiler to 33x144 in., the larger boilers being of the water-tube type. When the boiler is in operation a circulation of hot water is set up through the connecting piping and the tank. Any sludge remains in the tank and may be blown out through pipe *E*, while

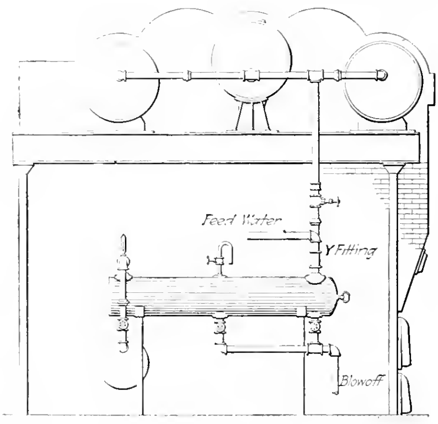

Fig. 3. Stirling Boiler Served by Purifier

the water is forced through an outlet at the top of the tank and returned to the boiler through the blowoff pipe *D*. There are three forces which tend to produce circulation through the system. The internal circulation in the boiler forces the water to the rear end, and it is at this point that pipe *B* enters the boiler just below the water level. The difference in weight of the water columns within and exterior to the boiler also tends to produce circulation, and this is augmented by the action of the ejector nozzle *N* and pressure from the boiler-feed pump. Water thus comes from the boiler at a temperature corresponding to the pressure, mixes with the feed at the Y fitting N and discharges against the head of the tank through the elbow K to obtain a uniform flow through the tank. The latter is made large enough so that the velocity of the water will be relatively slow, giving time for the foreign matter heavier than water to be deposited on the bottom of the tank. The purified water then returns through pipe D to the boiler. By properly proportioning the sizes of pipes B and C, the water in the tank can be maintained at a temperature but little lower than that in the boiler. The tank will therefore separate the suspended matter and scale-forming ingredients affected by temperature. If it is necessary to treat the water, the reagent should be mixed with the feed water before it enters the tank, so that the impurities will be precipitated in the purifier instead of in the boiler.

Scraper M has been provided to pull the deposited matter toward the blowoff at the opposite end of the tank. Valve F allows air to escape when first filling the tank and may also be used for drawing off samples of water for testing purposes.

On other types of boiler the operation is substantially the same. The pipe discharging to the tank is always tapped to that portion of the boiler just below the water line, toward which the water on the surface flows. The return pipe is connected to the water leg, mud drum or boiler blowoff, depending on the type of boiler. Fig. 3 shows the purifier connected to a Stirling boiler.

Examination Questions

Two sets of examination questions written from memory after the test was over:

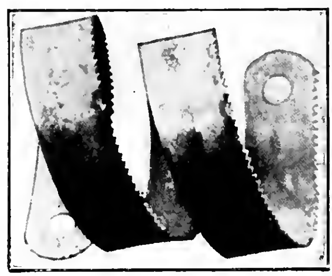
1. How would you determine the highest safe working pressure on a boiler of the horizontal type?
2. How would you determine the area of safety valve—first, lever valve; second, pop valve—required on a horizontal tubular boiler?
3. How could you determine at what pressure a lever valve was set to blow off, also a pop valve?
4. How would you figure out the number of braces required to properly support flat surfaces above the tubes in a boiler of the horizontal type?
5. Give the dimensions for riveted joints single and double, also the sizes of rivets required for the following thicknesses of metal: $\frac{5}{16}$ in.; $\frac{7}{16}$ in.; $\frac{3}{4}$ in. Give pitch of stay-bolts, also size for bracing the following area: 20x32 three-eighth-inch plate to sustain 120 lb. pressure.
6. Determine the capacity of a pump or injector necessary to supply a boiler rated at 100 hp. with sufficient water, the calculation to be based on the assumption that 30 lb. of water is evaporated per horsepower per hour.
7. Give your ideas for the proper connections of water column and steam gage to boilers. Make a sketch of same.
8. What is the best way to set two 60-in. boilers? Give thickness of walls, spaces and such dimensions as are necessary for the execution of the work. Describe the principle of fuel combustion, the effects of sulphur in fuel, the necessary elements and conditions for best results.
9. Describe what you would do in making an internal examination of a horizontal tubular boiler.
10. Describe what you would do in making an external examination of a boiler.
11. Give the names of the different types of boilers you are familiar with and how classified.
12. Give the names of the principal types of boilers in common use.
13. State what experience you have had in boiler construction, repairing or operation.
14. What in your opinion is the cause of leaky tubes?
15. How would you determine the point of leakage from an internal view of boiler, and how would you determine if inside plate was cracked or rivet broken from viewing the external part of boiler where the leakage was?
16. What, in your opinion, is the cause of boiler explosions?
17. What means would you suggest to minimize the hazard?

1. Draw a diagram showing the admission valves of a Corliss leaking and one of the exhaust valves leaking.
2. What is the effect on a cross-compound if the valves of the high-pressure sides are leaking?
3. If the receiver pressure is too high what effect has it? What would you do to equalize the work done in both engines?
4. How would you change the speed of the Corliss engine?
5. Draw a diagram of a high-speed engine, showing the valve leaking.
6. Which would you prefer—a simple slide-valve engine or an automatic cutoff, both having the same-sized cylinders and to run at the same speed doing the same work, and why? Is there any difference in horsepower?
7. Where is the steam cut off in a pump and can the valve motion be made to cut off in an ordinary steam pump any earlier in the stroke.
8. On a triple-expansion engine draw a diagram showing the intermediate admission valves and exhaust valve leaking.
9. What effect will it have on the low-pressure cylinder, if the admission valves are leaking?
10. In a Corliss engine, what determines the point of cutoff and how?
11. In an automatic cutoff engine what determines the point of cutoff and how?
12. If you want to change a Corliss engine with a single eccentric from noncondensing to condensing, what would you do; and with a double-eccentric engine what would you do?

Nonbreakable Hacksaw Blade

The chief claim for this hacksaw blade, as will readily be appreciated from the illustration, is its flexibility.

The blade shown, twisted into a coil one inch in diameter, was subsequently straightened out and run for the full life of the saw teeth.



NONBREAKABLE HACKSAW BLADES

This type of nonbreakable blade is the latest addition to the line made by E. C. Atkins & Co., Indianapolis, Ind.—*American Machinist.*

A Correction—Hubert E. Collins writes that he was in error in stating in his article on an "Interesting Steam-Pipe Installation," on page 288, issue of Mar. 2, that the main which he describes was covered with 85 per cent. magnesia. The covering used was the Nonpareil High-Pressure type, manufactured by the Armstrong Cork & Insulation Co., Inc.

Some Common Misconceptions—A mass of aluminum weighs one pound; a mass of lead of equal size weighs something more than four pounds. Some will thoughtlessly say that aluminum is more than four times lighter than lead. Weight (heaviness) is an attribute of matter; lightness is absence, or deficiency of weight. To say that one article is a certain number of times lighter than another is like saying of two vessels that one is four times emptier than the other.

It might be added that it is equally erroneous to say that one body or substance is colder than another There is no such thing as cold; there are only varying degrees of heat, although we commonly regard as cold those things that are below 98 deg. F., or below the temperature of the human body. A substance that is at the freezing temperature is quite hot compared with liquid air, as the latter boils violently when placed upon a cake of ice. Temperatures that are fatal to life are far below those used in metallurgical processes.

Properties of Saturated Air

By W. D. Ennis

SYNOPSIS—An explanation is given of underlying principles and method of computing a table of Properties of Air Saturated with Moisture, together with examples of applications of the table.

Most engineers are familiar with the steam table, or table of properties of saturated steam, but not as many of them are as well acquainted with the properties of saturated air. The table presented herewith is the result of computations made by senior students (of the class of 1915) in mechanical engineering at the Polytechnic Institute of Brooklyn: T. B. J. Merkt, Samuel Blakeman, George Wieber, Walter L. Betts, S. Ishimura, R. B. Fuller, Murray Harris, John DeGroot, Harvey Sand, Van Wyck Hewlett.

Before showing some of the uses of the table, the method of computing it will be explained. To begin with, the word "saturated," as applied to a mixture of air and water vapor, has a different meaning from that understood when we speak of "saturated" steam. When dry air and moisture are brought together at any temperature, the moisture vaporizes until the vapor pressure is that "corresponding" with the temperature, i.e., that pressure which, according to the steam table, is the pressure of saturated steam at the given temperature. The mixture is then called saturated air, and the water vapor in the mixture is saturated steam. If, however, the supply of water is insufficient, its pressure, after it is all vaporized, will be less than that which the steam tables give, and the vapor, or steam, will be superheated.

From the Marks and Davis steam tables, at 40 deg. F. the pressure of saturated steam is 0.1217 lb. per sq.in., and its density, or weight per cubic foot, is 0.000410 lb. With these data, we proceed to compute the properties of 1 cu.ft. of saturated air.

According to Dalton's law, in a mixture of two or more gases, the total pressure is the sum of the partial pressures of the constituents, and each partial pressure is that pressure which the gas in question would exert if it alone occupied the total space. If our mixture is 1 cu.ft. at standard atmospheric pressure (14.697 lb. per sq.in.) and 40 deg., the partial pressure of the air is 14.697 — 0.1217 = 14.5753 lb. per sq.in.

The weight of air in the mixture is computed from the formula:

$$W = \frac{144\,P}{R\,(T + 460)} = \frac{2.6986\,P}{T + 460}$$

where

W = Weight of dry air in 1 cu.ft. of mixture, lb.;
P = Partial pressure of air, lb. per sq.in.;
R = 53.36;
T = Temperature Fahrenheit.

The total weight of 1 cu.ft. of the saturated mixture is then

Weight of dry air + weight of steam, or

$$\frac{2.6986 \times 14.5753}{40 + 460} + 0.00041, =$$
$$0.0787 + 0.00041 = 0.07911 \text{ lb.}$$

(Note: 1 cu.ft. of dry air unmixed with moisture, at atmospheric pressure and 40 deg. F., would have weighed $\frac{2.6986 \times 14.697}{40 + 460} = 0.0794$ lb.)

The wetness, or absolute humidity, of the saturated air is defined as

Weight of steam ÷ weight of air, or
0.00041 ÷ 0.0787, = 0.00521.

The table shows that as the temperature increases, the steam pressure and weight of steam increase, while the weight of dry air and its pressure decrease. When a temperature of 212 deg. is reached, the mixture is *all steam*, the air pressure and weight are both zero, and the humidity has the greatest possible value. At all temperatures the mixture weighs less than the same volume of dry air would weigh at standard atmospheric pressure.

Unsaturated air contains less than the maximum proportion of steam for the existing temperature. The steam (consequently superheated) exerts a pressure p' less than the saturated pressure p. Its density, or weight per cubic foot, w' is similarly less than the saturation density w. What is called *relative humidity* is defined as

$$r = \frac{p'}{p} = \frac{w'}{w}$$

Using primes to denote unsaturated conditions,

$$P' = 14.697 - p'; \quad w' = w\frac{p'}{p}; \quad W' = W\frac{P'}{P}$$

and the absolute humidity of the unsaturated air is

$$r' = \frac{w'}{W'}$$

Some Applications

General Gas Equation—One of the commonest formulas in heat and power calculations is that relating to the volume, pressure and temperature of a gas:

$$W = \frac{1}{V} = \frac{144\,P}{R\,(T + 460)}$$

as already stated (V = volume of 1 lb. of gas in cu.ft.). For dry air, R = 53.36, but in nearly all engineering applications we deal not with dry, but with moist air. The value of R for such air is not 53.36, but $\frac{85.8\,w' + 53.36\,W'}{w' + W'}$.

As an illustration, consider a mixture at 200 deg. F., having a relative humidity of 0.90. At this temperature, the saturated steam pressure is p = 11.52. The partial pressure of the superheated steam in this unsaturated mixture is then by definition,

$$p' = r \times p = 0.90 \times 11.52 = 10.368 \textit{ lb. per sq.in.}$$

The weight of 1 cu.ft. of saturated steam at 200 deg. is

$$w = 0.02976 \textit{ lb.}$$

The weight of steam in the unsaturated mixture is

$$w' = rw = 0.90 \times 0.02976 = 0.026784 \textit{ lb.}$$

The partial pressure of dry air in the unsaturated mixture is

$$P' = 14.697 - p' = 14.697 - 10.368 = 4.329 \textit{ lb. per sq.in.}$$

The weight of the dry air is then

$$W' = W\frac{P'}{P} = 0.0130 \times \frac{4.329}{3.177} = 0.0178 \textit{ lb.}$$

Properties of Air Saturated with Moisture

At Normal Atmospheric Pressure P_B = 14.697 lb.

Note: P_B varies about ½ lb. per 1000 ft. of altitude. 7000 grains = 1 lb.

Column T = Temperature Fahrenheit
Column A = Weight of 1 cu.ft. of dry air, lb., = $2.6986 P_B \div (T + 460)$.
Column p = Steam pressure, lb. per sq.in., from steam table. Note: This is the maximum pressure that the steam can exert at the temperature T, so that the steam is saturated.
Column P = Dry air pressure, lb. per sq.in., = $P_B - p$.
Column w = Weight of steam in 1 cu.ft. of mixture (tabular density), lb. This is the maximum weight of steam that 1 cu.ft. of mixture can contain at the temperature T.
Column W = Weight of air in 1 cu.ft. of mixture, lb., = $2.6986 P \div (T + 460)$.
Column $\frac{w}{W}$ = Lb. of steam mixed with 1 lb. of dry air, or absolute humidity.
Column w + W = Weight of 1 cu.ft. of mixture, lb.

The value of R, instead of being 53.36, is then

$$\frac{(85.8 \times 0.026784) + (53.36 \times 0.0178)}{0.026784 + 0.0178} = 73, \text{ about}$$

Effect of Temperature on Humidity—If a mixture at 100 deg., having a relative humidity of 0.60, is cooled, say to 90 deg., the relative humidity will be increased. The original 1 cu.ft. of mixture will become

$$\frac{460 + 90}{460 + 100} = 0.982 \text{ cu.ft.}$$

From the table, this mixture originally contained, and still contains 0.60 × 0.002851 = 0.001711 lb. of moisture. The maximum amount which it could contain, if saturated, at 90 deg., is 0.982 × 0.002131 = 0.00209 lb. The new relative humidity is then 0.001711 ÷ 0.00209 = 0.82. Cooling might be carried on to a point at which this figure would exceed 1.0, when some of the moisture would separate out as liquid dew. In symbols,

$$\text{New relative humidity} = \frac{p_1' w_1}{p_1 w_2}\left(\frac{T_1 + 460}{T_2 + 460}\right)$$

where

T_1 and T_2 = Initial and final temperatures, respectively;

w_1 and w_2 = Corresponding tabular densities;

p_1 = Tabular steam pressure for T_1;

p_1' = Partial steam pressure of the unsaturated mixture at T_1.

Frosts—On a cool night in spring or autumn, the probability of a freezing temperature before morning depends largely on the relative humidity of the air. If this is high any considerable cooling will be likely to increase it beyond 1.0; that is, to cause a condensation of vapor as dew. Such condensation, the reverse of evaporation (which consumes heat), liberates heat and thus tends to keep the temperature from falling further. With a stated temperature at midnight, then, other things being equal, a freezing temperature before morning is less likely to be experienced if the relative humidity is high.

Air in Jet-Condenser Practice

By Everard Brown

While most of the larger steel works and other manufacturing plants operate many engines condensing, it is surprising to note the universally poor vacuum maintained. The range seems to be from 21 to 24 in., and it is seldom one finds an installation carrying 26 in. Manifestly, this condition does not obtain from choice, but rather because of the apparent difficulty, or impossibility, of doing better with the equipment in use.

It might seem that the type of equipment employed is at fault because the jet type of condenser is preferred for general mill purposes, both for central installations serving a number of engines and for individual units. That this is not the case is evidenced by the fact that there are installations where condensers of this type, both barometric and low-level, give as good results, for the service, as the surface type.

Inquiry among mill engineers as to the reason for such poor vacuum will usually elicit the reply that either there is leakage in the exhaust piping or the air-removing capacity of the equipment is too small. To those not familiar with mill-operating conditions, the former reason will no doubt appear inexcusable and reflect on the diligence of the engineer in charge, while the latter will reflect on the manufacturer of the condensing equipment for not supplying a sufficiently large air pump. Full realization of what the mechanical department in a manufacturing plant often has to contend with will materially lessen any blame for leaky piping. The blame can be laid at the door of the condenser builder more often, because he has not given proper consideration to leakage. Perhaps one of the reasons for this is his eagerness to get the order for the equipment, and by offering a smaller air pump he can keep the price down to an attractive figure. Should he get the order and it is found that the air pump is too small, he can always claim that there is excessive air leakage. This is bad practice because the bidder takes advantage of the purchaser, who usually believes that an air pump will be furnished of sufficient capacity to take care of at least a reasonable amount of leakage.

It may also happen that the bidder is not given sufficient reliable data as to operating conditions, in which event he can only base the size of the air pump upon the theoretical quantity of air that will enter the condenser, plus a certain percentage for leakage which, of necessity, can only be a vague assumption. As a consequence, the amount of this leakage is usually underestimated and the air-removing capacity of the condenser made too small.

Proposals for a certain-sized condenser plant were submitted by three different bidders, all based on the same set of specifications. Taking the proposal offering the largest air pump as a standard, it was found that one of the other bidders offered a pump of half the capacity and the third a pump of about two-thirds the capacity, based on an equal number of revolutions for each, which is probably as fair a way of making a comparison as any, because it is a comparison of the durability of the pumps. It is doubtful if the pump having the largest air-removing capacity was large enough, so that it is obvious what the result would be if one of the smaller pumps were put in. The speed at which a pump operates controls its capacity, and in the above instance it was intended that the smaller pump should run at a higher speed, which brings up the question of relatively high maintenance cost.

It would seem that condenser builders have established certain standard sizes of condensers and air pumps for handling given quantities of steam, apparently without due consideration of varying conditions. They can, of course, estimate with accuracy the amount of air that enters with the steam and water, provided there are no unusual conditions with which to contend; and experience should have told them long ago how much additional air-pump capacity is required because of unpreventable leaks.

The secret of a satisfactory condenser installation hinges primarily on the question of air removal, which means an air pump of sufficient capacity to take care of any reasonable amount of leakage. Oftentimes this leakage cannot be prevented because of local conditions, or its prevention proves more expensive to bring about than the cost of the extra steam required as a result of a poorer vacuum. How much better it would be to install an amply large pump and run it slowly during the colder weather or when the outfit is new and more efficient, and then, if necessary, speed it up a little as leaks begin to develop or as the hot weather sets in. Such an installation will also provide capacity for future increase in load on the condenser, a contingency which often arises in mill practice where increasing the load on equipment is common.

It will require a little more steam to operate a larger air pump, but when compared to the losses due to a poor vacuum or to the cost of maintaining an air-tight system, this becomes quite insignificant. A use for this extra steam as it is exhausted from the air pump can nearly always be found if looked for; such, for example, as heating feed water for boilers, an avenue that offers a chance for considerable saving in power costs and possibly one which has been overlooked in many cases.

Test of a 16-Hp. Petter Oil Engine

By Chas. S. Salfeld

Some time ago a 16-hp. Petter two-stroke-cycle semi-Diesel oil engine, made at Yeovil, England, was shipped to this country and subjected to a series of tests by the writer. The engine is of the single-cylinder, vertical, crank-case compression two-port type, 9¾-in. cylinder bore by 10½-in. stroke and running normally at 325 r.p.m. It is provided with a flywheel weighing 1000 lb. and supported by an outer bearing. The exhaust ports open and close at 75 per cent. of stroke and the scavenging ports at 88 per cent.

The fuel-injection pump, owing to wedge regulation, commences to inject at varying times, according to the load. At maximum load this occurs at about 46 deg. before the upper dead center; at rated load about 34 deg.; and at smaller loads, still later. The end of the injection period is constant at all loads and is reached when the crank has almost completed the compression stroke, that is, about 5 deg. before the dead center. The governor raises and lowers a wedge interposed between the pump lever and the pump plunger and thereby graduates the impulses according to the load.

The cylinder head is an adaptation of the well known Hornsby-Akroyd principle. Its upper part, against which the fuel is sprayed, is uncooled but usually remains black. No hot bulb of the generally accepted term is employed, but to facilitate starting a short nickel tube is provided. Water injection into the scavenging port is furnished, although it is not supposed to be used up to the rated load.

The engine is one of several British makes which are widely advertised as being capable of operating with a fuel consumption not exceeding one-half Imperial pint, which would be equivalent to 0.6 U. S. pint, or 0.075 U. S. gal. While the writer is convinced that such economy can be and is obtained with thoroughly well designed engines of this class, neither he nor several of his assistants were capable of realizing such consumption on this particular engine. The very best they ever obtained, but not by any means the average, was 0.597 lb., or 0.0886 U. S. gal. of 42.5-deg. distillate, which is an excess of 18 per cent. The cause was not far to seek and presented itself in the unreliable performance of the fuel pump and injector. Further satisfactory characteristics of the engine are its capability of operating without water injection even beyond the rated load, its high mechanical efficiency, and the equally high volumetric efficiency of the crank-case air pump.

Particularly by eliminating the water injection have the makers solved a problem which, of late, has been a source of considerable trouble and anxiety to a number of manufacturers. This has been done partly at the expense of power output. Until early in 1912 this size of engine was rated at 20 b.hp. and water injection was used. The makers then decided to rate it at 16 b.hp. and abandon the use of the injection water. The writer operated the engine at the maximum load the governor would permit, namely, 23 b.hp., then removed the governor wedge so that more oil could be admitted, and it was evident that a considerably higher horsepower might yet have been developed with water injection.

During the principal trials the fuel used was distillate of 0.826 sp.gr., or 39.5 deg. Baumé. Tests with crude oil and with fuel oil were also made, and these will be found appended. The first named tests gave the following results:

Approx. Load	0	¼	½	¾	⅞	1	1⅓
B.hp.	0	4.025	8.1	12.3	14.9	16.45	22.1
R.p.m.	338	335	335	335	334	334	318
M.e.p.	12.6	14.0	19.6	24.6	29.2	30.1	38.5
Net i.hp.	8.45	9.3	13.0	16.3	19.3	19.9	24.25
Net mech. eff...	0	43.3	62.3	75.6	77.3	82.7	91.1
Oil per b.hp....	...	...	...	0.636	0.627	0.613	0.635

The average volumetric efficiency of the crank-case air-pump was 80.4 per cent., which was practically constant at all loads. At maximum load (22 b.hp.) the scavenging pressure was 3.6 lb. per sq.in. and the compression pressure 140 lb. The explosion pressure varied from 250 to 318 lb. and the exhaust pressure was about 28 lb.

The following test was carried out with Peruvian crude oil of 0.895 sp.gr. (26 deg. Baumé), 105 deg. F. flash point, and 18,601 B.t.u. per lb.:

B. Hp.	R.p.m.	Fuel per B. Hp.-Hr. Lb.	Fuel per B. Hp.-Hr. U. S. Gal.	
16.4	334	0.625	0.0837	With injection water
16.3	332	0.638	0.085	Without injection water
15.5	335	0.618	0.083	
14.2	338	0.626	0.084	
10.0	340	0.761	0.102	
5.2	344	1.23	0.165	
0	345	5.42 per hr.	0.726 per hr.	

The consumption of 28 deg. fuel oil (0.886 sp.gr.) was as follows:

B. Hp.	R.p.m.	Fuel per B. Hp.-Hr. Lb.	Fuel per B. Hp.-Hr. U. S. Gal.
15.9	322	0.646	0.087
14.9	324	0.676	0.091
9.5	325	0.893	0.121
5.1	334	1.33	0.18

The best consumption obtained with 12.5 deg. distillate was:

B. Hp.	R.p.m.	Fuel per B. Hp.-Hr. Lb.	Fuel per B. Hp.-Hr. U. S. Gal.	British Imperial Pints
15.1	326	0.597	0.088	0.59
13.8	328	0.606	0.089	0.598
9.85	335	0.703	0.104	0.694
5.1	333	1.456	0.217	1.435

The regularity of running was satisfactory except at no load, when considerable "hunting" occurred. This was not due to any defect in the governing apparatus, but to insufficient heat in the combustion chamber, the compression pressure of 140 lb. apparently being a little low. Nor did this "hunting" occur with all fuels; with crude oil it was altogether absent, but with fuel oil and with distillate it was distinctly noticeable. A throttle valve on the air inlet would have been a remedy, but none was provided. The exhaust was visible with all fuels and at all loads, but was in no way objectionable.

Effect of Temperature on Capacity of Centrifugal Pumps

By John Howard

At a recent test of a centrifugal boiler-feed pump an opportunity was afforded to determine the effect of varying temperatures upon the capacity. It was a standard Platt 3-in. three-stage pump, driven by a Terry steam

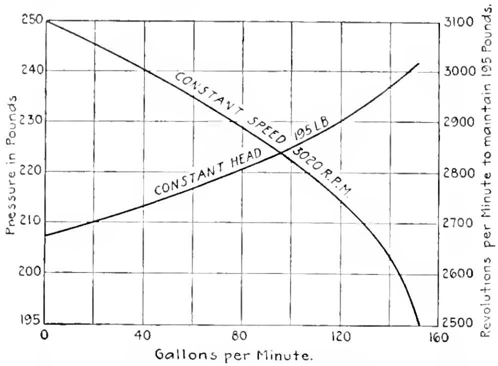

Fig. 1. Capacity Test for Constant Head and Constant Speed

turbine, and designed for 150 gal. per min. against 195 lb. pressure at 3000 r.p.m. As the head on the suction was only about 30 in. above the center line of the pump, the builders would not guarantee to handle water at a temperature greater than 180 deg. F. The water was measured by a G. E. flow meter which was afterward calibrated and found correct.

The capacity test gave the results for constant head and for constant speed, shown by curves in Fig. 1. The

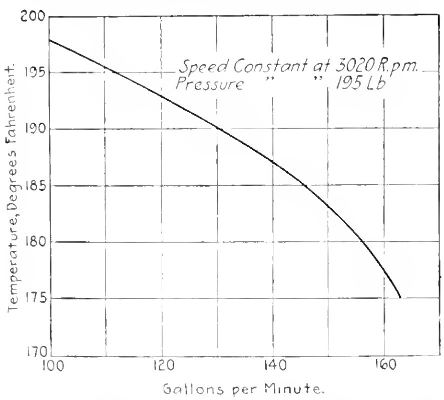

Fig. 2. Results of Temperature-Capacity Test

first curve was obtained by the use of a pump governor, and the second when the governor was cut out, the capacity being varied by throttling the discharge.

In order to make the temperature-capacity test, the temperature of the water in the open heater from which the pump took its suction was varied by controlling the amount of steam passing into it. The result is shown by the curve in Fig. 2. The great variation is undoubtedly due to the extremely small head on the suction side of the pump.

While the guarantee was for only 180 deg., it was found that by speeding up the pump somewhat, water at 190 deg. could be handled safely.

Power Costs in a Tenant Building

By Alfred A. Winter

At a time when we are all interested in figures on economical power costs, based either on theoretical calculations or test results of newly constructed uptodate equipments, I venture to show cost figures from an out-of-date plant, such as a large number of engineers have in their care. These figures are not record breaking, and no doubt some who are skilled in obtaining real efficiency will throw up their hands in dismay. But the thought that it is sometimes well to see ourselves as we really are, impels me to show our figures for 1913 and 1914.

The plant has two Babcock & Wilcox boilers (total normal rating 175 hp.) equipped with Murphy furnaces, and one deck tubular boiler, flat-grate, 150-hp. in reserve, and two high-speed, single-valve engines—one a 22x18-in. and one a 14x14-in., also a 10-kw. direct-connected unit for night lighting, as the plant runs only in the daytime. The larger engine has two driving pulleys on its shaft, one running a belt drive through certain of the buildings and one driving a 100-kw. belted generator.

The smaller engine is direct-connected to a 75-kw. generator. The power is about equally divided between shaft and electric drive and is used for various purposes of manufacturing, this being a property with tenants, to whom power is sold.

POWER COSTS FOR 1913 AND 1914

Items	1913	1914
Taxes	$562.50	$562.50
Insurance	225.00	225.00
Water rent	500.00	500.00
Coal	6,420.45	5,305.65
Labor (operating)	4,144.00	4,151.50
Labor (extra repairing)	503.45	373.01
Supplies for operating repairing—		
Oils	171.66	136.34
Packing	47.71	13.26
Boiler compound	136.50	134.62
Boiler-room supplies	51.05	68.80
Furnace and stoker supplies	264.35	.....
Pipe, valves and fittings	49.31	119.44
Lumber and millwork	.....	3.58
Sand, cement, stone and lime	.....	9.35
Electrical supplies	32.42	43.56
Tools	14.07	40.04
Hardware	.....	4.71
Miscellaneous	13.90	34.13
Repairing (outside labor)—		
Boiler, furnaces and stokers	283.10	314.13
Engineer and pumps	133.30	12.00
Electrical	10.88	24.50
Belts	7.55	.....
Roofs, spouts, etc.	.....	38.58
Stack	315.30	.....
Pipe fittings	.....	324.00
Miscellaneous	3.50	50.30
Total operation and repair expenses	$13,890.00	$12,489.00
Depreciation on $37,500 (4 per cent.)	1,500.00	1,500.00
Total	$15,390.00	$13,989.00

Horsepower	1913	1914
Generated at boilers	428	382
Loss—condensation, friction and transmission	85	85
Delivered to tenants	343	297
Cost at boilers (without depreciation account)	$32.50	$33.00
Cost at boiler (with depreciation account)	36.00	37.00
Cost delivered to tenants (without depreciation account)	40.00	42.00
Cost delivered to tenants (with depreciation account)	45.00	47.00

Operating Hydro - Electric Plants without Attendants

By J. M. Wanchope

Two power plants were recently installed by a mining company in northern Idaho, which are normally operated without attention, except once a day when the mine electrician looks them over.

The company buys most of the power used in its mine and mill, it being delivered at 2300 volts, three-phase. Having several water rights on small streams, it was decided to put them to use. One location was a short distance from the mine, where a head of 400 ft. with sufficient water to develop 150 kw. could be obtained. Another was found where, by utilizing three small streams with heads of 100, 160 and 250 ft., respectively, sufficient water to develop another 150 kw. was obtained.

The waterwheels used were of Pelton type with belt drive to the generators. As the plant had three heads, three wheels were secured to one shaft, each being adapted to a different head. The nozzle of each wheel was fitted with a deflector to direct the water from the wheel without stopping the flow.

Each plant was fitted with a common flyball engine governor, driven by a belt from the wheel shaft and so adjusted that with a rise in speed of from 5 to 10 per cent. above normal a small weight was released, which in falling released a heavy one. This was so connected to the deflector lever that the latter was moved to a position to cut off the water from the wheel, causing the unit to stop.

The generators operate in parallel with the power company, feeding into the mining company's lines on the customer's side of the meter, thus decreasing by their output the power purchased. The electric company thus provided the governing, as the generators were operated under constant load, the nozzle being set according to the amount of water available.

Automatic switches were used for the generators with no-voltage and overload trips on them. In case the electric company lost their load the effect was practically the same as a short-circuit on the small plants, due to the heavy load thrown on them. The switches would then instantly open, and the wheels and generators would start to speed up, causing the trip on the flyball governor to release the weights which raised the deflectors, thus shutting down the units. Of course, when this happened the electrician at the mine or mill knew that the load had been dropped and started the units up again as soon as the power company had returned the voltage to their line.

As the mining company was billed for the power used partly on the maximum amperes drawn from the line of the power company as determined by a graphic ammeter, it paid the mining company to keep the peak as low as possible. The two plants were operated with a leading power factor up to the capacity of the generators in current, to keep the current drawn from the line as near unity as possible, the mine load being composed of induction motors and naturally lagging. Power-factor meters were installed at each plant and in the substation of the power company on the mining company's feeder. The plants operated nicely under these conditions. There would have been no returns if an attendant had been kept at each plant, but under the conditions as stated they returned a fair interest on the investment.

Just for Fun

[More stories of stupidity and ignorance competing with "Some Original Ideas," as printed Jan. 19, 1915.]

Still Thirsty

A chief of a small electric-light plant, being somewhat dry on sundry occasions, decided to tap the line leading to his boiler-feed pump, where cool palatable water was being handled. What was his surprise to find his dipper dry! He had tapped the suction which operated under 12 or 14 inches of vacuum.—*J. W. Fowlkes, Denver, Colo.*

A STEAMLESS ENGINE, A NEW POWER MOTOR

After the horseless carriage and wireless telegraph now comes the steamless engine, a rotary power motor that revolves of itself without the aid of steam heat, oil, gas or electricity, or any other external source of energy, and gives forth power that can be employed and made use of.

It could be called a "wheel within a wheel" motor, or a "planetary" motor, as, like a planet of the solar system, it revolves of its own momentum. It is in the shape of a flywheel or pulley and turns on an axis or shaft, being practical and efficient and simple of construction. It is called the Burr Evans Motor. The inventor is a practical mechanical and mining engineer now in Placerville.

The motor can be made of any size desired, from one inch to forty feet or larger in diameter. The smaller sizes will keep clocks wound-up and furnish power for any and all purposes about the home and farm. When a large amount of power is required, to operate for instance a large electric generating or pumping plant ten or more of the larger size motors can be attached to one axis or shaft. The medium size motors, from one to five meters in diameter, will be the most used on and about farms and for pumping water cheaply to irrigate lands to raise food-stuffs and for compressing air for mining and mechanical work.

The cost of operating the motor is infinitesimal. After the principle involved, that causes the motor to revolve, is understood, it is plainly evident that it will operate and supply power. As a cheap power producer it will be a great and lasting benefit to mankind in general. It is so simple that the wonder is not that it has been thought of, but that it has been delayed so long.

A New Power-Creating Motor. No External Energy Required.

A machine, that could be called an "Automatic Fly Wheel Power Motor," which will supply power at a very nominal cost per horse power, has recently been perfected. It creates energy automatically on about the same hypothesis as water is raised gradually from the ocean surface upward and floated as clouds in land and dropped as rain, which eventually falls in a large body as at Niagara and creates power, and then returns to the ocean sea and rises again and thus goes round and round as it were, producing power each time on its downward course. Thus it is with the Burr Evans Motor.

The machine is based on an entirely new principle of an automatically revolving flywheel, which of its own momentum gives forth power in any quantity desired according to the diameter of the motor, which can be from one inch to fifty feet or more. And where a large amount of power is required, twenty or more of the larger size motors can be placed on one center shaft.

After the motor is placed in operation the cost of producing power will be only the ordinary wear and tear of the machine, which can be cut down to next to nothing per horse power by using the modern hard and tough metals and self oiling ball bearings in the construction of the machine. The motor can be made in quantities at a very reasonable cost, and it requires no care or attention when in operation.

The motor will be especially useful and beneficial to mankind in general for generating electricity at a nominal cost at any place in small or large quantities, and for pumping water cheaply for irrigating farm lands to raise foodstuffs for the increasing millions of human beings.

The inventor, Mr. Burr Evans, is a practical mechanics and mining engineer and is now at Placerville.

It is true of most discoveries that after they are brought to light they are almost self evident. Thus it is with the Burr Evans Motor.

Achievement

In the February (1915) issue of "Arches," a monthly journal published at Ruskin, Tenn., there is an article headed "Achievement," from which the following is an extract:

"So much has been accomplished lately, and in such a short time that no one dares to say that anything is impossible, for so many of the things that are in every day use, were once—only a short time ago—said to be impossible. But today we are used to seeing the impossible accomplished."

Thus it is with the Burr Evans Automatic Fly Wheel Power Motor, at first thought it may seem impossible that the Motor will operate of itself as claimed, but like the sewing machine, the wireless, etc., after the principle is seen and understood, it looks simple and a matter of course, and the only wonder is that it was not thought of sooner.

In the same issue of said journal is another article in regard to obtaining energy direct from coal, in which it is stated as follows, to wit:

"When it is attained, an almost incalculable addition will be made to the mechanical energy employed by man. The idea of taking power direct from its natural sources is in accord with the spirit of the age. We are becoming impatient of the old, indirect, cumbersome ways, and what is more important, we are beginning to appreciate better the wastefulness of many of them. But in the case of coal it would seem that still another step would be made which would carry us back of coal itself to the source of energy that we find stored in it. *That source is the sunshine.*"

And Sunshine is simply diffused electricity held in suspension in the atmosphere as it were, and all it requires is an electric generator, operated by some inexpensive method, to gather in and consolidate this electric-sunshine energy in any quantity desired to be used for *Power* at any place and at any time. And the Burr Evans Automatic Flywheel Power Motor will supply the inexpensive method with which to continually operate millions of electric generators at every place in the world where power may be needed.

Where the Water Went

It is necessary to carry a rather high pressure of steam at the Depot building here, and the water comes back so hot that steam comes out of the overflow, which I can close, as it is in the boiler room.

One night, while I was cleaning fires, the tank ran dry and I opened the make-up valve, leaving the overflow closed, which backed the water up in the return pipe. On discovering my mistake I opened the overflow and relieved the pipe. In the meantime the car inspector had tapped the pipe in the building to heat wash water and, having placed his bucket of water and turned on the steam, stepped outside a moment. On returning he found the bucket empty, and accused his partner of emptying it. Although he is supposed to thoroughly understand steam heat, he still contends that his partner, instead of the engineer, emptied the water.

This is amusing, but not the most stupid occurrence that has come under my observation.—*Willis W. Nelson, Spokane, Wash.*

A Leaning Chimney Plumbed

By Thomas S. Clark*

Many methods have been employed to bring back to the vertical position tall columns such as chimneys, shafts, towers, and the like, which have leaned or settled out of plumb. The procedure has often been very expensive and hazardous as well as slow. In the case of chimneys it has compelled shutting down the boilers and a consequent loss in output of the manufacturing plant. A new, unique and inexpensive method was recently employed to straighten quickly a 100-ft. factory chimney in Brooklyn, N. Y., without interruption to the plant.

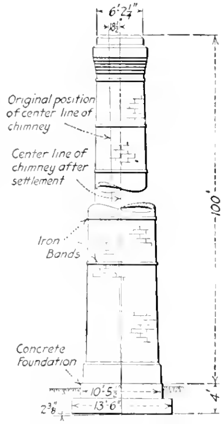

Fig. 1. Leaning Chimney in Brooklyn, 100 Ft. High

The Problem

Under one side of the foundation the soil had softened, and settlement had taken place, due to leakage from a water pipe near the foot of the foundation, whose existence had been forgotten. Fig. 1 shows the leaning chimney.

To excavate on the low side of the foundation to the depth of the footing course, crib under it, and attempt to jack the structure back plumb, would have involved large cost, loss of time, and not a little risk. The great weight of the 100-ft. column and the additional pressure due to the leaning would have required powerful jacks and a substantial footing to jack against. There would have been danger also of cracking the unreinforced spread foundation, and additional foundation would have had to be placed before the jacks and cribbing could have been removed safely.

Another method to straighten a leaning chimney, employed to some extent in Europe, is to saw out a course or a portion of a course of brickwork on the side of the columns away from the direction of lean, in wedge-shape, with an ordinary two-man crosscut saw, and allow the portion of the chimney above the cut to settle back. This method is, to say the least, not entirely satisfactory nor does it remedy the defect entirely, as the portion below is still out of plumb and the bearing surface of the foundation footing is not brought to the horizontal. For these reasons these two methods were abandoned.

The chimney was in operation, so it was not possible to determine the amount of its lean by plumbing to a center on the inside. The deviation from the vertical was therefore determined with a transit by a simple triangulation; it was found to be 18½ in. From this figure, with the known height of the chimney, it was determined that the toe of the footing on the high side must be settled 2⅜ in. on a line exactly opposite the direction of the lean. The problem was to remove just enough earth between the center of the foundation and the toe of the high side to gradually settle the foundation back 2⅜ in. at the toe. Levels were taken on the high side and an indicating plumbline fastened to the side of the chimney.

How the Work Was Done

A trench was excavated on the high side to the depth of the foundation, about 4 ft., the length of the trench equal to the square side, and its width equal to half the width of the foundation, or about 8 ft. Four 2-in. wrought-iron pipes, 8 ft. long (half the width of the foundation), were sharpened sawtooth fashion at one end. These pipes were successively driven under the high side of the foundation near its center (Fig. 2), then withdrawn, and emptied of the material in them by driving a steel rod through the pipe. Successive insertions were made about a foot apart. As the pipes were withdrawn, the adjacent earth crushed into the holes left.

In this way but a small quantity of earth was removed at a time, and but a small quantity gave way at a time; the yielding occurred just where wanted. The chimney settled back gradually, with no shock or no danger. The amount of settlement, its direction, and the rapidity of settlement were always in absolute control. The telltale plumb-bob gave the direction as well as the amount of movement.

At one period of the operation the chimney began to settle slightly out of line. It was only necessary to drive the pipes more often at a certain point to bring the shaft back to line.

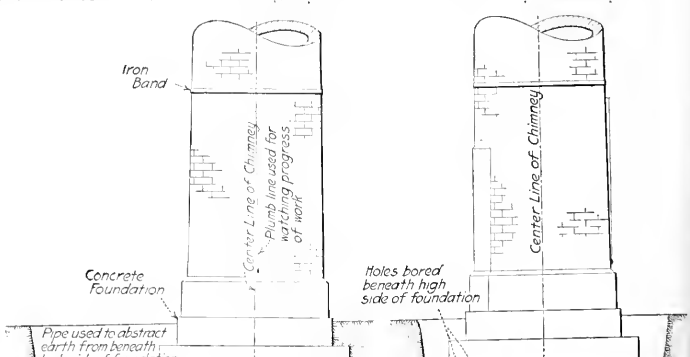

Fig. 2. Method of Removing Earth under High Side to Bring the Chimney Back to Plumb

When the column was again plumb the trench was filled up. The underground leak in the drain pipe had been previously stopped to prevent further softening of the earth on one side. The chimney has since remained intact.

The work was done by the Alphons Custodis Chimney Construction Co., of New York. The method was devised by the writer.—*Engineering News.*

Editorials

The Engineer at Public Hearings

Operating engineers seldom have to address legislative committees, public-service commissioners or municipal officials in formal hearings, but when they do it is worth while to know how to do it. As a class, engineers are men of deeds rather than of words, while lawyers are fairly characterized by the latter qualification. It is not easy to carry a petition successfully through a public body, and the causes which tend toward failure in this direction deserve careful consideration.

Engineers seeking legislation or other regulatory action must first of all present their cases upon the solid foundation of facts. Hearsay evidence cuts very little figure with the average committeeman, but a few essential facts and figures throwing light upon the problem in hand, set forth in a plain, logical way, will do wonders in commanding a respectful hearing. Often it pays, no doubt, to club together and retain counsel to look after the legal side of proposed measures; but above all, it is essential to stick absolutely to known facts and conditions and not to attempt to strengthen the case by introducing evidence of uncertain nature. It is better to say "I don't know" a hundred times in a forenoon before a committee, when the witness or proponent of a measure is not fully informed, than to try to "bluff through" on suppositions—a lesson that is none too easily learned in other walks of life.

A fair degree of consideration for the views of one's opponents is desirable, so far as it does not jeopardize the objects of the petitioners. Thus, a bill may be drawn to limit central-station rates in a way that will make life more tolerable for the plant engineer. The latter ought to be able to gain his object without attacking the desirability of giving existing capital a reasonable return. In advocating any measure the proponents ought to be prepared to meet the question of its effect on present business organizations. One of the greatest defects seen in legislative committee rooms is the inability to see more than one side of a question—a defect which narrows the character of evidence presented and often leads to disaster when the finding comes through. The engineer cannot be expected to present a case with the skill of a Webster or a Choate, but he can certainly make sure of his facts and stand on those, even in the face of severe cross-examination. Restraint in advocating any cause goes further than excessive one-sidedness.

Recent observation of the work of engineers in hearings emphasizes the importance of presenting only pertinent data, of avoiding tempting side-issues and personal grievances not affected by the proposed measures, and of putting in evidence bearing toward a definite demonstration of the need for a given bill. The burden of refuting a measure may be thrown upon the engineers' opponents in many cases. The avoidance of needless work is as important as the presentation of facts bearing directly on the matter in hand. Mere assertions that a bill is desirable count for little. Coöperation is absolutely essential in "framing up" a proper line of attack in supporting legislation on behalf of the engineer, and simple, direct methods are invaluable in dealing with public authorities.

There Is No Royal Road

Knowledge is not to be found by waiting with idle brain and hands. Knowledge may be acquired only by those whose desires are sufficiently strong to urge them to make the effort, both mentally and physically, to win it. The fields of knowledge are unfenced. There are no barbed-wire entanglements to obstruct the way, no trenches across the road, to be won only by fixed bayonets and the strenuous charge or spectacular bravery. Neither is the road to knowledge the velvet-covered royal way made smooth by the toil of others. He who seeks must build the road for himself. Each step means the expenditure of time and effort, with no limit upon the results that may be attained, except the self-imposed limitations of the seeker.

The means of acquiring knowledge are within the reach of all. Free libraries and reading rooms are open to all who care to enter, and in them may be found books and periodicals covering almost every subject. Attendants are there who will inform the seeker where he may find books and articles upon the desired subject. A letter, costing two cents to mail and inclosing a stamp for a reply, will bring an answer or suggestions as to where the answer to nearly any question may be attained, not obtained. The printing press has made books low in cost, and reasonably few are required to cover any one line of research. But no book is of any use until taken from the shelf and opened. Ages ago someone said, "You must creep before you can walk, walk before you can run." The aviator does not jump into his machine and immediately reach the height of the clouds. The tower is not started at its full height and built down to the ground.

In building the tower the first step is excavating for its foundation, by clearing away the soft, springy surface to a firm footing. A foundation must be laid before the builders are ready to start on the tower. The aviator starts his machine on the ground and gradually rises. In learning to walk each step in advance must be made by itself and completed. There is no short cut; no royal road. Experience is the only real teacher. The higher branches of any subject cannot be understood until the beginner has learned to understand the fundamentals of that subject, has learned to reason, and each one must learn to think for himself. No power outside of the individual can cause his brain to work. No power can teach unless the brain is ready to receive and able to understand. One may be able to repeat a rule, parrot-like, word for word, but unless the reason for that rule is clearly understood it is of little value, for it cannot be applied with intelligence.

Charting the Plant

How many engineers can show a blueprint or any kind of a plan of any portion of their plant, or of any of its equipment? How many have a list of the machinery in their plant, giving information in regard to its size, date of installation, make and purpose? Yet without these, they cannot promptly answer requests for information from the head office.

Construction plans showing the relative locations of pipes and the different pieces of apparatus, of electric-wiring ducts and panel boards, of valves and the purpose they serve are often laughed at when the apparatus is installed. They help, however, in later locating new equipment without interference from a long forgotten sewer or buried pipe line. It is often hours and weeks before the new man on the job is broken in and can perform all the duties of his position without questioning one of the older men. In the one-man plant many tedious hours are spent in doping out the various lines of pipes and their valves. Many a shutdown is caused by the lack of some simple little diagram or plan, one that a man could make in a week or even a day. What the lack of that plan costs can only be measured by the size of the plant affected. One man's time for a week may be forty hours, which is the same as forty men losing one hour each, or four hundred losing six minutes each. And six minutes is a very short shutdown.

The lack of plans is rarely the fault of the engineer, the man in charge of the plant. He often has all that he can do to keep it running. Lack of plans is due to the endeavor to cut down cost, that terribly high first cost, and often to trying to save time, because it would take too long to make a drawing to scale. No one seems to realize that if the scale drawing is not made in the office before construction, a full-sized model is built in the field by cut, try and fit methods. You can get out of paying for the drawings, but you cannot escape paying for the unnecessary waste of time caused by the lack of drawings. True, you may not be able to see the amount you pay for measures made in the field, for cutting and fitting, but pay you do, either in money or in time, not only in the first cost, but in upkeep, in making repairs.

Lubricants

Lubricating oils are made up from a few easily obtainable base oils or greases. The number of combinations and their proportions are unlimited, but the function which each ingredient has in the compound appears to be unknown to the purchasing public. We do not know exactly what qualities are improved by adding certain oils, or whether what are popularly known as adulterants may not be better than the oils with which they are mixed. Knowledge of this kind can only be gained by long and careful test, the expense of which no one firm should stand.

If a consumer understood why John Smith's No. 3XX oil is all right in the heat of a closed engine room, but refuses to work after the room is properly ventilated, he could discuss the oil question more intelligently. As it is now, oil is bought on representations of the most general sort and on the trial and error system. There is not always a certainty that the same brand of oil does not change while it is being stored by the purchaser. Who knows what the effect may be of pouring a new barrel of oil into a tank in which there remains a few inches of some old oil, especially when he knows the composition of neither? There may be chemical changes going on even with mineral oils. We can be confident that there are changes with time if the oils are of animal or vegetable origin.

This is a serious problem. It is not so much that the saving in oil would amount to much. It would not, but the saving in power is important. Power is mostly generated to be transformed into heat by way of friction. In some sections of the country power costs so little that it has hardly to be considered, but generally, the engineer is held responsible for the size of the coal bill, and a man who can cut the consumption is worth more than one who does not take into consideration all the possible wastes that may be going on. In some plants the engineer's responsibility is assumed to end at the door of his plant, but most owners would welcome his assistance in reducing costs, even to his suggesting the oil to be used in the shop or mill. The man whose pay envelope depends on the low cost of power has a right to ask that every precaution be taken to see that his power is intelligently consumed.

This problem is too large and of too universal interest to expect that any one maker of oil will shoulder the burden. Some university or other public institution should assume it. We know much about oils, but our knowledge is based more on their manufacture and chemical composition than on physical tests, and while the composition of an oil may be duplicated if known, it is its physical properties that interest the engineer.

Dissatisfaction in Massachusetts

If the present engineers and firemen's license law in Massachusetts is so woefully wrong and objectionable as the supporters of the new license bill would have us believe, it seems strange that it should have taken about twenty years to find it out.

No matter how good a law may be, it will not find universal favor. The present law in Massachusetts may have its little defects. Even so, why should a new bill be introduced? Are amendments to the present law, where needed, impossible? Those for and those against the bill now before the Massachusetts legislature should know that the function of license laws is to promote public safety. With this in mind as the fundamental basis to work on, the present situation ought to be easily adjusted to the satisfaction of all without destroying a law which, on the whole, has been long and widely recognized as good.

The letter, "Live Steam vs. Live Men" on page 412, is printed, not because of its news value, for there is nothing unique about it, but to call attention again to the dangerous conditions that are permitted to exist and the necessity for regulations which will prevent them. How naïve the observation that "It (the bill) was supported by a number of engineers and opposed by a number of manufacturers."

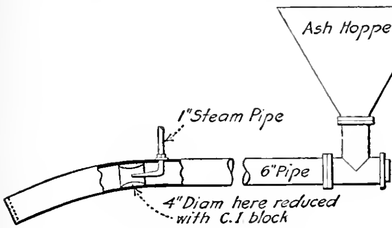
"Aye, there's the rub."

When a daily paper thus throws its influence against a good measure, it is only natural that its motives should be questioned.

Correspondence

Live-Steam Ash Ejector

E. H. Clarke inquires in the issue of Dec. 22, 1914, as to why his ash ejector will not work. I believe that if he will plug the end of the 6-in. pipe at the hopper end and fit a nozzle about 7/8 in. diameter, as shown in the illustration, about three feet from the discharge end, he will get



Vacuum Ash Handler

over his trouble, as it is far easier to draw ashes out by a partial vacuum than to blow them out. At the same time, I think that less steam will be taken with the suction outfit, although steam ash ejectors of any type are very wasteful and should not be used if it is possible to use an elevator or conveyor.

E. R. Pearce.

Rochdale, England.

Protecting Dry Batteries

Dry batteries are used extensively for operating bells, tank signals, ignition work on engines, etc., and to many engineers it is a constant source of worry to keep them in good condition. The nature of the work demanded of the batteries often calls for their use under damp, hot, dry or other unfavorable conditions. The life of the average dry battery depends more on the conditions in which it works than on the actual current drawn from it.

The writer has adopted the scheme of protecting batteries from dampness and changes in temperature by covering them with paraffin, the results being not only increased life of the battery, but also increased efficiency. All that is necessary is to secure a light wooden or even pasteboard box large enough to hold the required number of cells and sufficiently tight to hold melted paraffin. The box should be of such a shape that the batteries may be set on end with about half an inch between cells, and deep enough so that they may be covered completely, including binding posts and connections, to a depth of at least half an inch. The batteries should be connected as usual and the terminal wires led outside the box where a switch may be connected if desired. Paraffin is then melted over a steam bath or in a double boiler and the box filled. It should be remembered that the paraffin will shrink in cooling, and for this reason it is necessary to cover the batteries to a considerable depth to insure their being completely covered after cooling.

A set of cells fixed in this manner is waterproof and proof against drying out. They will last at least twice as long as they would if not covered. The writer has records of sets that have given service in ignition work for from sixteen to twenty months. For bell work they should last longer. The cost of covering the batteries in this manner is very small. Any suitable-sized box may be used and the cost of paraffin is not over twenty-five cents for a set of four batteries.

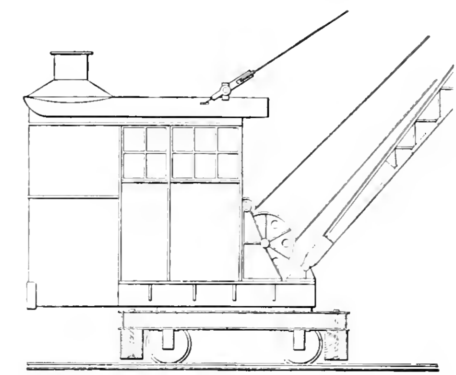
James H. Beattie.

Washington, D. C.

Operating a Locomotive Crane

On a locomotive crane which I was operating, the bottom of the truck frame was about 24 in. from the top of the rail. When the wheels jumped the track the first thing to strike was the bottom of the axle boxes, and the weight of the apparatus (about 70 tons) would fall on the boxes on one side, meaning that two new boxes (if all four wheels went off the rails) had to be replaced before the crane could be operated again, beside letting the crane sink down to the axles, as the track was laid on filled-in ground.

To overcome this difficulty I used two timbers that were in the old lumber pile and bolted them fast under



Timbers under Crane to Prevent Damage and Facilitate Replacing when Derailed

the truck frame, leaving about a two-inch clearance between the bottom of the timber and the top of the rails. When the crane jumped the track again it could only sink two inches and rest on the timbers both back and front. After that it was only necessary to swing the loaded bucket over the rails, raise it to the top of the boom and lower the latter till its weight together with that of the bucket overbalanced the back end of the crane. Then when the wheels were clear of the rails, by setting a jack or a heavy block on a slant against the side of the frame and raising the boom, the crane would tilt over and the wheels would fall back on the rails. When one end was on the rails the position of the boom was reversed and the same operation performed on the other end.

Instead of taking four or five hours with five or six men, as formerly, to get the crane back on the track, it takes about fifteen minutes with one man besides the operator. No heavy lifting, no broken boxes, and little loss of time.

JOHN H. HONEY.

New York City.

Cost of Operating Vacuum Ash-Handling Systems

In the Feb. 9 issue of POWER the Girtanner-Daviess Co. revives the discussion on the cost of operating vacuum ash-handling systems, which was carried on in the issues of July 7, Sept. 8 and 15, and Oct. 20 of last year.

In this discussion the error is made of assuming that repairs and depreciation are synonymous. The yearly repair cost of $32 is compared with the 40 per cent. depreciation of the system given in my previous discussion. The fact that the cost of repairs for the first year is but a nominal sum is no assurance that the equipment will not go down in the second year of its operation. To get at the actual rate of depreciation, the two years and more would have to be considered. Any system of accounting that does not take into consideration all the items comprising the cost of ash removal, and that over a number of years, is going to prove misleading.

While it is true that my experience with the vacuum system of ash removal was limited to a single installation, and that of the blower type, it nevertheless gave me a good impression of the abrading power of swiftly moving ashes on iron and steel pipe, with its consequent effect on the cost per ton of ash removal.

From an operating standpoint, success or failure of a vacuum ash-handling system depends on the amount and composition of the ashes. An installation that is considered a success in the East where a low-ash coal is available may prove a failure in the West where coal running upward of 20 per cent. ash containing a high proportion of silica is frequently encountered.

There is no denying that the vacuum system of ash removal is a convenience so far as the labor of handling is concerned, although pulling and breaking clinker into a 6-in. hole is not so convenient as pulling them into a bucket conveyor or car, and if the cost can be kept down to a reasonable amount, the vacuum system should soon prove itself the champion in its field. Personally, however, I do not look for its general adoption.

C. O. SANDSTROM.

Kansas City, Mo.

The article in the Feb. 9 issue emanating from Messrs. Girtanner-Daviess is interesting reading. Discussion of engineering questions, however, in an engineering journal should be accompanied by such array of data as will be really informative to engineers. The information given in the letter referred to does not constitute engineering data, but I trust that from the experience of Messrs. Girtanner-Daviess such data may shortly be forthcoming so that engineers may receive some much needed information concerning a system or plan which has its undoubted merits.

GEORGE L. PRENTISS,
Parson Mfg. Co.

New York, N. Y.

In reply to the above letters by Mr. Sandstrom and Mr. Prentiss of the Parson Manufacturing Co., we have the following to offer: Since our last letter we have had the opportunity to investigate one of our systems and find that in the straight pipe, hoppers and all parts against which the ashes do not directly impinge the wear is not excessive. Over 18,000 tons of ashes, clinkers and coke passed through the line in ten months and the wall of the straight pipe was reduced less than 1/8 in. In the bends of the pipe, which are made in four sections, the second section, which leads from the straight line into the curve, is the one that shows the most rapid wear. In this case over 2500 tons of ashes passed the given point before replacement was necessary. The cost of replacing this section is about $10, or 0.4c. per ton of ash handled. It was not necessary to replace the other sections in this particular installation, although 8000 tons has been the limit in other installations.

According to the above data it is estimated that the straight pipe is good for the conveyance of at least 200,000 tons of ashes, and on this basis the depreciation would be about 10 per cent. on the line. This, of course, represents maximum operation, and where the service is less the life of the straight pipe, made from specially hard chilled cast iron 1 in. thick, would be indefinite. In other words, the installation on a 7- or 8-ton-per-day performance, would last longer than the boilers or other equipment which it serves.

Some of the points mentioned by the parties discussing this subject are based on ordinary pipe of the usual thickness which costs more per pound and wears out more quickly, requires additional labor, costs more for upkeep and depreciates more rapidly.

If there is any further information desired, or any direct inquiry made, we shall be glad to give specific data on installations in operation for 18 months.

R. H. MILLER,
Girtanner-Daviess.

St. Louis, Mo.

Live Steam versus Live Men

Here is a copy of a clipping taken from our local paper four years back:

> A hearing was held Friday before the committee on labor on the bill which provides for the licensing of steam engineers and the appointment of a chief engineer with a brood of assistants—all drawing live steam from the state treasury. It was supported by a number of engineers and opposed by a number of manufacturers. The committee is expected to blow the whistle for the recall of this bill.

And here is a bit of personal experience in our own city of very recent date by a local engineer:

With a friend I visited a neighboring power plant in which a boiler fifteen or twenty years old was doing duty. The first thing that I noticed was a lever safety valve supporting at the outer end of the lever, not only the weight which went with it, but a six-quart pail containing a varied assortment of bolts, old iron, etc. For the uninformed I will say that this would hold the steam in the boiler to a pressure perhaps twice that for which it was built, or even more, when from its age the pressure should probably not be allowed to exceed two-thirds that for which it was originally designed. Being curious, I asked the engineer (?) what steam pressure he carried. He took me to the steam gage and rapped the pipe a number of times; the pointer each time would find a new position, showing that it was out of order. Also, there was a gage-glass and only two gage-cocks, but as there was a lively fire under the boiler, I did not care to ascertain if they were working properly, so took a hurried departure, inviting my friend to come along and fearing for the safety of the 25 men working within one hundred feet of this "live steam" which threatened their lives through the gross carelessness or ignorance of the man in charge, the owner or both.

Would it not be well to have a boiler-inspection and engineer's license law on our statute books before we attend the funeral of a friend, or perhaps a son or brother, killed by a boiler or engine accident, even if those who enforce it do draw "live steam" from the state treasury?

I will vouch for the above facts, substantially as presented.

A CONNECTICUT ENGINEER.

Bristol, Conn.

The Diesel Engine Defended

In the article on "Oil Engine Tendencies" in the Feb. 9 issue we note among the objections which can be raised against the Diesel engine that "it is complicated in design, necessitating strict attention to the minutest details and requires a very high grade of workmanship." We are led to wonder why, and since when, have sound workmanship and conscientious care and attention become objectionable. Surely, it is one of the great merits of the Diesel engine that those who build it thoughtfully bring to bear upon its production the best of brains and labor. No complication of design requires this; the engine is essentially simple. This accuracy of construction and honesty of material and workmanship are demanded by the higher pressures in this class of engine.

By years of experience the reputable and more practiced Diesel-engine builders in Europe have eliminated the troubles first encountered with these higher pressures. The correct practices in four-stroke-cycle design have long since been firmly established, and it is of this knowledge that we availed ourselves when we became the sole licensees of the Swedish Diesel Engine Co., a firm with 17 years' specialized experience.

It is correct to state that close adjustment must be maintained at all times, but Mr. Ward goes astray when he adds that skilled attendance with corresponding high cost is essential. The adjustments are extremely infrequent, for the wear upon these engines is so slow that it does not become sufficiently pronounced to need attention in less than 10,000 operating hours, and frequently more.

The only requirement of the attendance is that it shall be intelligent. The distinction between the terms "skilled" and "intelligent" is important and must be observed. The one implies high wages and difficulties of supply; the other brings the attendance to an ordinary level. With the simple instructions we are issuing for the care and maintenance of our Diesel-type engines any engineer of average clearheadedness will be able to operate them with a maximum of satisfaction, obtaining prolonged and economical service.

The estimate that between 400,000 and 500,000 hp. in the aggregate is supplied by Diesel engines in Europe is far from the mark. The writer made a close computation about 12 months ago and arrived at the total of 1,800,000 hp., but by this date the figure will have been exceeded. The firm which made of Diesel's project a practicable engine and translated his ideas into a sound commercial prime mover has itself sold over 400,000 hp., or as much as Mr. Ward estimated for the lower limit of the total European output.

McIntosh & Seymour Corp.

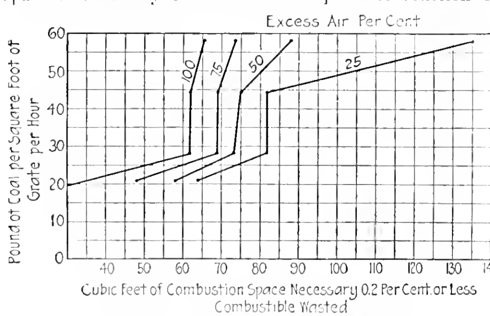
Auburn, N. Y.

Bureau of Mines Paper on Combustion

I have carefully studied the Bureau of Mines Technical Paper No. 63, on "Factors Governing the Combustion of Coal in Boiler Furnaces," and find it interesting. The object and scope of the investigation promise information that engineers are eager to have. It is true that there is a lack of knowledge of the underlying principles of correct furnace design, but perhaps when this investigation is completed there will be available information really useful in practice.

Recorded results show that practically the same amount of combustion space is required for burning both 28.4 and 44.3 lb. of coal per square foot of grate per hour. This is the case for all percentages of excess air. This is more noticeable when presented graphically as shown herewith. It requires about 40 per cent. more combustion space to produce 0.2 per cent. or less combustible in the gases, at a combustion rate of 21 lb. per square foot than at 28 lb.; therefore, it does not seem reasonable that it would require the same space for a rating of 44 lb. as 28 lb. Also, above 44 lb., as is shown by the chart, the space required increases.

This paper shows that a long and spacious combustion space is necessary to allow for complete combustion of the gases and increased efficiency.



CURVES FROM BUREAU OF MINES PAPER

From the bulletin's illustration, Fig. 10, on the variations in furnace conditions during test No. 121, it will be noted that the average temperature at section *G* was about 300 deg. F. less than at section *A*, a distance of about 29 ft. Upon referring to the data on this test it will be found that the rating was exceptionally high, 61 lb. per square foot. Also one figures that the loss caused by the drop in temperature amounts to more than the loss that would result from incomplete combustion.

Furthermore, this loss due to a restricted combustion space occurs for short periods during peaks and would not balance the floor space and investment and maintenance cost of space necessary for complete combustion.

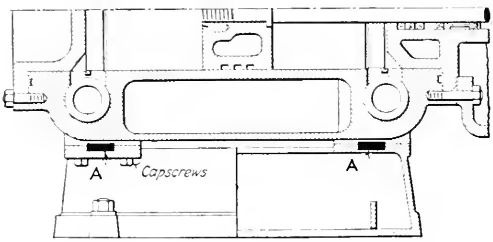
Information on the amount of combustion space needed for certain grades of coals burned at certain ratings is necessary if we are to calculate the investment and maintenance costs.

Meridian, Miss. CHARLES M. ROGERS.

Replacing Broken Capscrews

The letter by C. L. Juno regarding broken capscrews, on page 891 in the issue of Dec. 22, reminds me of a somewhat similar job.

One day it was noticed that one ammonia compressor fastened to its pedestal base with twelve 1¼-in. capscrews was moving a little and that three of the capscrews were broken and most of the others loose. The machine was



KEYS TO TAKE STRAIN FROM CAPSCREWS

shut down, the broken pieces drilled out, as we had plenty of room and good tools, and new capscrews put in.

We soon found two more broken ones, and as time went on it was a common thing to find broken or loose capscrews, and to hold those two compressors steady became a troublesome problem, although we made a new set of capscrews with bodies a snug fit in the holes through the pedestal. Finally, slots *A* were cut 1 in. deep and 3 in. wide at both ends on both sides, making 1x3-in. slots, or keyways, one-half in the pedestal and the other half in the cylinder flange, and extending clear across.

Tight-fitting keys were made and driven into these slots after the capscrews had all been pulled up as tight as possible. This cured the trouble, as the strain was on the wedges instead of on the capscrews.

Chicago, Ill. A. G. SOLOMON.

Mr. Williams' Rejoinder

In the Mar. 2 issue a reference is made to the Hall of Records' test, under the title "Some Dates to Remember," which suggests, at least indirectly, that the New York Edison Co. is endeavoring to withhold the results of the test from publication. On the contrary, we have repeatedly urged that the report be completed and signed at the earliest practicable moment. The test—probably the most complete ever made of a private plant—was conducted under the supervision of a committee consisting of some of our most eminent practical and theoretical engineers, as representatives of the City, the Bureau of Municipal Research and ourselves.

Numerically, the representatives of the Edison company on the committee are in a minority. Quite apart from this, however, the character of those who have been in charge of the proceedings should preclude any suggestion of influence, undue or otherwise, concerning their final action, whether in favor of or against the operation of the private plant or the service of this company. After the completion of the test, some time has been required for analysis and study before the preparation of the report. All this we understand is now practically complete, and it is expected that the report will soon be ready for publication.

Knowing that you would not even unwittingly do injustice either to the gentlemen who have given so much time to this important question or to this company, we feel that you will take such fair means as may be necessary to avoid misunderstanding, through inference or otherwise, from the editorial in question.

ARTHUR WILLIAMS,
General Inspector, New York Edison Co.

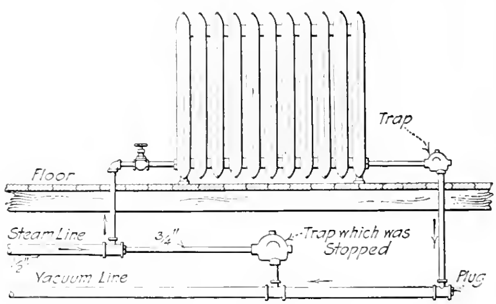
New York City.

[We are glad to learn that Mr. Williams is as anxious as ourselves to see the report on the Hall of Records' test made public. The impression is current that the representatives of and sympathizers with the Edison company on the committee, through zealous efforts to serve their clients' interests, were largely responsible for the delay.—EDITOR.]

Why a Radiator Would Not Work

In part of a direct-heating equipment, a two-pipe radiator connected to a vacuum return system failed to heat. There was about one pound pressure on the steam side and about three inches of vacuum on the return line.

At first the case seemed puzzling, especially as the admission valve and the thermostatic return-end trap proved to be unobstructed and all the other radiators in the building were heating nicely. An examination of the lines leading to this particular unit showed that it was the end one of the series. In other words, it was fed by the



TRAP PREVENTING CIRCULATION OF RADIATOR

extreme end of the steam line and tapped by the extreme end of the vacuum or return line.

As shown in the sketch, a trap had been installed in a jumper across the space beneath the floor where the radiator was, the supposition being that the arrangement would keep this extreme end dry. However, when the cap cover was removed from the trap an old lead pencil was found firmly wedged under the thermostat. This, of course, propped it up and completely destroyed its function. A short-circuit was thus formed, shunting the heating unit entirely. When the obstruction was removed, the trap closed and the radiator promptly warmed up.

Philadelphia, Penn. EDWARD T. BINNS.

Incorrect Diagrams from Compressor

The ammonia compressor was a vertical, two-cylinder, single-acting machine with two cranks at 90 deg., driven by a water turbine. Only one ammonia indicator

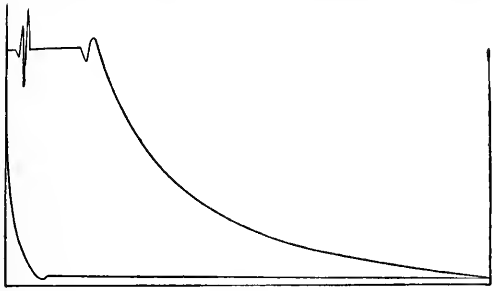


Fig. 1

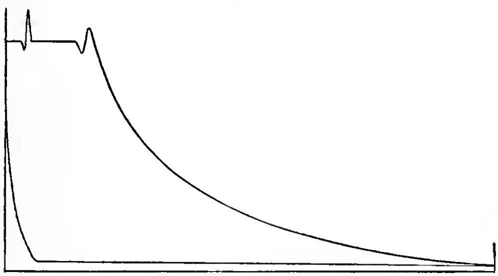

Fig. 2. Correct Diagrams

(Thompson type) was available, so pipes were led from the two cylinders to a three-way cock between the two cylinders. As the two cranks were at an angle other than 180 deg. to each other, it was necessary to attach a reducing rig to each crosshead. The two pantographs used, being direct-reducing rigs, caused both diagrams to fail

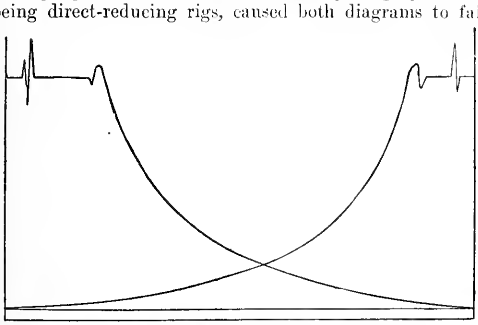

Fig. 3. Diagrams Incorrectly Taken

at the left end of the card, and made it desirable, if not necessary, to take them from the two cylinders on separate cards. Normal diagrams are shown in Figs. 1 and 2.

During the noon hour while I was away for lunch, the man operating the indicator did some investigating and devised a short cut to suit himself. Finding by experiment that one reducing rig, acting indirectly with respect to the one for the other cylinder, would put the two diagrams on opposite ends of the same card, and forgetting that the function of a reducing rig is to move the indicator drum in time with the piston to which it is attached, he discarded one pantograph and got the diagrams, Fig. 3.

When the pencil point wore down and the diagrams became faint, he unscrewed the handle from the pencil mechanism and jammed the point so hard against the drum that the pencil arm bent sufficiently to catch under the end of the front pedestal shaft and cut off the tops of the diagrams as shown in Fig. 4. No less than half

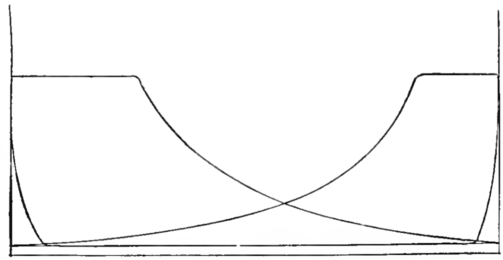

Fig. 4. Top of Diagrams Missing

a dozen such diagrams were taken and delivered to the man operating the planimeter, who integrated the areas and entered them on the log sheet without question.

F. V. Larkin.

So. Bethlehem, Penn.

Corliss Governor Compensator

The issue of Nov. 24, page 746, describes a device used to assist a flyball governor to maintain the speed of an engine within 1 per cent. from no load to a 25 per cent. overload. It is stated that one of these compensators has been in use for five years, giving good results, and that it should prove of value in rolling mills, sawmills, etc., where the variation in the load is great.

Judging from the illustration and the description, it is my opinion that it would be useless, if not a detriment, even on engines operating with a comparatively steady load.

Suppose the load should suddenly become greater; the reduction in the speed of the engine would cause the governor to drop for a longer cutoff, thus throwing the compensator out of level. This in turn would cause the mercury to shift to the lower end of the tube and by its weight hasten the downward movement of the governor. So far its work is admirable, but what would take place when the extra load goes off?

The governor tends to rise for a shorter cutoff and, in addition to lifting itself, is burdened with the extra weight of the mercury in the lower end of the compensator. This will require a higher speed of the governor and of the engine than if the device were not used.

When the extra load came on and the mercury took the lower end of the tube, the governor would not allow the engine to drop to as low a speed as if the mercury tube were not used. On the other hand, the governor would require a higher speed in order to raise the additional weight to a point where the tube would be level, or inclined the opposite way if necessary. What is gained one way is counteracted in the other, and should the fluctuations in load be great and frequent, the device might prove to be a detriment.

Another statement says the division walls prevent any sudden shifting of the mercury. It seems that to hold the speed within narrow limits the shifting should be sudden, and if the device provided for this in both directions, without the necessity of lifting it at the expense of the speed of the governor after it is once out of level, the results would approach the ideal.

I am inclined to think the description does not cover the ground; that something is omitted that would explain the apparent defect, because if it has been used for five years with good results, we have no right to dispute the statement.

The article also says "it has the same effect as automatically increasing or decreasing the weight of the balls," etc. This is true, but which way will the change in speed of the engine be for a given change in the governor balls? By test, the engine was found to run slower for an increase in the weight of the governor balls and *vice versa*, the dead weight or counterpoise weight remaining unchanged. Therefore, when the tube shifts for a longer cutoff it produces the same effect as if the balls were made lighter, and an opposite shift produces the same effect as if they were heavier.

Joseph Stewart.

Hamilton, Ohio.

Using Short Gage-Glasses

Among other things bought in a job lot were about four dozen gage-glasses of good quality but too short for any of our regular connections. I hit upon the following way of making use of them:

The upper packing nut was replaced by a reducing coupling, threaded to suit, into which a short brass pipe was screwed. The lower end of this pipe was threaded to receive a pipe cap, which had been bored out a neat fit over the gage-glass. This formed a good stuffing-box for lower pressure. It happened in this case that the bore of the pipe was just right for the glass, otherwise a washer at the end of the pipe would have been necessary, to form the bottom of the stuffing-box.

Short glasses may be utilized on low-pressure work by using a piece of hose to join the ends wherever they may come, thus forming a flexible joint. Long receiver-tank glasses will often last longer when in two parts than in one.

Arthur D. Palmer.

Dorchester, Mass.

Why the Old Engineer Lost His Job

Coming back to Boston after five years in South America, the first thing I did was to visit my old friend, Bill, the engineer. Long before I can remember—in fact, before I was born—he was there at the plant. I had thought many times of him, his big, smiling face, as he sat in a large wooden armchair in the engine-room doorway smoking his old pipe; and he always had a friendly word for us kids.

Arriving at the engine room, I was surprised not to see Bill in the doorway; even the chair was missing. The old engine had been displaced by a turbine, and at the desk was a stranger reading a blueprint.

I asked for Old Bill (I never did know his last name) and was told I would find him in the pipe shop. It made me feel good to hear that he was still at the plant and it did not take me long to cross the yard. The first man I met was Bill, but what a different man!

"Are you Bill, the engineer?"

"Yes—I used to be."

"Used to be; what's the trouble; why are you not now?"

"Well," said he, "the 'Old Man' died and his son took charge a couple of years ago, and that fixed me all right. He put in new machinery and then he wanted me to make tests on the boilers and turbine, and to send a monthly report of everything to the office. I didn't know how to do those things. They got a new engineer, but kept me around the plant, and there you are. Many a time I wish I was dead, as this come-down is awful."

The thought came to me right there, how many engineers of the old school will go the same way, because they don't know!

H. C. Harris.

Boston, Mass.

Corrosion of Iron and Steel Pipe

There are no reliable data as to the relative ability of iron and steel to resist corrosion. Furthermore, it is a difficult matter to identify the two materials without the acid-etching test. Some time ago, an engineer with many years' experience in the installation of steam and hot-water heating plants remarked that he could tell whether the pipe was iron or steel by the way a die cut. Some short pieces of pipe were submitted to him to separate the iron from the steel. His attempt met with such indifferent success, as shown by the acid test, that he remarked: "There's one thing certain, I don't know iron from steel."

Besides threading easier, he believed that iron pipe resisted corrosion better than steel. Both these beliefs were shaken when he learned that he could not distinguish between the two.

The popular notion is that if it corrodes easily, it is steel; if it offers considerable resistance to corrosion, it is iron.

Some years ago the purchasing agent for a packing house ordered from the mill a number of bars of strictly wrought iron. There was no wrought iron in the plant, everything being soft and medium steel. The manager had the order filled from the steel stock, saying: "If they discover the difference we'll refund their money and give them the steel." The manager had some misgivings until another order was received from the same agent for more iron. This is an incident of which I have personal knowledge.

Later, I was employed in two different packing houses and was amused by the stories of the wonderful durability of wrought iron and the utter worthlessness of steel under packing-house conditions. There is much difference of opinion among those who ought to know; one makes a test that proves conclusively that steel corrodes faster than iron; then another makes a test that proves the contrary. The only vital difference I have been able to find is in the price, steel being cheaper.

Kansas City, Mo.

Inquiries of General Interest

Conversion of Heat into Work during Expansion—Why should steam lose any of its heat when expanding and doing work, if it loses none while expanding and doing no work?

W. R. W.

Heat and energy are mutually interchangeable, and when work is done in the process of expansion it is performed not by loss but by conversion of some of the heat of the steam into energy, each heat unit thus transformed being converted into 778 foot-pounds of energy, and as a consequence of the transformation, the remaining heat in the steam must be less than the heat which it contained before doing the work.

Brake Power of Engine—What brake horsepower is developed by an engine when the length of brake arm is 60 in., tare weight of brake 20 lb., total pressure of brake arm 156 lb., and brake wheel makes 200 r.p.m.?

T. R.

The brake horsepower is given by the formula

$$\frac{\text{Length of brake arm in feet} \times 2\pi \times \text{net weight or pressure lb.} \times \text{r.p.m.}}{33{,}000}$$

hence there would be

$$\frac{\frac{60}{12} \times 2 \times 3.1416 \times (156 - 20) \times 200}{33{,}000} = 25.89 \text{ b.hp.}$$

Metering Fuel Gas at Different Pressures—What would be the relative weight of equal volumes of fuel gas measured by a volumetric meter at 8 oz. and at 12 oz. pressure?

R. V. S.

For the same temperature the density would be directly as the absolute pressure. Taking the pressure of the atmosphere at 14.7 lb., or 235.2 oz., per sq.in., and assuming the gas pressures are quoted in ounces per square inch in excess of atmospheric pressure, then for 8 oz. pressure the absolute pressure would be

$$235.2 + 8 = 243.2 \text{ oz.}$$

and for 12 oz. pressure it would be

$$235.2 + 12 = 247.2 \text{ oz. per sq.in.},$$

hence, a given volume metered at a pressure of 12 oz. would be $\frac{247.2}{243.2}$ as much or about 1.6 per cent. more than when metered at a pressure of 8 oz. above atmospheric pressure.

Weight of Plunger When Submerged—When submerged in water, what would be the weight of a hollow bronze pump plunger 18 in. in diameter by 70 in. long, having ends 4 in. thick and sides ¾ in. thick?

S. C.

The weight immersed will be the difference between the weight of the plunger in air and the weight of the volume of water displaced. The volume displaced would be $(18 \times 18 \times 0.7854) \times 70 = 17{,}812.9$ cu.in., and taking the weight of water as 0.0361 lb. per cu.in., the weight of water displaced would be $17{,}812.9 \times 0.0361 = 643.046$ lb. The hollow part of the plunger being a cylinder 16½ in. in diameter by 62 in. long, the net volume of metal would be

$$17{,}812.9 - [(16\tfrac{1}{2} \times 16\tfrac{1}{2} \times 0.7854) \times 62] = 4555.7 \text{ cu.in.}$$

and taking the weight of bronze as 0.3195 lb. per cu.in., the weight of the plunger in air would be

$$4555.7 \times 0.3195 = 1455.55 \text{ lb.}$$

so that the weight of the plunger submerged would be

$$1455.55 - 643.046 = 812.51 \text{ lb.}$$

Effect of Short-Circuit in Field Coils of Alternator—What would be the effect of a short-circuit in the field coils of an alternator?

W. C. R.

It would depend somewhat upon the windings and the way they are connected. If the machine is either one-, two- or three-phase there would be a decrease in the voltage. If the windings of the three-phase machine are delta connected there will be local current set up in them which may be so serious as to cause overloading that would affect the lights connected to the machine. One ground in the field, with the rest of the system insulated, would have no effect, but if combined with a ground on some other part of the circuit it would cut out one or more of the field coils.

Origin of "Horsepower"—What is the origin of the term horsepower?

R. C.

Before the introduction of steam engines, the work of horses was employed for driving mills, pumps and other machinery, and the power required for their operation was commonly expressed in the number of horses required, and numerous estimates were used for the average working power of a horse. For rating the power of their steam engines Boulton and Watt adopted an estimate based upon their observations of the power of strong draft horses employed 8 hr. per day at London breweries. They found that a horse was able to go at the rate of 2½ miles per hour and at the same time raise a weight of 150 lb. by means of a rope led over a pulley, and the rate of work performed, viz.,

$$\frac{2\tfrac{1}{2} \times 5280 \text{ ft.} \times 150 \text{ lb.}}{60} = 33{,}000 \text{ ft.-lb. per min.}$$

thus established as a horsepower, has been continued as the standard among English-speaking peoples.

Size of Common Exhaust Pipe—What is the rule for finding the diameter of a common exhaust pipe for engines having, respectively, 4-in., 6-in. and 7-in. exhaust connections without materially increasing the back pressure?

P. E. M.

The relative flow of steam of the same density in different pipes varies as

$$\sqrt{\frac{d^6}{d + 3.6}}$$

in which d = diameter in inches. Assuming that the exhaust is at the same pressure in each pipe at the point where they are joined together, then without materially altering the back pressure from what it would be from an equal extension of each exhaust pipe, the diameter of the common exhaust pipe would be the value of d in the equation

$$\sqrt{\frac{d^6}{d + 3.6}} = \sqrt{\frac{4^6}{4 + 3.6}} + \sqrt{\frac{6^6}{6 + 3.6}} + \sqrt{\frac{7^6}{7 + 3.6}} = 198.27$$

By assigning different values to d the nearest even pipe size required is found to be between 9 and 10 in. and therefore a common exhaust pipe of 10 in. diameter should be employed.

Capacity of Closed Water Heater—What quantity of water can be heated from 60 deg. F. to 180 deg. F. by a sufficient supply of exhaust steam at 4-lb. gage pressure in a closed heater containing 21 three-inch iron U-tubes having an average length of 16 ft.?

P. B. B.

Standard 3-in. iron lap-welded boiler tubes have an internal diameter of 2.782 in., and the heating surface would amount to

$$\frac{2.782}{12} \times 3.1416 \times 16 \times 21 = 244.72 \text{ sq.ft.}$$

Taking the average temperature of the steam as 218 deg. F., and average temperature of the water as 120 deg. F., the average temperature difference would be 98 deg. F., for which there would be a condensation of about 18 lb. of steam per square foot of pipe surface per hour, and as each pound of steam would liberate about 966 B.t.u., the total heat transmitted to the water would amount to

$$966 \times 18 \times 244.72 = 4{,}255{,}191 \text{ B.t.u. per hr.}$$

and as each pound of water raised from 60 to 180 deg. F. would require

$$180 - 60 = 120 \text{ B.t.u.}$$

there would be

$$4{,}255{,}191 \div 120 = 35{,}459.9 \text{ lb.}$$

or about

$$35{,}456 \div 8.33 = 4256 \text{ gal. of water heated per hour.}$$

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Hearing on Massachusetts Licensing Bill

Several hundred engineers and firemen attended a hearing at Boston, Mass., on Mar. 10, given by the legislative committee on mercantile affairs upon House Bill 1111, a measure introduced by various interests to render the licensing of engineers and firemen easier than under the present law. The hearing was one of the most hotly contested of the session, operating engineers from all parts of the state registering their opposition to the proposed changes in the law.

ABSTRACT OF THE BILL

The bill provides that to be eligible to apply for examination for a fireman's license, a person must have been employed as a fireman for not less than one year. The examination must be of a practical character, to ascertain whether the applicant has thorough knowledge of the functions of a steam boiler and its appurtenances, of the proper methods of operation and cleaning, how to proceed in case of accident, low water, or in the event of signs of distress; of packing handholes, manholes, valve stems and pipe flanges, and of the proper condition and management of boilers and their accessories, including pumps and other feeding devices.

Steam engineers' licenses are required by the bill in the operation of all engines of 25 hp. and over, with the usual exceptions of railroad locomotives, agricultural engines, etc., instead of the 9-hp. limitation of the present law. Thirty days are allowed for evidence of a second violation, in place of one week as at present. To be eligible for a first-class engineer's license, a person must have held a second-class license or must have been in charge of an engine or engines of over 150-hp. rating each, for a period of not less than two years, or must have served as a steam-engine erector, mechanical engineer or master mechanic of a plant having an engine or engines of over 150 hp. rating each, for not less than three years. The examination for a first-class engineer's license is required to be of a practical character to show whether the applicant has thorough knowledge of the construction, proper care and safe operation of steam engines and their appurtenances.

A second-class engineer's license entitles a steam engineer to have charge of any steam engine or engines not exceeding 150 hp. each, under charge of a first-class licensed engineer. To be eligible for a second-class license, a person must have operated a steam engine or engines for not less than one year, or must have served as a steam-engine erector, mechanical engineer or as master mechanic for not less than two years. The examination covers about the same range of topics as for a first-class license with the exception that knowledge of engine construction is not required. A person seeking a third-class engineer's license may take an examination upon presentation of a request signed by the engine owner or user, such license entitling the holder to operate a particular engine or engines without limit as to size. In other particulars the bill generally follows the existing law. It provides for the retention of all existing licenses and for their exchange, when desired, for licenses under the new law, according to a tabulation which need not be reproduced at this time.

Edward P. Butts, chief engineer of the American Writing Paper Co., Holyoke, the original petitioner for the bill, was the first speaker. He pointed out that under the present law engines and boilers are held to be equal as hazards. He contended that the boiler presents the greater risk, indicated by the fact that most boilers are insured against accident, but comparatively few engines. Constant attendance, he held, is essential in the boiler room, but not at the engine. The present law is complex, in his opinion, and the petitioners object strenuously to the lack of uniformity in examinations for licenses. The character of the examinations depends too much upon the discretion of local inspectors and is frequently too technical. Mr. Butts contended that firemen should not be examined on points in boiler construction nor engineers on details of engine design, claiming that the examiners should ascertain merely whether a man is competent to run the equipment without any extended theoretical knowledge of it. He held it to be unfair to owners of plants using water power a large part of the year to require them to hire skilled engineers for twelve months, when steam-auxiliary service may be needed only for two or three. Another point which the bill is designed to care for is the elimination of the first-class engineer as a necessity to the operation of portable engines. Connecticut has no such license law as Massachusetts, and the speaker contended that the operation of engines and boilers is just as safe there as in the Bay State.

William McCorkindale, Holyoke, representing the Parsons Paper Co., attacked the questions given candidates for a second-class engineer's license on the ground that they are too technical. In a specific instance one candidate failed through inability to tell the examiners the physical properties of steam, the ratio of expansion in turbine blades, and why a fusible plug melts when low water occurs in a boiler.

C. A. Crocker, Chemical Paper Manufacturing Co., Holyoke, said that too much discretion in the enforcement of the existing law is placed upon the inspectors in local districts. He felt that the bill provides as well for safety as the existing law and pointed out that a man to have charge of a large plant should not necessarily have a fireman's license.

James O'Brien, Lee Marble Works, Lee, said that the present law requires his concern to put a steam engineer on each channeling machine because the engine is rated at 12 hp. This, he said, has been a great embarrassment, because specially trained men are required to operate channelers in quarries. Under the present law he could not even utilize the services of the manufacturer's erectors in the operation of channelers. He cited the case of an experienced erector employed by the Sullivan Machinery Co., Claremont, N. H., to instruct Russians and other purchasers in the use of channelers made by this company. This erector could not obtain a Massachusetts license because he was unable to answer purely technical questions about steam engineering. The present law limits engines to 9 hp. without a licensed engineer, and the speaker urged that a 25-hp. limit be adopted. He said that at present a man with a third-class license could run a single engine not exceeding 50 hp. in rating, but if such a machine broke down and the employer wanted to run two 10-hp. engines or two 25-hp. engines by the same man, there would be a violation of the statute.

Mr. O'Brien said that these restrictions made it much harder for Massachusetts companies to compete with concerns in other states and led indirectly to the employment of fewer engineers than would be the case under the proposed law. Thus, in Georgia, no license is required to operate quarry machines by steam, and there is no law in Vermont which licenses engineers and firemen. He thought that in these industrial plants special licenses should be given in many cases. He said that in the paper industry conditions are fully as troublesome through the present law, which may force electrification of many mills if operators of paper machines are not allowed to start and stop their steam-driven apparatus without the immediate supervision of licensed engineers. The ruling of an inspector now on duty in the Connecticut Valley, that a certain mill should employ a steam engineer for each paper machine, threatens to increase the payroll by $300 per week.

George P. Gilmore, an engineer with the American Printing Co., Fall River, brought out the point that the number of engineers' licenses issued has fallen from 97 first-class in 1911 to 62 in 1913, and from 186 second-class to 115. He stated that there are 1726 first-class licenses outstanding in Massachusetts today and 1796 second-class. At the present rate of increase it will take twenty-eight years to replace the present number of first-class engineers and eighteen years to replace the second-class men. He objected vigorously to the absence of any appeal from the decisions of the examining board.

Capt. White, Lowell Paper Tube Corporation, Lowell, contended that the law should specifically limit the powers and scope of examiners. Requirements for licenses should be definite, as in the Navy, where the speaker had spent 36 years. The naval examination of firemen is always oral and purely practical. Capt. White bewailed the fact that a man can fire a torpedo-boat boiler and still be unable to get a fireman's license for a Massachusetts stationary plant.

Frank Dresser, American Steel & Wire Co., Worcester, pointed out that in his opinion the bill does not impair safety. The United States Steel Corporation does not consider the holder of an engineer's or fireman's license as necessarily qualified for plant operation. The company desires to know what sort of an examination was given and does not favor the present non-standardized methods. Knowledge of stresses in steel is unessential to the proper handling of power plants, the speaker contended. The company at present employs 125 engineers and firemen at Worcester, and in normal business periods 200.

Frederick M. Ives, for the Massachusetts Electric Lighting Association, Boston, also favored the bill.

Clifford Anderson, for the Norton Co., Worcester, said that one of the best engineers in the state operates a 250-hp. steam engine, a 500-hp. gas engine, and a 1000-hp. steam turbine in the company's plant, on a special license. This engineer, who has maintained the engine service for twelve years without a minute's loss of time, who has run the gas engine with a loss of only 0.5 per cent. in working time, and who has run the turbine unit one year and three months without a moment's stoppage due to machinery trouble, cannot get a first-class license in any other plant because of his inability to answer highly technical questions put by the examiners. The speaker attacked the present law on the grounds that it keeps out competent men, and he criticized examinations upon theoretical points.

Samuel M. Green, Springfield, Mass., consulting engineer, appeared on behalf of the Springfield Board of Trade and a large number of paper and other manufacturers in the Connecticut Valley. He said that his clients do not consider that the Massachusetts license is an index of a man's ability to operate a given plant and that often the examinations contain foolish questions. The bill stipulates that the examination of both engineers and firemen shall be of a distinctly practical nature. Mr. Green stated that the American Society of Mechanical Engineers has been considering a standard set of regulations governing the licensing of engineers and firemen, but that it had withdrawn the plan of closely following the Massachusetts law in this respect. The speaker contended that there are numerous inconsistencies in the present law which work hardships to the plant owner. Thus, the law now holds that an engine of over 50 hp. must be operated by a man with a second-class license. By reducing the speed of a 60-hp. engine on a paper machine 15 per cent., for example, its rating may be cut down so that it can be run by a third-class engineer. In one plant the owner employed a technical graduate as plant engineer. He was refused a license because he had not fired a boiler for a year. At the Hotel Kimball, Springfield, an engineer from New York State was refused opportunity to take the Massachusetts examination because he had not resided in the latter state for from four to six weeks. Mr. Green contended that firing is not an essential preliminary to an engineer's job.

OPPOSITION TO THE BILL

A. M. Huddell, Boston, who said he represented 13,000 men affiliated with the Massachusetts branch of the International Union of Steam and Operating Engineers, maintained that the bill jeopardizes public safety and contended that while uniform examinations and uniform enforcement of the present law are desirable, the present bill should not be substituted. If the bill passes, third-class plants will be legislated out of existence. Mr. Huddell attacked the provision of the bill allowing thirty days to pass instead of the present seven after an inspector has found a plant improperly manned, before a violation can be charged. He said that an inspector ought to be permitted to enter a plant at any hour rather than at a so called "reasonable" hour, as stated in the bill. Manufacturers can get all the relief they desire from the present law if it is properly enforced. The speaker advocated the establishment of a mechanical department separate from the District Police, who now enforce the boiler and engine laws of the state.

D. G. Kimball, Roxbury, Mass., representing the National Association of Stationary Engineers, said that the entire plant should be in charge of the chief engineer, whereas the bill tends to divide the responsibility of the plant between the engineer and the fireman. He protested vigorously against lowering the standard of the examination and set forth the importance of an engineer's acquiring a broad knowledge of his profession, including both theory and practice. "Our aim," said Mr. Kimball, "is to enable an engineer to rise higher in his work. He should study and keep up with his trade, and we favor the present law because it tends to that end."

C. C. Harris, Springfield, Mass., president of the Brotherhood of Power Workers, held that it is unsafe to place a man in charge of a steam plant unless he knows something of the construction of engines. He cited instances of accidents to paper-mill steam-driven machinery through the mishandling of the equipment by unlicensed men. Failure to drain the pipes in one case cost two lives, through an explosion which followed suddenly turning on steam.

Thomas Hawley, head of the Hawley School of Engineering, Boston, was a vigorous opponent of the bill. Mr. Hawley said that the present law had served well for over twenty years; that it had led to great improvements in the handling of plants and had enormously diminished the number of explosions, besides raising the caliber of engineers and firemen. The proposed measure does not provide any really easier examinations and is a step in the wrong direction. The speaker ridiculed the inconsistency of the bill in requiring a man to work a year as a fireman before getting a fireman's license. The present law permits a man to start in as a helper. A way must be provided by which a man can enter the business.

The speaker pointed out that the present examinations are practical. Thousands of firemen have been examined on the operation of boilers and not on their responsible care. Under the terms of the bill a man practically unqualified could be put in control of equipment on which he has not been examined. The examinations are not unduly difficult. The speaker favored requiring that the applicant be able to understand the English language before a license be granted. In the Slater Mills, at Webster, Mass., a disastrous explosion occurred because a fireman who did not understand English closed a stop valve instead of opening another valve, as ordered. "Trick" questions are not used in the examinations. Mr. Hawley said that the bill is unnecessary; that a line must be drawn somewhere in establishing the limits of engine size for a new class of license, and pointed out that just above and below such a line there is always room for complaint. He condemned as particularly dangerous the section of the bill providing that a third-class license can be issued to enable a man to operate any particular steam-engine plant, there being no limit on size here. A man has to get a job before he can get a third-class license, under the bill. Special licenses are troublesome and should be discouraged. Mr. Hawley brought out the point that familiarity with marine engines and boilers by no means fitted a man to run stationary plants. Torpedo-boat equipment, for example, is different from that of a factory or central-station plant. In one case a navy fireman knew nothing about the location of the fusible plug in a stationary boiler.

T. N. Kelly, Lowell, Mass., criticized the division of responsibility between the fireman and the engineer and said that under the present law an extra first-class fireman's license provides for correcting local differences due to water-power service a part of the year. H. M. Comerford, Boston, took the same ground.

Capt. George Dimand, Lawrence, Mass., opposed the bill on the ground that it would work hardship to both employer and employee. Division of authority between engine room and fire room is most undesirable. The bill would allow any fireman after running one year to take charge of any boiler plant. This is an insufficient time for a man to grasp the operation of the plant as a whole.

The bill was also opposed by Elmer Stevens, Cambridge, Mass., representing the New England Power League. He contended that the personnel of engineers in Massachusetts has improved under the existing law, emphasized the fairness of the present law, and touched upon the certainty of a square deal in examinations. The committee reserved its decision.

The Computation of a Rate

At the recent convention of the Indiana Engineering Society H. O. Garman, chief engineer of the Public Service Commission of Indiana, discussed a simple method of computing a rate, which was thought fair and reasonable to the different classes of consumers and would give a reasonable return to the investor. As expressed by Mr. Garman, the difficulty now with a great many rates placed on file with the commission by the utilities is that they are too complicated for the ordinary consumer to understand. In many cases the latter, in trying to choose, for instance, an electric rate, is compelled to give up in despair and seek the advice of an expert in selecting a rate that will be economical. The ordinary user is completely lost when he comes in contact with such terms as "load factor," "connected load," "maximum demand," "assessed demand," "measured demand," "off-peak load," "fixed charges," readiness-to-serve charge," "energy charge," etc. The tendency now is toward a simplified rate schedule which can be more nearly understood by the ordinary consumer.

The rate evils, as they have been discovered in Indiana, are not so much rates that are unreasonably high as they are rates that are grossly discriminatory. The unjust discriminations have been brought about by competitive conditions and by lack of publicity.

The failure of the general public to realize that there is a "readiness-to-serve charge" gives rise to a great deal of dissatisfaction. When they can be educated to understand that there is such a charge, they see why it is necessary to charge the small consumer at an apparently higher rate than the larger one. The former feels that he is being persecuted because he is a helpless small consumer, when, in fact, in many cases it would not be possible to furnish him service at all at a rate within his reach were it not for the large user.

Those officers of the public upon whose shoulders falls the duty of fixing these rates are becoming convinced that more simplicity is needed. It works out better to have rates that are less scientific, so called, and more easily understood by the greater number of consumers; and after all, the utility is not so much interested in a scientific rate as it is in the gross return that a rate will bring. In other words, what seems to be needed most in rate schedules is less scientific obscurity, a reasonable gross income to the utility and more simplicity and uniformity for the consumers.

Every correct rate should take into account three elements of cost to the utility: Readiness-to-serve cost, energy cost, and customer's cost. Some of the elements of cost entering into readiness-to-serve cost are: Interest return on agreed valuation, rentals, part of allowance for obsolescence, taxes, insurance, and part of the operating costs. The energy cost is made up principally of the so called operating costs, while the customer's cost is made up of items that are directly traceable to the customer, such as reading meter, billing, collecting, testing meter, and the like.

To make the rate matter clearer to the ordinary consumer, an example will be taken by way of illustration. Assume, for instance, three classes of consumers of electricity—power, stores and residences. Assume the cost per kilowatt of demand per month to be $1.20, $3.40 and $4.60, respectively. Assume the energy cost to be $0.01 per kilowatt-hour and the customer's cost per month to be $0.40. Then a table can be computed showing the varying cost per kilowatt-hour, as the hours' use of the demand varies from 15 min. to 24 hr. in one day.

VARYING COST PER KILOWATT-HOUR AS TIME OF USING DEMAND VARIES

Hr. Use of Demand in 24 Hr.	Cost per Kw.-hr, Power	Stores	Residences
0.25	$0.223	$0.517	$0.677
0.50	0.117	0.266	0.346
1.00	0.063	0.137	0.177
1.50	0.046	0.094	0.121
2.00	0.037	0.073	0.093
3.00	0.028	0.052	0.066
4.00	0.023	0.042	0.052
5.00	0.021	0.035	0.043
6.00	0.019	0.031	0.038
7.00	0.018	0.028	0.034
8.00	0.017	0.026	0.031
9.00	0.016	0.024	0.029
10.00	0.015	0.023	0.027
11.00	0.015	0.022	0.025
12.00	0.014	0.021	0.024
24.00	0.012	0.015	0.017

Mr. Garman was well aware that there were many conditions and kinds of service which would seem to justify a multitude of rates, all of which might stand the test of fairness and reasonableness, but in the practical administration of a rate schedule it seemed best to take advantage of averages and work toward simplicity of schedule.

Heating Boiler Bursts

A heating boiler being installed in the new Country Club building by the C. C. Hartwell Steam Fitting Co. burst Mar. 3 on being tested, according to a New Orleans (La.) correspondent. Robert Snow, in charge of the job, was badly scalded, though he may recover. That he was so seriously injured was thought to be due to his heroism in forcing his way to the cutoff valve so as to shut off the steam. But for this action it is considered likely that Ernest Keppler, a helper, who sprained his ankle in trying to get away from the danger, would have been scalded to death. Joseph Martinez and William L. Purduit, also employed on the installation, sustained burns of the face and hands.

Snow and his helpers had just completed the erection of the boiler, and in making a test the pressure had been raised quickly to capacity. It was stated that the workmen, relying on a larger factor of safety than seems to have existed, raised the pressure past capacity for the sake of a thorough test.

BUSINESS ITEMS

The E. Keeler Co. of Williamsport, Penn., has been awarded a contract for 18 water tube boilers by the Illinois State Board of Control. Nine of these are 300 hp. and nine 400 hp., with automatic stokers.

The Buffalo Forge Co., Buffalo, N. Y., is sending out a new catalog (No. 201) on Niagara Conoidal Fans. It contains many illustrations of actual installations, complete tables for capacities, speeds and horsepowers for all sizes of fans, as well as dimensions and characteristic curves. Copies are sent to consulting engineers, manufacturers, architects, etc., on request.

The Yarnall-Waring Co., Chestnut Hill, Philadelphia, has just received orders for four "Lea" V-notch recording liquid meters in combination with Webster feed water heaters aggregating 1,125,000 lb. per hour capacity, from E. I. duPont DeNemours Powder Co., Wilmington, Del., following original installation of "Lea" system by them two years ago. Also an order for a 275,000 lb. per hour capacity "Lea" V-notch recording liquid meter for the new power plant of the Victor Talking Machine Co., Camden, N. J., following the installation of a 150,000 lb. per hour "Lea" instrument by them two years ago.

OBITUARY

WILLIAM H. ARMSTRONG

William H. Armstrong, Grand Worthy Chief of the Universal Craftsmen Council of Engineers of the World, died Mar. 16, at St. Rose's Hospital, New York City. He was one of the best known operating chiefs in the engineering profession, in both land and marine service. He was for many years chief engineer of the Rogers Peet Co. Building at Broadway and Warren St.

Mr. Armstrong was an active member of a number of engineering organizations, including Elmer E. Chambers Council, No. 5, U. C. C. of E.; Stephenson Association, N. A. S. E., and the United Engineers of Greater New York. He was Past Master of Ocean Lodge, No. 156, F. & A. M.

PERSONALS

W. H. Hoyt, C. E. 1890, College of Engineering, University of Minnesota, member of the American Society of Civil Engineers, assistant chief engineer of the Duluth, Missabe & Northern R.R., has been elected president of the Minnesota State Surveyors' and Engineers' Society.

Maj. A. B. Blevins, president of the North Louisiana Interurban & Electric Co., died from heart failure Mar. 4 at his home in Shreveport, La. He was the founder of the Town of New Birmingham, Tex., and one of the earliest developers of the iron-ore region of Texas. He went to Louisiana in 1912 and had been working ever since on the interurban line which is to connect Shreveport and Monroe, La.

ENGINEERING AFFAIRS

The American Boiler Manufacturers' Association has called a meeting of boiler manufacturers and others interested, to approve the code of uniform boiler specifications recently completed by the American Society of Mechanical Engineers. The meeting will be held at the Fort Pitt Hotel, Pittsburgh, Penn., Mar. 29, at 10 a.m.

Boston Engineers' Club announces the following program for the coming month: Thursday, Mar. 25, 1915, "Locomotives, Ancient and Modern," illustrated talk by George W. Stetson; Thursday, Apr. 1, 1915, Franklin A. Snow will describe some of his contracting experiences in South America; Thursday, Apr. 8, 1915, "Butte, Montana," an illustrated talk on modern mine development and operation, by George A. Packard; Thursday, Apr. 15, 1915, "Trees in Spring," illustrated talk by George Winthrop Lee; Thursday, Apr. 22, 1915, "Autogenous Welding and Cutting by Means of the Oxy-Acetylene Torch," illustrated talk by Henry Cave.

University of Illinois Notes—Prof. C. R. Richards, of the department of mechanical engineering of the University of Illinois, has designed a hydraulic absorption dynamometer, several of which have been built in the college shops. One is to be connected to the new 60-hp. six-cylinder Peerless automobile engine in the mechanical engineering laboratory. The engineering experiment station is conducting tests of various building materials to determine their coefficients of heat transmission. The work is being done by L. C. Lichty, research fellow, under the direction of Prof. L. A. Harding, of the department of mechanical engineering. The results of the tests are expected to be of especial value to heating and ventilating engineers. Apparatus for testing steam nozzles has just been installed in the mechanical engineering laboratory. Prof. O. A. Leutwiler and Messrs. H. W. Waterfall and A. B. Domonoske, of the department of mechanical engineering, are conducting an interesting series of tests on a friction clutch for the purpose of determining the relative value of different commercial materials used for clutch linings.

Accidents Due to Poor Lighting—That fully 25 per cent. of the accidents to workmen are caused by insufficient lighting for men working at night, is the opinion of experts who have made a study of the subject. It is estimated that $250,000,000 is the average annual cost of injuries to workmen in the United States alone, and that over 50 per cent. of these accidents are preventable.—"Popular Mechanics."

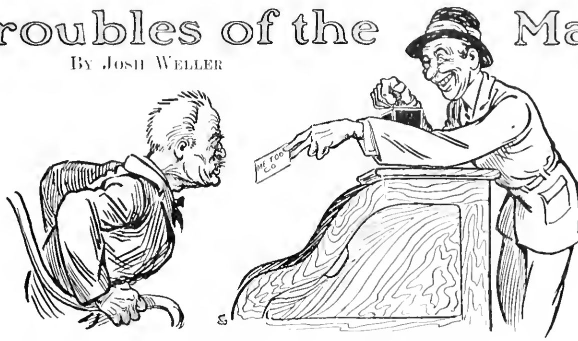
Troubles of the Manager

By Josh Weller



THE salesmen "lay" for me at night, they wait for me at morn;
I know they will be on my trail when Gabriel blows his horn.
They take my time when I should work, they do not seem to care;
I have no chance to change my pants, no time to pray or swear.
Oh, Holy Moses, Holy Smoke and Holy Mack'rel, too,
Look down at once and tell me quick, what can I, should I, do?

I BOUGHT a monster bulldog once, with teeth like Teddy R.;
I tied him at my office door and left that door ajar.
I chuckled low, I chuckled long, and then I chuckled some;
I said, "We'll see some royal sport when those fresh salesmen come."
They came at last, they came in force, that bloody salesmen gang;
They had a dentist with them, and he pulled each blooming fang.

I BOUGHT a pound of strychnine once and put it on some meat,
The rascals sniffed and smelled of it; they were too wise to eat.
I nearly killed a salesman once, a sassy red-haired runt,
He talked of testing furnace gas or some such crazy stunt.
I broke his neck, I broke his back, I broke his head and slats;
I threw him on a garbage pile to feed the dogs and rats.

NEXT morning when I came down town my eyes popped from my head,
The salesman on the garbage pile had risen from the dead.
He stayed and talked and talked and stayed and used up all my day;
At last I bought his worthless junk, there was no other way.
I sat before my fire one night to warm my frosted foot,
A salesman cuss came down the flue and filled the house with soot.

HE talked of scale and soot and ash and said my tubes were bad,
My heating surface punk, or worse. He sold me all he had.
Then when I got my nightie on, my "Now I lay me" said,
I found another salesman hiding underneath my bed.
There is no joy in life for me, no rest where'er I go,
Some salesman's always butting in, this world's a vale of woe.

AND when at last I shuffle off and hike for Peter's gate,
I'll find some salesman waiting for me there as sure as fate.
And if I give the scamp the slip and get inside the wall,
He'll steal St. Peter's golden keys and catch me after all.
Ha, ha, ha, ha, ho, ho, ho, ho, and likewise hee, hee, hee,
At last I know what I shall do, just watch my smoke and see.

I'LL buy a ticket right straight through to Satan's warm domain;
The bunch will all be after me, they'll all be on my train.
I'll bribe the Devil and his imps, I'll bribe them till I'm broke,
But I'll get those salesmen in the pit and pile on lots of coke.
And when one tries to scramble out he'll find me standing by,
Armed with a red-hot pitchfork, and I'll jab him in the eye.

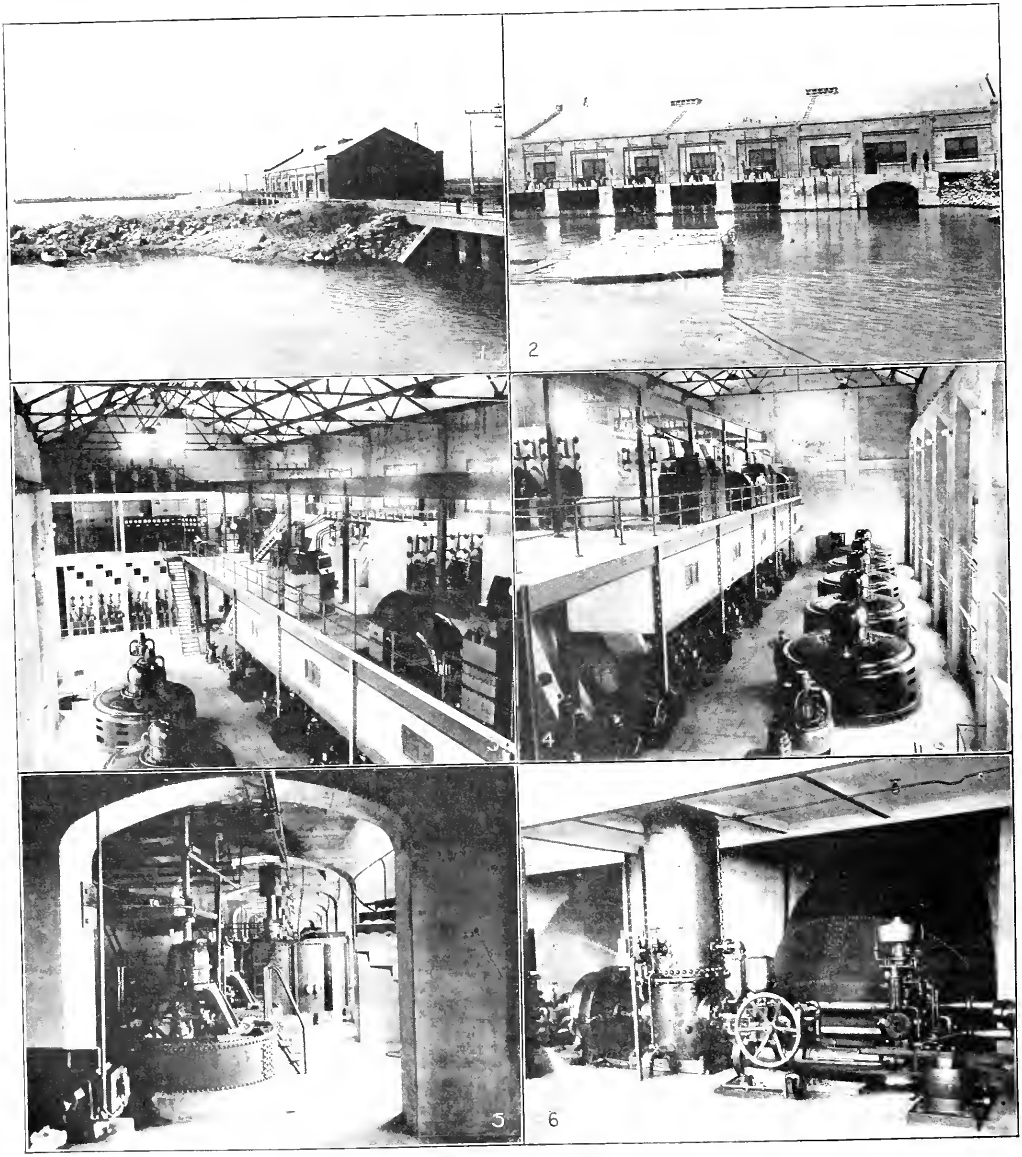
Read the Above to the Next Salesman That Calls on You

Federal Project at Minidoka, Idaho

By A. P. Connor

SYNOPSIS—The Minidoka project of irrigation consists of the Snake River dam to impound the water which supplies two main canals and which is also used to operate five 1200-kw. turbo-generator units at the power house. The current generated is transmitted to four pumping stations at distances of from twelve to twenty miles from the power plant, elevating the water from the main canal into canals at a higher elevation. The pumps have a capacity of about 125 sec.-ft. each.

The Minidoka project, situated in the counties of Lincoln and Cassica, Idaho, is typical of some of the Federal



Figs. 1-6. Views of the Minidoka Power Plant

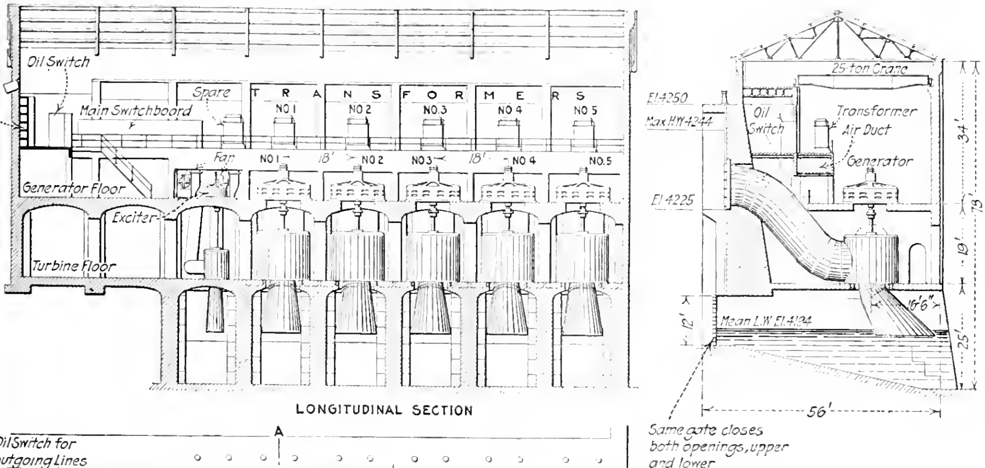
Government's undertakings requiring power for operation. In this case a storage dam 1300 ft. long impounds the water of an 18,000-square mile watershed and is supplemented by diversion dams 600 ft. long. The dams are of the earth- and rock-fill type, having an average height of 50 to 52 ft., and raise the water level sufficiently to supply two systems of canals having an aggregate length of 130 miles, and supplying 190 miles of smaller canals.

In addition, power is taken from the impounded waters hydro-electrically and transmitted to pumping stations at the terminals of these main canals where the water is pumped to higher levels for distribution to branch canals. At present about 6000 kw. is generated. This power is to supply water to 70 miles of main and 60 miles of branch canals by means of pumping stations located at distances of from 12 to 20 miles from the dam. The water is stored in Lakes Jackson and Walcott, and the average run-off is about 7,200,000 acre-feet. The altitude of the project is 4200 ft. above sea level. The hydro-electric generating units work under an average head of 35 ft.

In Fig. 1 is shown the main-dam, power house and the high-tension transmission line, looking from Lake Walcott. The power house is built of concrete and is a part of the dam; its general appearance from the intake side is shown in Fig. 2. Interior views are shown in Figs. 3, 4, 5 and 6. The maximum inside width of the building is 45 ft., and the usable width for the generators is about 20 ft., requiring a somewhat contracted arrangement of the units and apparatus.

The sub-basement of the power house is in reality a tunnel space for the passage of water through the dam whenever the lower gates of the dam are opened. The basement provides for the hydraulic portion of the plant, such as the penstocks, turbines and incidental casings. On the main floor are the generators, auxiliary apparatus and accessories. The gallery is for the switchboard, transformers, high-tension switches and the like.

The main transformers are in the power station and step up the voltage of the generators from 2300 to 33,000 volts, the connections being delta on the low-tension side and Y or star on the high-tension side. A spare transformer is provided for emergencies. The transformers



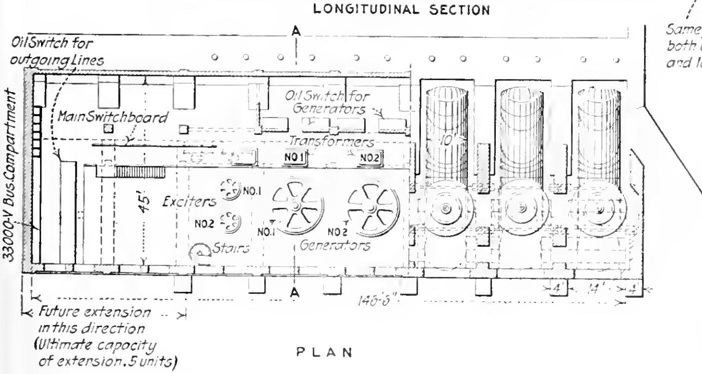


FIG. 7. SHOWING THE ARRANGEMENT OF THE POWER-PLANT APPARATUS

are air-cooled by means of motor-driven fans. The air duct for the same is suspended from the gallery and is shown in Figs. 3 and 4 above the control apparatus for the generating sets, etc.

GENERATORS

The vertical-type, revolving-field generators at present installed consist of five 1200-kw., 2300-volt, three-phase, 60-cycle and two small direct-current generator exciter sets which also run the station motors. The rated capacity of each alternator is 1400 kv.-a. at 85 per cent. power factor at a speed of 400 r.p.m. The generators are arranged on the main floor and connected with their turbines by extended shafts. The 120-kw. exciters are compound-wound, for 125 volts at 125 r.p.m.

TURBINES

The 1800-hp. main turbines are of the inward-flow, axial-discharge, single-runner type fitted with pivot gates. Those for the exciters are 180-hp. All of the turbines are between the arched columns in the basement, and ladders and passageways enable every part to be reached easily for inspection or repair.

The turbines are arranged for low head and are supplied with penstocks 10 ft. in diameter directed toward the turbines at a 45-deg. angle, with curved ends to reduce friction. Fig. 6 is a view of the governing apparatus. The penstocks are practically self-supported and are uncovered. The larger ones are closed by gates weighing 5 tons each, and operated by 6-hp. motors which receive energy from the 125-volt, direct-current busses. The gates for the exciter turbines are operated by a 2-hp. motor. The mechanism of the gates is outside the power station over the gates and is inclosed. The gates are arranged to close the upper and lower outlets in the dam so that when the upper one connecting with the penstock is open the lower one opening through the dam will be closed, and when the latter is open the former will be closed. This enables each gate to do double duty and avoids the need of two sets. They may be operated by hand when desired.

The draft tube of each turbine is enlarged at the end to improve the discharge. The penstocks and draft tubes are made of boiler iron in riveted sections. The station is provided with a 25-ton traveling crane for handling heavy pieces.

General

There are two main canals running from the dam, known as the Main North-Side Canal and the Main South-Side Canal, and these are filled with water by gravity. The latter is about 15 miles long and terminates adjacent to canals known as G, H and J, which are situated on higher levels. A transmission line is run 12 miles across the country from the power station to these canals to feed the motors at the pump houses. The pumping station No. 1 takes the water from the Main South-Side Canal and raises it to the level of Canal G, which is about 20 miles long. About a mile distant water is taken from Canal G and raised to Canal H through No. 2 pumping station. Canal H is about 25 miles long, and Canal J is fed with water from H through another station, No. 3. Pumping station No. 4 is on a transmission line on the north side of Snake River and takes water from the North-Side Canal. This station is about 20 miles from the dam, by air line, and about 30 miles by following the transmission lines. These are shown in Fig. 8. The layout of the system is such that the transmission lines are tied in and are run to include the various towns on the project. The main object of the power is, however, the pumping.

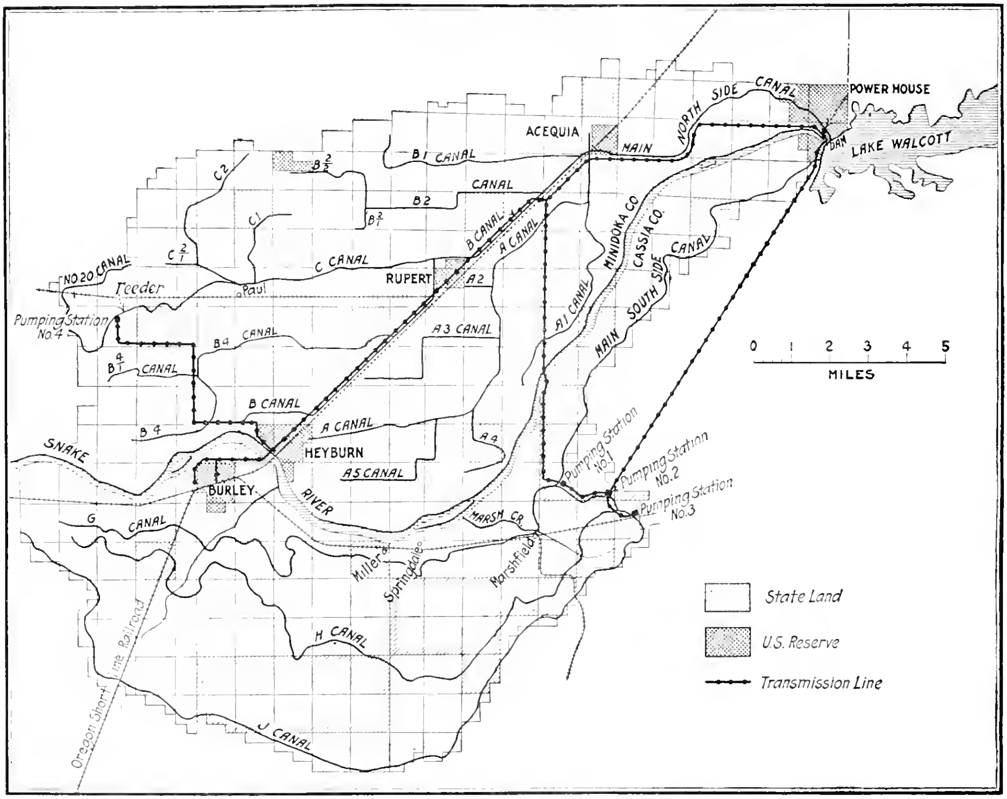

Fig. 8. Map of the Minidoka Project, Showing the Area, Its Canals and Transmission Lines

The pumping stations are buildings of substantial dimensions and are equipped with ample pumping units for the duty expected at each location. Each station has air-cooled step-down transformers. Exciter and motor-generator sets are provided for the minor direct current required for small motors and lighting in the pumping stations.

The ultimate capacity of the pumping stations in pumping units is as follows: No. 1, four pumping units, each of 125 sec.-ft. capacity; No. 2, three pumping units, each of 124 sec.-ft. capacity; No. 3, one pumping unit of 125 sec.-ft. capacity; No. 4 is about the size of that for No. 3.

Details of a pumping unit are shown in Fig. 9. It is driven by a 2200-volt synchronous, three-phase, vertical motor. The pumps are of the centrifugal type, taking the water centrally and forcing it out peripherally. The pumps are arranged to be always submerged, and the amount of water supplied and raised by each is controlled by gates with lips, which close the ingress openings to the pumps. The gates in each case are operated through a lever mechanism actuated by a float disposed in the incoming water, Fig. 9.

A baffle plate is provided above the entrance of each pump to keep out obstructions and to serve as a guide for the lip-operating rods. A grating in front of the water

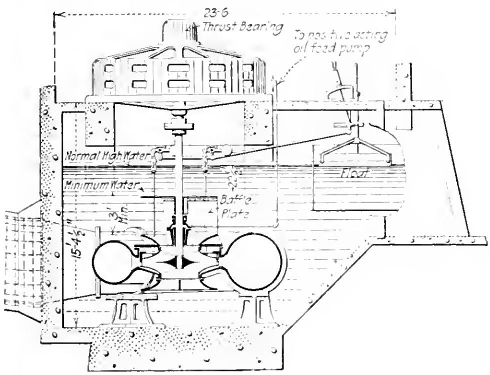

Fig. 9. Vertical Section of a Pumping Unit

entrance of each pumping station keeps out general rubbish and ice. The float mechanism has a lever and rack for raising it independently of the water.

The water raised by the pumps is diverted through an upwardly curved pipe or duct, from which it goes to its respective canal.

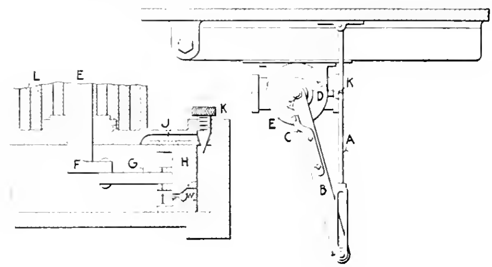
Morrow Furnace System

The Morrow system is an automatic furnace door-closing device to assist combustion, to obtain the maximum amount of heat from the fuel and to eliminate smoke. The equipment consists of a check with a supplementary device for holding the door of a furnace wide open while the fireman is putting in the fuel, and which on the release of the catch allows the door to swing to a closed position, hesitating long enough when partly closed to allow an inrush of the required amount of air necessary for combustion.

The checks are mounted upon the furnace door and are operatively connected by the links *A* (see illustration), with the boiler front. *B* is the operating arm, which is connected to the link *A* at one end and to the retarding mechanism at the other. *C* is a spring detent, which, when the furnace door is open, will engage within the notch *D*, formed in the upper surface of the casing of the device, so as to retain the door in an open position. In the sectional view through the closing device, the vertical shaft *E*, operated by the arm *B*, is provided with a crank *F* at its lower end, which is connected to the link *G* with the piston *H*. A check valve *I* opens to admit the retarding fluid when the furnace door is opened, but prevents the fluid from passing through the piston, when the piston moves in a direction to close the door.

The bypass *J* extending around the piston is controlled by the needle valve *K*, by the adjustment of which the flow of liquid is governed through the bypass, which regulates the speed at which the door will close.

When the furnace door is opened it moves the upper end of the casing of the closing device relatively to the spring detent *C*, until the latter engages within the notch *D*, thereby holding the door open. After firing, the door is given a slight push inwardly, which unseats the detent



Details of the Morrow Furnace System

C and permits the spring *L* to close the door. The operation of the spring is controlled by the movement of the piston *H*, which is governed by the bypassing of the fluid through the passage *J*.

This device is the invention of J. H. Morrow, chief engineer, Great Northern Hotel, Chicago, Ill.

Rules for Weight of Cast-Iron Pipes

The usual method adopted for calculating the weight of cast-iron pipes consists in finding the cubic contents of the metal in inches, and multiplying that by the weight of one cubic inch of cast iron = 0.26 lb.

EXAMPLE—Taking a pipe 12 in. internal diameter, ½ in. thick, 9 ft. long, we have outside diameter 13 in. = 132.732 sq in. area, internal diameter 12 in. = 113.097 in. area.

132.732 — 113.097 = 19.635 sq in. sectional area.
9 ft. = 108 in., hence
19.635 × 108 = 2120.58 cu.in. of cast iron, and
2120.58 × 0.26 = 551.35 lb.

The two flanges, or one socket, are usually reckoned equal to one foot length of pipe.

Another formula for calculating the weight of cast-iron pipes is

$$W = 2.45\,(D^2 - d^2);\ \text{or}\ 2.45\,(D + d) \times (D - d)$$

in which

W = Weight per lineal foot in pounds;
D = External diameter of pipe in inches;
d = Internal diameter of pipe in inches;
2.34 = A constant.

A very useful approximate rule for the weight of cast-iron pipes is, for a pipe 9 ft long, with flanges at each end, and 1 in. thick, allow 1 cwt. for every inch in diameter, keeping the thickness and weight proportional, either more or less.

EXAMPLES—A 12-in. pipe, 9 ft. long, flanges at each end, 1 in. thick, will weigh approximately 12 cwt.

A 12-in. pipe, 9 ft. long, flanges at each end, ¾ in. thick = 9 cwt.

A 10-in. pipe, 9 ft. long, flanges at each end, ½ in. thick = 5 cwt.

—Björling.

Small Condensing Turbines

By W. J. A. London*

SYNOPSIS—An unusually interesting article on the considerations entering into the design of small condensing turbines, with particular reference to the Terry "return-flow" machine.

Since the introduction of the small direct-connected turbine on a commercial basis, some eight years ago, until recently, fully 90 per cent. of the machines called for were intended for noncondensing service. In the few cases where they were called upon to operate condensing, such as for marine work, little attempt was made at economy, as the operation of these machines condensing was more a matter of convenience than of water rate. It has been acknowledged that the designing of small turbines is much different from that of large machines, for were a small turbine designed on the same principles and lines as a big machine, a hopeless commercial failure would result. There have, therefore, been two distinct fields in turbine work; the principles governing the designs of small and large machines being so much at variance that they might be said to be almost as different as the designs of a steam and a gas engine.

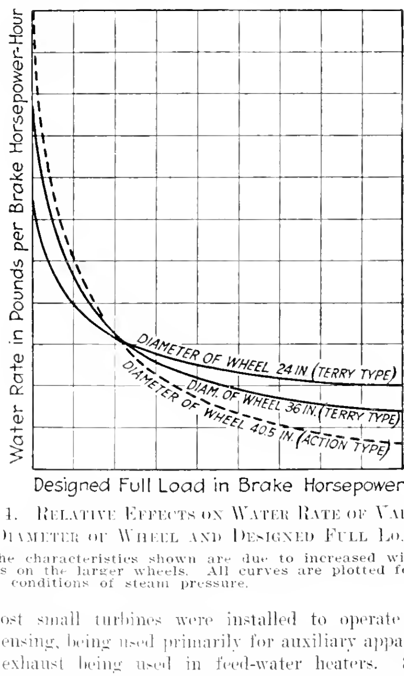


FIG. 1. RELATIVE EFFECTS ON WATER RATE OF VARYING DIAMETER OF WHEEL AND DESIGNED FULL LOAD

The characteristics shown are due to increased windage losses on the larger wheels. All curves are plotted for the same conditions of steam pressure.

Most small turbines were installed to operate noncondensing, being used primarily for auxiliary apparatus, the exhaust being used in feed-water heaters. Small isolated plants were operated noncondensing, the exhaust steam being used for industrial or heating purposes.

For isolated plants, such as small pumping installations of, say 150 to 500 hp., where economy was of much importance and the saving by operating condensing sufficient to offset the first cost, maintenance, etc., the turbine has been at a disadvantage as compared with the reciprocating engine.

The average thermal efficiency of small turbines is in the neighborhood of 40 per cent. With this efficiency all exhaust steam can be utilized without "blowing off," so that no higher efficiency is required or even desirable.

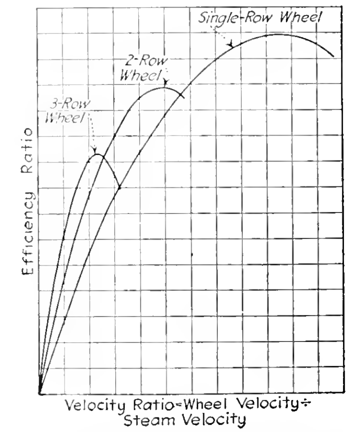

FIG. 2. RELATIVE EFFICIENCIES OF IMPULSE WHEELS WITH VARIOUS NUMBERS OF ROWS OF BUCKETS

Forty per cent. efficiency does not represent the highest available in this class of machine, but it is conceded to be about the highest commercial efficiency. The cost of small turbines varies approximately directly as the square of the diameter of the runner, whereas the efficiency is increased approximately only inversely as the square root of the runner diameter, so any saving in steam consumption must be accompanied by a marked increase in first cost.

Above 500 to 600 hp. the field of the large turbine, where water-rate efficiency is of paramount importance, is approached. These machines operate condensing in the same proportion that the small machines operate noncondensing, and the whole problem of design must be attacked on a totally different fundamental basis.

For powers of, say 150 to 500 hp., condensing, where high efficiencies were desirable, the reciprocating engine until recently had no serious competitor in the steam turbine. The reason for this is obvious. The reciprocating engine was developed, and the meager demand for small high-efficiency turbines did not warrant the manufacture of special machines, and furthermore, the customer would not pay the price that would have to be charged.

Conditions have changed rapidly during the last two years or so, and there is now a big demand for small condensing turbines of high efficiency, both high- and low-pressure, which has led to the development of a third class of machine to meet the requirements of this market. To distinguish this class from the small and the large machines, it is permissible to call it the "in-

*Chief engineer, the Terry Steam Turbine Co.

termediate design." This design should have, as far as possible, the simplicity and accessibility of the small machine with an efficiency approaching that obtainable with the larger units.

When Parsons and DeLaval built their first turbines the main trouble was not with the turbine itself, but with the "other end," or the driven unit. A turbine is of little use by itself, and it was not until it was demonstrated that it had come to stay that generator, pump and blower makers awoke to the fact that they must remodel their apparatus to meet turbine requirements.

Rapid as the turbine development has been, it would have been more so had it not been for the slow development of the "other end." And past events have again repeated themselves in the field of the "intermediate design." This machine would not have been possible had it not been for the rapid strides that have taken place along the following lines: (a) The manufacture at reasonable cost of high-tensile steel for turbine wheels; (b) the increase in permissible speed of generators, blowers, etc.; and (c) the introduction on a commercial basis of the speed-reducing gear.

In POWER of Oct. 28, 1913, a brief description was given of the return-flow condensing steam turbine that had just been developed by the Terry Steam Turbine Co. for this so called "intermediate field."

On the completion of tests of the first machine, several modifications and improvements naturally suggested themselves and are incorporated in the latest designs. For turbines of small power the latest tests show some remarkably good efficiencies, as will be seen by the details of the tests published herewith.

One of the main changes in design has been to carry the principle of the horizontally divided case to the last extreme. In the original return-flow machine the casing was divided horizontally, but the center diaphragms and the center-diaphragm glands were not, whereas in the machine shown all diaphragms, and diaphragm and end glands are thus split, reducing disassembling and assembling time to a minimum. See Fig. 5, right.

In the larger frames another important change has been made. The high-pressure wheel of the Terry type which was incorporated in the first machine has been superseded by a two-row multi-velocity type of wheel running at a high peripheral speed. Extensive experiments have shown that, up to certain peripheral speeds and certain powers with a given thermal drop, the Terry type of bucket is well adapted, but beyond this range the two-row bladed wheel has the advantage. See Fig. 5.

There are several factors entering into the correct design of a wheel of this type other than the actual or theoretical blade efficiency, which make this problem interesting and more complex than one would suppose from a superficial study of the subject on a purely blade-efficiency basis. Disk friction, the power transmitted or rated power of the machine, commercial considerations regarding first cost (which controls the selling price), are all big factors independent of any blade-efficiency theory.

The return-flow turbine is designed so that the pressure in the first stage will be about 2 to 5 lb. above the atmosphere. With ordinary steam pressures of, say 150 lb., and allowing two impulses, the peripheral velocity of the buckets must be about 636 ft. per sec. for best efficiency. At 3600 r.p.m. this calls for a pitch diameter of 40½ in. For three reversals the diameter of wheel would be in the neighborhood of 24 to 26 in.

Fig. 1 shows the relative efficiencies of three types of wheels and the important relation that skin friction and windage bear to the overall efficiency. A "two-velocity stage" wheel is more efficient from a blade-efficiency stand-

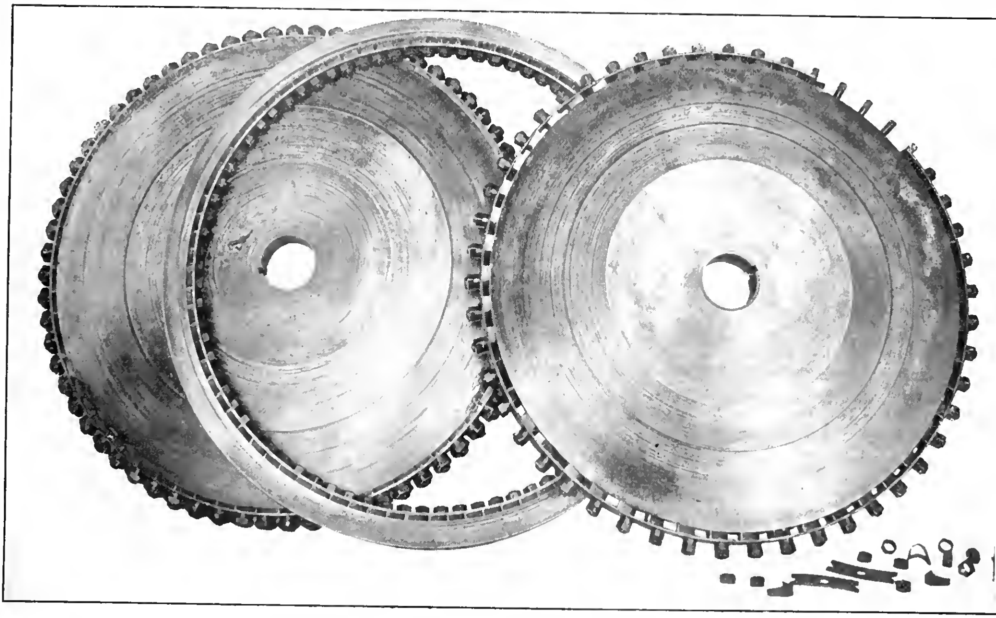

FIG. 3. WHEELS AND GUIDE VANES OF EARLY TERRY TURBINE

point than a "three- or four-velocity stage" (see Fig. 2), yet the friction created by the increased diameter is far more undesirable than one would at first imagine, and the advantage gained by augmented blade efficiency is more than offset by the added losses in other directions.

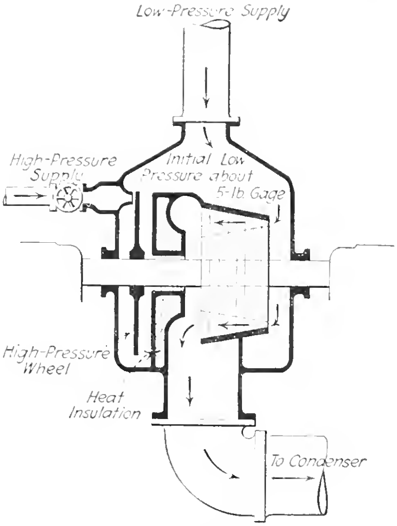

Fig. 4. Diagrammatic Section of Return-Flow Turbine

The various formulas of Stodola, Lewicki, Odell and others, for skin friction of disks, show clearly how big a factor this can be, and while these formulas are somewhat vague and indefinite regarding certain conditions that have to be taken into account, they all agree that this friction loss varies as the second to the 2.5 power of the diameter of the wheel and nearly as the cube of the peripheral velocity. Again, these formulas do not take into account the windage of the blading, which is obviously greater in a bladed wheel than on a bucket wheel.

In reverting to the bladed type of wheel in the high-pressure end, instead of the semicircular-type bucket, it is interesting to note in passing that the first turbine experimented with by E. C. Terry in 1893 was on this principle. Fig. 3 shows the wheels and guide blades of this early machine, the patent number of which is 508,-190.

The Terry type of machine is, primarily and essentially, a noncondensing turbine. Its simplicity and consequent unlikelihood of derangement make it an ideal machine for the duties that it is called upon to perform. Within certain limits of speed, vacuum, etc., the two- or three-stage Terry combination makes an equally good condensing machine, having a thermal efficiency as high as that of the single-stage noncondensing design; but when confronted with the necessity for high speeds, high vacuum and larger powers, the wheel becomes impracticable at the low-pressure end owing to its inability to handle a large volume of steam to the best advantage. In the later machines, therefore, the low-pressure wheel has been replaced by a series of single velocity-stage impulse wheels. That practically all authorities agree that this type of wheel for low-pressure work forms the ultimate turbine element is evidenced by the fact that it is being adopted by practically all turbine builders of both large and small machines, with the one exception of the builders of the reaction, or Parsons, type; and that this type of machine is not adaptable to small powers is evidenced by the fact that the builders themselves resort to the impulse principle in their smaller designs.

Again, the "composite design" of velocity staging in the high-pressure end and pressure staging in the low-pressure must be the last word in turbine development if latest designs of practically all the turbine builders both here and in Europe are any criterion. [See the article on page 436 of this issue.—Editor.]

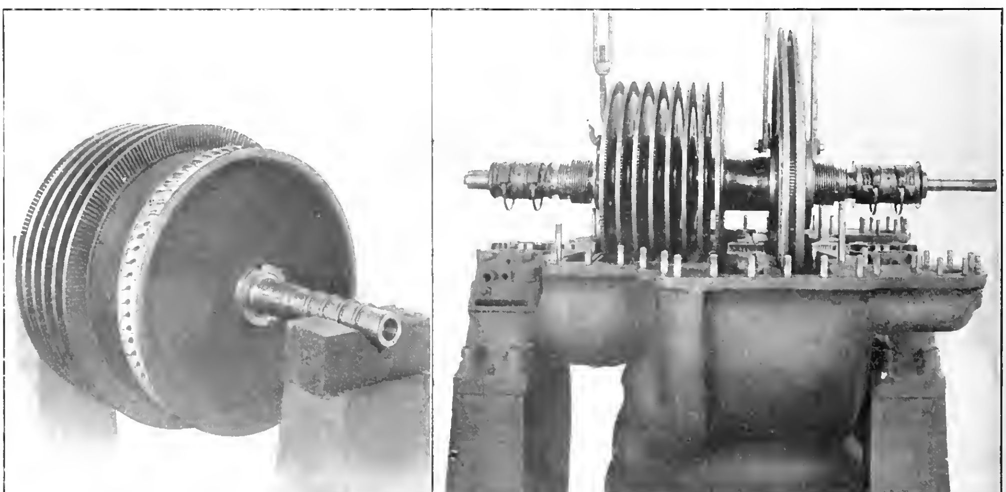

Fig. 5. Rotors of Old and New Designs of Return-Flow Turbines

Old design of rotor having Terry high-pressure bucket wheel

Rotor of new machine having two rows of impulse blading on the high-pressure wheel

The obvious advantage of high vacuum in a turbine, particularly in a low-pressure turbine, with the difficulty of designing, building or keeping glands vacuum tight without the necessity of a water seal with its attendant

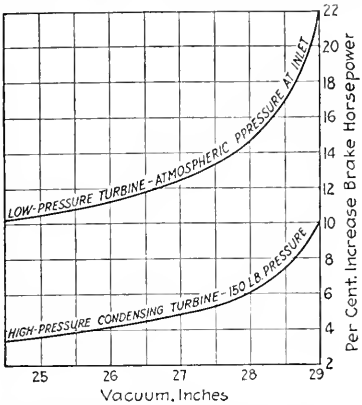

FIG. 6. PERCENTAGE INCREASE IN POWER AVAILABLE (THEORETICAL) PER INCH VACUUM WITH CONDENSING TURBINES

complete envelope of steam above atmospheric pressure, eliminating the possibility of air leaking into the casing. The rotor and the lower half of the casing of the return-flow machine are shown in Fig. 5.

One other important feature in connection with the arrangement of glands on the return-flow turbine is that no supplementary steam supply is necessary for sealing them when under full load, and even at light loads any steam that finds its way through must pass through the low-pressure end of the turbine, thereby doing work, whereas with the ordinary type of steam-sealed glands all the steam which does manage to escape goes directly to the condenser without doing any further work. That this auxiliary steam supply can amount to quite a factor is evidenced by various tests that have been made. Of course, when a machine is new the glands are tight, so that the leakage during this period is imperceptible, but after setting the machine for commercial operation or if it has been in operation for some time, it is hard to know without repeated tests what this steam leakage amounts to. In big machines this is never, however, a serious amount, but in small ones it can be quite a big percentage of the total steam used.

A careful analytical study of the performance of labyrinth glands was made and published by H. M. Mar-

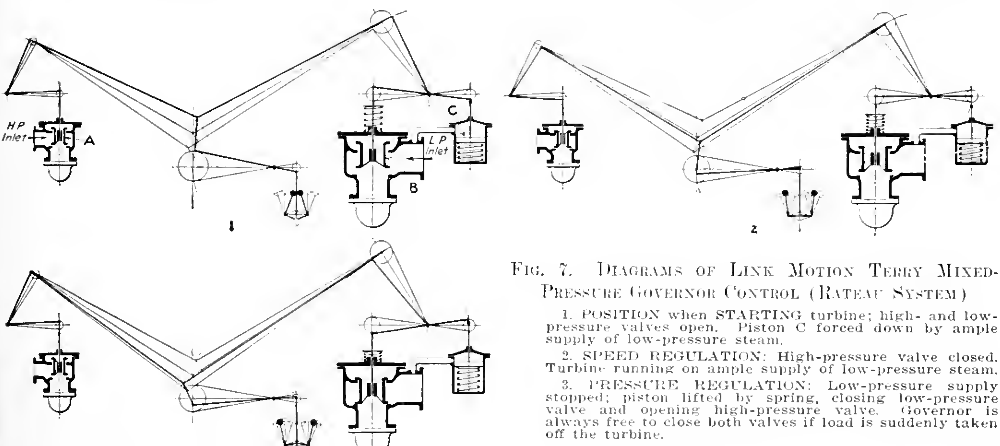

FIG. 7. DIAGRAMS OF LINK MOTION TERRY MIXED-PRESSURE GOVERNOR CONTROL (RATEAU SYSTEM)

1. POSITION when STARTING turbine; high- and low-pressure valves open. Piston C forced down by ample supply of low-pressure steam.

2. SPEED REGULATION: High-pressure valve closed. Turbine running on ample supply of low-pressure steam.

3. PRESSURE REGULATION: Low-pressure supply stopped; piston lifted by spring, closing low-pressure valve and opening high-pressure valve. Governor is always free to close both valves if load is suddenly taken off the turbine.

piping and subsequent sediment troubles, led to the departure from the orthodox straight-flow principle to the return-flow design for the elimination of this long-standing bugbear in turbine work. This question of gland leakage often results in trouble between the turbine and the condenser makers when trying to meet guarantees, while the customer looks on and sees the machine run at a lower vacuum than called for and pays the coal bill anyway.

It is often advocated that with a steam seal on the glands and a little steam blowing outward into the engine room there cannot be any air leaking into the turbine. This contention is wrong, as has been demonstrated many times. It often happens that there is a counter current going on, air traveling along one part of the gland and steam passing out of the glands in the opposite direction, this condition being the hardest possible phenomenon to detect. Fig. 4 shows diagrammatically the construction of the return-flow turbine with the low-pressure end in a

tin, and the formula derived from his experiments is given in his book on steam turbines, as follows:

$$W = 68\,A\sqrt{\frac{P_1\left(1-\frac{l}{x^2}\right)}{V_1\,(N+log_e\,x)}}$$

where

W = Weight discharged in pounds per second;

A = Area in square feet available for flow;

P_1 = Initial absolute pressure in pounds per square inch;

V_1 = Initial specific volume of the steam;

N = Number of points at which the steam is wire drawn;

$x = \frac{P_1}{P_2}$, where P_2 denotes the absolute pressure on final discharge from the last ring of the packing.

This formula checks up fairly closely with actual tests made by the writer on a 2000-kw. machine having a mean labyrinth diameter of 8 in. and 12 elements or restrictions.

From the formula it will be seen that the amount of steam passed by a labyrinth gland is directly proportional to the diameter of the glands. This diameter of

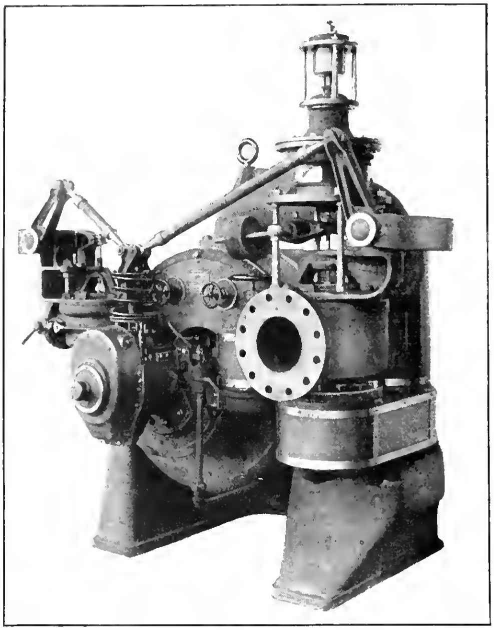

FIG. 8. TERRY RETURN-FLOW TURBINE WITH RATEAU MIXED-PRESSURE CONTROL MECHANISM

gland does not follow any relation to the output of the turbine, and it will be seen that the smaller the machine the larger the percentage of steam that will be passed by the gland; so, as mentioned above, while the amount of steam passed by a labyrinth gland in large machines can be an insignificant factor, it is obvious that in the small machines it can be a serious item. For instance, the figures mentioned above in connection with the 2000-kw. machine show the total steam passed as 177 lb. per hr. On the basis of 15 lb. per kw. this would give a percentage loss due to the glands of 0.6 per cent., whereas reducing this quantity in the ratio of the diameter of the glands, namely, 8 in. to, say 5 in. on a 200-kw. machine, the gland leakage would be reduced to 111 lb., but the percentage of the total steam consumption would be increased to 2.5 per cent., the latter based on a water rate for the smaller machines of 22 lb. per kw.-hr.

Fig. 6 shows the theoretical saving per inch of vacuum in a straight high-pressure condensing and a low-pressure turbine. In the low-pressure machine the vacuum is, therefore, of much importance. We must not look upon this as a question of efficiency so much as a question of how much horsepower one can obtain from a given amount of exhaust steam. Then it means that increasing the vacuum from 27 in. to 28 in. the amount of power available from a fixed quantity of exhaust steam is increased 15 per cent. No precaution is too great for the purchaser to take to insure himself against losses at this point irrespective of any guarantees that may be given either from the turbine or the condenser builder.

The success of the low-pressure turbine intelligently installed is undisputed, but the bulk of the research and development work has been along the lines of the larger machines. The marked saving in these machines has naturally led to the introduction of the low-pressure turbine in small plants such as breweries, ice plants, etc., with just as successful results as with the larger units. Low-pressure turbines of 50 hp. and more have recently been installed, and many more installations are in course of construction. With the exception of a few isolated cases where a fixed supply of exhaust steam can be depended upon indefinitely, the low-pressure turbine has given place to the mixed-pressure machine, the latter having the advantage that should anything happen to the engine or other source of low-pressure steam supply, the full power of the turbine can be obtained when operated with high- or mixed-pressure steam. The return-flow turbine is particularly applicable to low- and mixed-pressure work, as the effect of vacuum in a machine of this kind is of much more importance than in a high-pressure condensing machine.

For satisfactory operation under mixed-pressure conditions and where the low-pressure supply is liable to decrease or fail, a special arrangement of governor mechanism is designed, so that the high-pressure steam is automatically admitted to make up for any deficiency in the low-pressure supply. The system employed by the Terry Steam Turbine Co. on its mixed-pressure turbines is what is known as the mixed-pressure Rateau control, manufactured under license from the Rateau Steam Regenerator Co., the design being modified to eliminate the complicated oil-relay mechanism necessary on larger machines.

The direct-connected governor of the Terry type is used directly connected to the governor valves. The

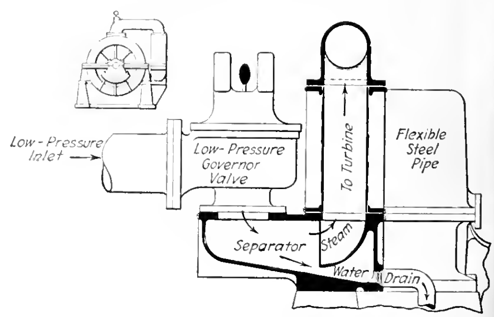

FIG. 9. ARRANGEMENT OF LOW-PRESSURE STEAM INLET ON RETURN-FLOW TURBINE

principle of this mechanism is shown in Fig. 7, and a photograph of the actual machine fitted with this control is shown in Fig. 8. All the levers are mounted on ball bearings to eliminate friction as far as possible. The governor running at high speed has more power than the usual low-speed geared governor and the mechanism itself being balanced by counterweights as shown in Fig. 8, the governor is relieved of all external loads other than to operate the balanced valves.

In all turbine practice, both in high- and low-pressure machines, the question of pipe connections and the elimination of stresses on the turbine is well known to be a serious problem. This is particularly so with the big piping necessary for low-pressure machines, and it is again of further importance in the smaller units, which, on account of their compact size and light weight are susceptible to distortion from outside stresses. The common practice is to bolt the low-pressure valve and piping directly to the turbine casing. This entails considerable risk of pulling the turbine and, consequently, the whole unit out of line, causing vibrations and generally unsatisfactory running. To eliminate this in the return-flow turbine the low-pressure steam supply is not rigidly connected with the turbine proper, but is bolted to an entrainer or separator which in itself is bolted rigidly to the bedplate (see Fig. 9). From this entrainer the steam is led vertically through a flexible steel pipe which leads to the top of the turbine casing. In this way no outside stresses due to the heavy low-pressure steam-supply piping are thrown on the turbine itself. Furthermore, by the introduction of this additional entrainer, drier steam is obtainable in the turbine than would be the case were the inlet piping connected directly to the turbine proper.

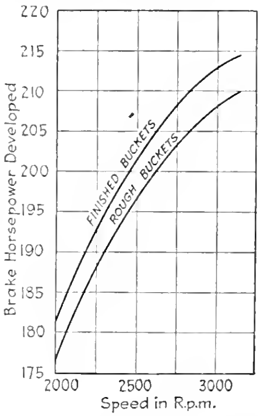

FIG. 10. TESTS OF IMPULSE WHEELS, SHOWING EFFECT OF FINISHING BLADES

Throughout the design of the machine special attention was paid to obtaining the best possible water rate consistent with a compact and reliable mechanical design, and the figures given in the table of some recent tests show some remarkably high efficiencies for turbines of such small power.

The last degree of efficiency can be obtained only by a careful study of the correct areas through the blade passages and by special attention to the finish of the blading in the wheels to eliminate friction and eddies. By the adoption of drawn material for the blading, true areas can be obtained. This machine, as built, conforms closely to calculations, as has been evidenced repeatedly by the careful observation of pressure drops through the various stages, these falling almost exactly in line with the calculated drops. The adoption of polished wheels further enhances the efficiency.

Some interesting experiments were carried out to determine the effect of rough and finished blades and wheels. Fig. 10 shows two curves, one with rough drop-forged blades, the other with blades polished to a true section and with the wheel polished.

Nine-Foot Return-Tubular Boiler

The first 108-in. diameter return-tubular boiler recorded under the laws of the Commonwealth of Massachusetts was recently built at the shops of the D. M.

Dillon Steam Boiler Works, Fitchburg, in accordance with the Massachusetts state laws, for a safe working pressure of 125 lb. The recorded number given to it at the State House in Boston is 974.

The boiler is 9 ft. in diameter and 18 ft. long. The firebox-steel shell plates, and the flange-steel heads are ⅝ in. thick. The boiler has 200 4-in. by 18-ft. Parkesburg charcoal-iron tubes, and has a butt-strap, double-riveted steam drum 30 in. diameter by 6 ft. long. The bare boiler without tubes weighs 27,000 lb. (13½ tons) and complete with all castings and fittings, 84,440 lb. (42.22 tons).

In order to make the boiler lighter for transportation but sixteen tubes were put in at the time of shipment. These were to brace the tube sheet, the rest of the holes being plugged so that the boiler would not sink in case it fell overboard while unloading it from the vessel to the lighter, or in case it was necessary to float it from the boat to the shore. It was shipped to Porto Rico.

The boiler is of interest on account of its large diameter, and because it is the first of its size recorded under the laws of the Commonwealth of Massachusetts.

Metallurgical and Special Furnaces*

By Osborn Monnett†

SYNOPSIS—Industrial furnaces, hand-fired or stoker equipped, specially designed to eliminate smoke.

In studying the smoke problem it will be noticed that there are a great many furnaces burning coal and making smoke other than those installed under a boiler. In the various industries common to a large city enormous quantities of coal are consumed in metallurgical and special furnaces which have no application whatever to the generation of steam. The nature of the work demanded of these furnaces is such as to make them peculiarly susceptible to the making of smoke; in fact, some of the processes require such a low rate of combustion that it is difficult to get the proper temperature for complete combustion. In this class one of the worst smokers has been the ordinary hand-fired annealing oven.

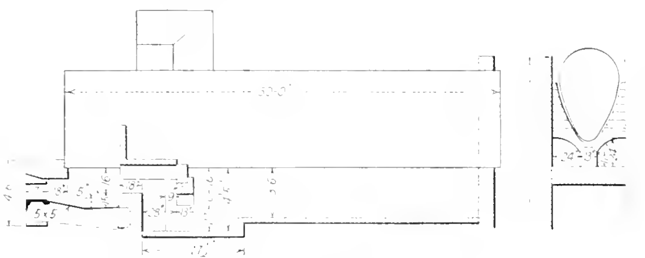

Fig. 1. Fertilizer Tank with Modified Double-Arch Bridge-Wall Setting

On a large scale the use of powdered coal has successfully cleaned up this class of plant and has generally resulted in a substantial saving of fuel over the hand firing, although the investment required is considerable. On a smaller scale, or where the product is of small size, such as automobile parts, producer gas has been successfully used. Producer gas is also well adapted for enameling ovens, and china, pottery and terra cotta kilns.

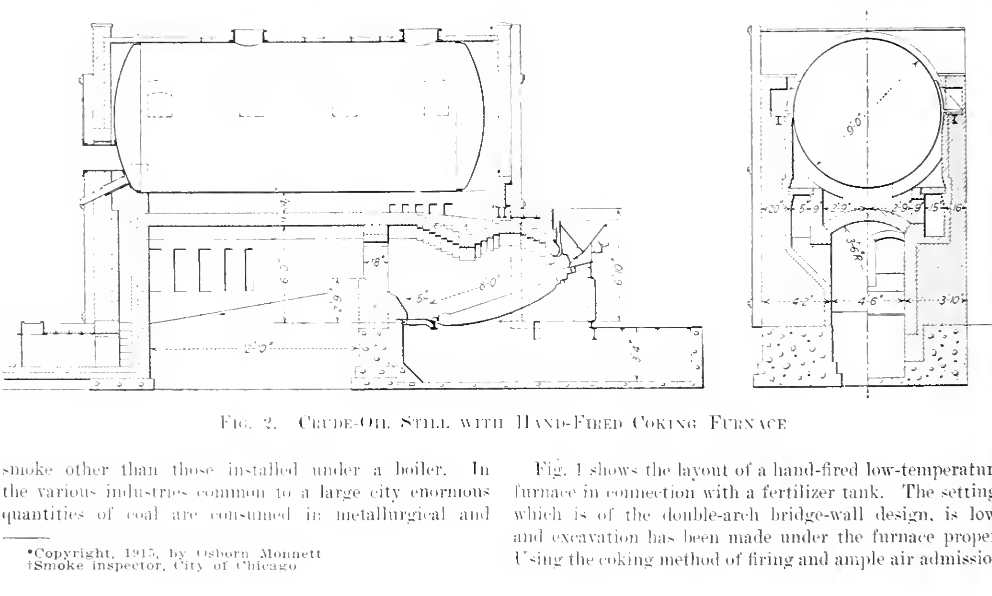

Fig. 2. Crude-Oil Still with Hand-Fired Coking Furnace

Fig. 1 shows the layout of a hand-fired low-temperature furnace in connection with a fertilizer tank. The setting, which is of the double-arch bridge-wall design, is low, and excavation has been made under the furnace proper. Using the coking method of firing and ample air admission

*Copyright, 1915, by Osborn Monnett
†Smoke inspector, City of Chicago

for the semibituminous coal, this furnace can be operated without dense smoke, but it requires careful attention and this is difficult to get in this class of plant.

A crude-oil still, with a special hand-fired furnace arranged for low rates of combustion, is shown in Fig. 2. This furnace is designed for the coking method of firing with semibituminous coal. There is considerable brickwork in the furnace, designed not only to give good mixture, but also to isolate the shell from the heat to prevent burning of the still. Too high a temperature at any one point would be disastrous, so the furnace is provided with a spring arch the entire length of the tank. Coal is charged on the front of the grate and pushed down when fully coked.

Natural gas and fuel oil are also used for this and similar work where the price is low enough so that these fuels may compete favorably with coal. When burning the latter any of the various gravity-feed furnaces can be used. Fig. 3, showing a small Burke furnace attached to a pot annealing oven, is typical of this class of service. Powdered coal and producer gas are also being used in this work. There is probably no class of metallurgical work in which one or the other of the above fuels will not give satisfaction.

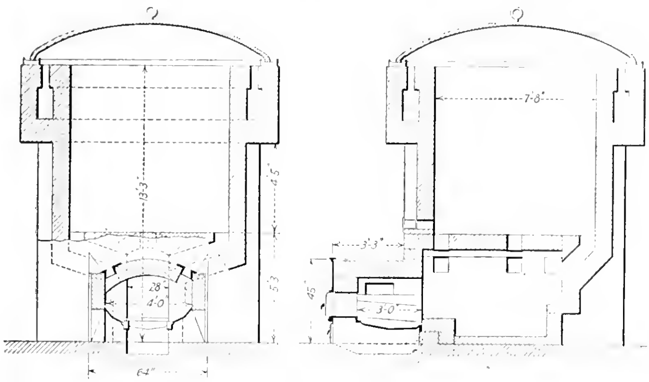

Fig. 3. Pot Annealing Oven and Burke Gravity-Feed Furnace

As mentioned before, the underfeed stoker is peculiarly adapted to special furnace work, owing to the fact that the necessary air for combustion is supplied by mechanical means. Figs. 4 and 5 show typical reheating furnaces equipped with this type of stoker. Rotary drying is another service in which the underfeed stoker works out well. Natural draft on this work is an uncertain quantity, placing at a disadvantage stokers depending on a stack for their air supply. A furnace arranged for connection to a rotary dryer is shown in Fig. 6. This outfit is adapted to the drying of fertilizer, garbage, blood, sand, sugar-beet pulp, or any similar substance from which it is desired to drive off the moisture.

Ocean Volume to Land Area—One per cent. of the contents of the oceans would cover all the land areas of the globe to a depth of 290 ft.—U. S. Geological Survey.

⁂

Horsepower and Torque Defined—It is important to understand clearly the difference between horsepower and torque. The former is the rate of doing work, while the latter is only one of the quantities making up horsepower. The torque of a motor is sometimes defined as the pull or force exerted at the surface of the armature, multiplied by the radius of the armature. For commercial purposes, however, is is defined as the pull exerted at a certain radius from the shaft center. For convenience this pull is usually expressed in pounds and the radius in feet, which, multiplied by the peripheral speed, gives an expression in foot-pounds which is readily reducible to horsepower. Assuming that the force is applied at a distance of one foot from the center of the shaft so that r (radius) = 1, then

$$\text{torque (T)} = \frac{\text{hp} \times 33{,}000}{2\pi \times \text{r.p.m.}} = \frac{\text{hp} \times 5252}{\text{r.p.m.}}$$

From this it is evident that for a given motor and a given horsepower, the torque varies inversely as the speed. If the first definition of torque is assumed, that is, the force acting at the surface of the armature—it is apparent that the torque would be dependent on the diameter of the armature as well as the speed; whereas, by the second definition, it is independent of the armature diameter. In motor applications one is concerned with the torque exerted on the motor shaft and not at the surface of the armature.

High-Tension Switching Systems

By John A. Randolph

SYNOPSIS—Factors determining the extent and arrangement of high-tension switching equipment to be employed, and descriptions of several of the more common systems in use.

In determining the arrangement of a high-tension switching system several fundamental factors must be considered. One is the nature of the service, inasmuch as the scheme of connections for a lighting and industrial service is generally different from that of a system feeding railways. Another is the type of station (central station or substation), which will largely determine certain features of the design. The magnitude and extent of service will also have an important bearing, as will the number of high-tension feeders and the voltage to be carried. The distance of the station from its center of distribution is a vital factor, as is also the space available for installation purposes. Safety to life and property should not be overlooked, although this is perhaps of more importance in the design of the compartments and supports than in the determination of the diagrammatic layout. Furthermore, the money available for construction purposes is a governing factor, and precautions must be taken to insure continuity of service at all times.

In regard to the nature of the general service, it can be said of the railway system that, owing to the large amount of exposed conductors, such as third rails, trolley wires, underground contact rails and ground returns, the liability to short-circuits and consequent interruptions in operation is somewhat greater than on lighting systems, especially such of the latter as are installed in underground conduits. Therefore, greater precautions against shutdowns are advisable for the railway station.

The number of high-tension feeders and the voltage carried will depend largely upon the extent of the service and the distance of the source of supply from the distribution center. If the generating station, for instance, is run by hydro-electric power and is located in the mountains a long distance from the point at which the energy is used, it will be necessary to make the number of high-tension feeders as low as possible in order to save transmission-line costs. To do this the line voltage must be raised in order to transmit the given power over the limited cross-section of conductor. This will permit a comparatively small number of high-tension switches being used, but they will be larger and more cumbersome than those for lower voltages. Wide clearances between conductors and between live parts and ground must be maintained in extra high-voltage work; therefore, more space is required for a given amount of apparatus and conductors than in the case of lower-voltage installations. If this space is limited it may be necessary to limit the output of the station. Here also, the factor of safety to life and property is of more importance than in other cases.

The money available for construction purposes is a determining factor in that it may be necessary to sacrifice many advantageous features to save expense. This is often hazardous, but exigencies may demand it. To conform to this restriction it may be necessary to use but one bus, with a correspondingly smaller number of switches, or to otherwise arrange the switching apparatus in the simplest possible manner, which is by no means the safest. However, in connection with the first cost, the future continuity of service should be borne in mind. Lack of patronage, due to unreliable service, may cause the company to lose in a comparatively short time an amount greater than the saving effected by limiting the flexibility of the switching system.

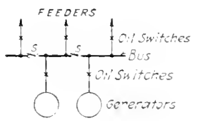

FIG. 1.

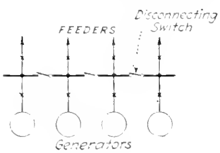

FIG. 2.

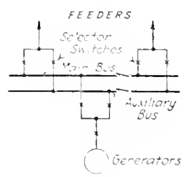

FIG. 3.

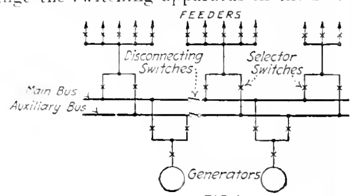

FIG. 4.

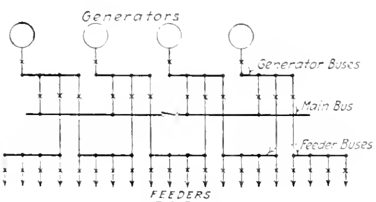

FIG. 5

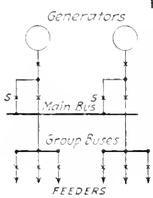

FIG. 6.

Single-Bus System

The simplest method generally employed for the arrangement of switches and buses on a high-tension system is shown in Fig. 1 (the "bus" in this case signifying one set of busbars). One bus is used to which all the generators and feeders are directly connected, there being only one oil switch to each generator and to each feeder circuit. Disconnecting switches *S* are generally installed for isolating sections on which serious defects exist or on which it is desired to make repairs. This arrangement is often used in railway substations. To add to the flexibility of such a plan, the machines and feeders are sometimes connected to the busbars at the same points, disconnecting switches being placed between these points, as in Fig. 2. This provides better facilities for the isolation of feeders and machines with their corresponding bus sections.

The single-bus system has the advantage of minimum space and comparatively low initial cost, but it has the disadvantage of not making possible the ready transfer of machines or feeders from the sections to which they are normally connected, to other sections. On a single-bus system such as shown in Figs. 1 and 2, the machines and feeders always receive or deliver their energy at a fixed point. Moreover, if a sectionalizing switch is opened, the sections on either side of the gap are entirely separated and work independently.

Two-Bus System

In the larger modern central stations, it is customary to install two buses—the main bus and the auxiliary bus. There are several methods by which the feeders and generators may be connected to the buses. In one of these, shown in Fig. 3, two selector switches with each feeder and alternator permit a connection to either of the two buses. Sectionalizing switches are also located at intervals in each bus. With this arrangement, if it becomes necessary to isolate a section of either bus the feeders and machines previously connected to that section can be easily transferred to the other bus without interruption in the service. Moreover, if the demand on one bus becomes so heavy that it is in danger of becoming overloaded, part of the load can be transferred to the other bus; or, where two buses are used, it is possible to so divide the load on the station that accidents occurring on one part of the system will not affect the system as a whole.

Group System

An arrangement commonly employed in central stations and on railway systems using a number of substations for distribution is shown in Fig. 4. In this scheme a main and an auxiliary bus are used, but the feeders, instead of having independent connections to the two operating buses, are connected to group buses which, in turn, are connected by selector switches to the main and auxiliary buses. An advantage of this arrangement is that fewer selector switches are necessary; also, in cases of emergency, a number of feeders can be transferred simultaneously from one operating bus to the other, thus saving time and simplifying the work of the operator.

Another diagram making use of a group bus for feeders is shown in Fig. 5. In addition to the main bus and the feeder group buses, there is a series of generator buses. Four circuits are connected to each generator bus section—one comprising the feed from the generator or other source of power, another a connection to the main bus, and the other two serving to connect the generator bus to two adjacent feeder group buses. The function of the main bus is to tie all the individual buses together and to maintain the power supply on any generator bus after its particular machine has been shut down. Furthermore, it serves to equalize the load on all the generators. The outgoing feeders are connected to the group buses. Inasmuch as every group bus is connected to two adjacent generator buses, it is possible to isolate a generator or group bus without serious inconvenience to the system as a whole. Moreover, all or a part of the main bus can be disconnected from the rest of the system without interrupting the service. Another advantage is that one or two groups of feeders can be fed from either one or two generators independently of the rest of the system. This affords especial convenience in testing.

An arrangement somewhat similar to that of Fig. 5, but incapable of as many combinations, is shown in Fig. 6. A main operating bus is used whereby all the generators and all the feeder groups, or both, may be tied together through the main bus switches S. The generators may be disconnected at will as long as the main bus is kept alive and the switches S are closed. Moreover, the individual feeder groups may be isolated from the main bus as long as the respective generators for those groups are kept running. A disadvantage of this system is that an isolated group, if kept alive, is absolutely dependent upon one particular generator. Furthermore, if the main feed line of the group is out of commission the group itself is also put out of service. The same result will ensue if the generator bus is out of service. In the more flexible arrangement of Fig. 5 these disadvantages do not exist, inasmuch as every group has a connection to two separate generator buses.

Multiple-Voltage System

In the systems described thus far the voltage on the buses has been the same as that of the generators. However, where two or more services with different voltages are to be supplied from one central station, it is often

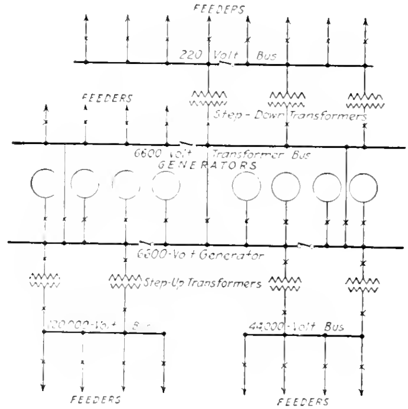

Fig. 7.

advisable to install a separate bus for each service; such an arrangement is illustrated in Fig. 7. The generator voltage of 6600 determines the pressure of the generator bus. However, for the 40,000- and 120,000-volt services, separate buses are installed whose power supply comes from the generator bus, but with the voltage increased by means of step-up transformers. A 220-volt bus for low-tension work is fed through step-down transformers whose primaries are joined to a 6600-volt bus fed directly from the generator bus. For flexibility the various buses are divided into sections, and between these sections are switches which can be quickly opened or closed at the will of the operator.

⁂

The Expansion of Steam Lines may be found by the formula

$$E = C \times (T - t) \times L$$

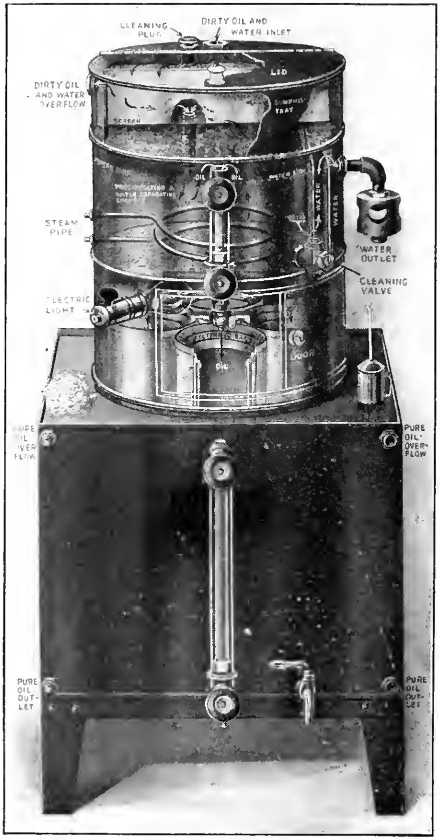
when

E = Expansion in inches;
T — t = Temperature difference;
L = Length of pipe in inches;
C = The coefficient of expansion of the metal of which the pipe is made.

The coefficients of expansion of various pipe materials are: Cast iron, 0.0000065; steel, 0.0000067; wrought iron, 0.0000068, copper, 0.0000095; brass, 0.0000105.

Nugent Improved Oil Filter

The accompanying illustration shows one of the standard filters now being made by Wm. W. Nugent & Co., of Chicago. This particular design may be circular or square in section. It is made in eight different sizes, the capacities being from 6 to 100 gal. per hr., respectively. Multiplication of the filtering chambers will, of course, give an apparatus of any desired capacity. The cylindrical filtering and water-separating section, shown at the top in the illustration, is independent of the reservoir, and is supplied separately if desired. A tank suitable for oil storage may be available at the plant and if appearances do not count an oil barrel may be used. In the latter case the barrel is turned upright and the filtering chamber set over the open end.



Nugent Improved Oil Filter

From the phantom view the path of the oil from inlet to storage may be traced. In the top part are two semicircular sections, one known as the dumping tray and the rear half as the screen chamber. If the filter is connected to an oiling system, the dirty oil and water which may be present enter the dumping tray through the inlet shown. By raising the lid it may also be poured into this compartment. In the vertical wall separating the two sections is a fine-mesh copper screen through which the oil passes into the screen chamber. From here it flows downward through a short pipe into the water-separating and precipitating chamber. It enters under the surface of the water, rises to the top and overflows into a central pipe supplying the filtering bags. The water passes under the inner partition, shown at the right of the chamber, and over the second partition to the outlet.

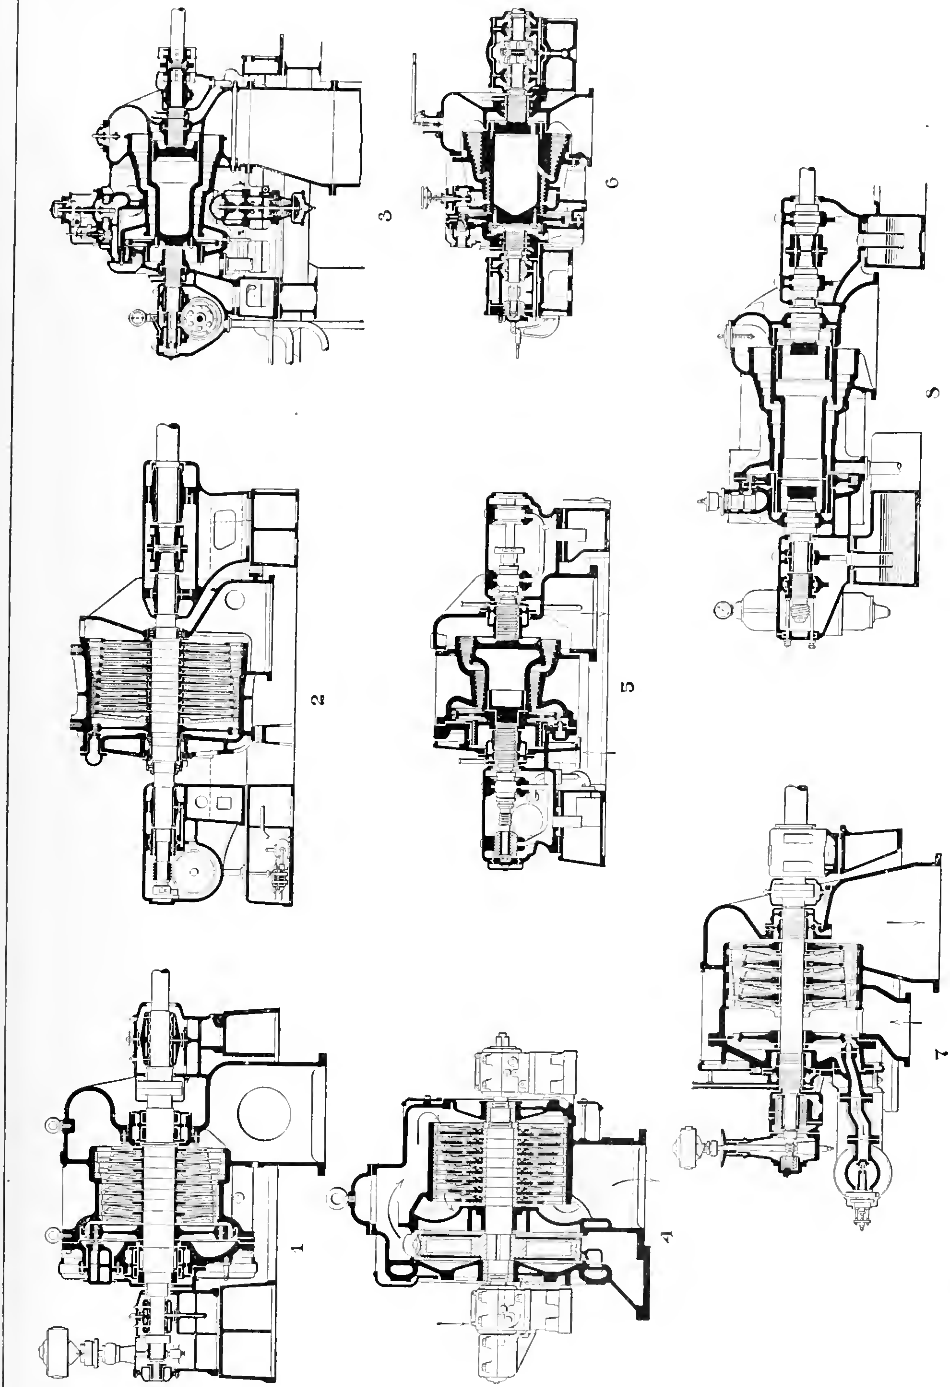
Depending on the size of the filter, one, two, three, four, six or eight sets of filtering bags are provided, three in a set, all on independent rings. The two smaller ones are made of comparatively thin fabric, while the material forming the largest is much heavier. An electric light has been provided so that the filters may be inspected through the sliding door shown in the illustration. The machines having four, six or eight sets of bags are suspended from a central spindle and each may be rotated to a position in front of the door. The cock controlling the drip at this point may be closed and the bags inspected or cleaned. The pipe leading from the screen chamber is of such a size that it cannot supply enough oil to flood the filters. If more should come to the dumping tray than can be cared for, the surplus escapes through the overflow at the top and eventually is returned to the filter. Other features are the steam coil in the water-separating chamber and the facilities for cleaning.

The Composite-Type Steam Turbine

Five years ago we called attention to the evident tendency to unification in turbine types, and the adoption by several builders of the velocity-stage for the initial expansion, and by the builders of velocity-stage turbines of single-velocity impulse or reaction stages for the lower ranges. We pointed out that by allowing the initial expansion to take place in a single set of nozzles, and using a velocity-stage of two rows of moving and a single row of reversing buckets to absorb the velocity so generated, the steam is reduced in pressure from, say 150, to 30 lb. before it is introduced to the turbine case, decreasing the pressure upon the balancing plates or dummies, diminishing the temperature to which the rotor drum and shell are subjected, and eliminating the long section of short blades, admittedly the least efficient of the reaction turbine, on account of their large windage in the dense medium of the high-pressure steam, and of the large proportion of their clearance to the active surface.

The anticipations expressed in this article have been realized, and we present upon the opposite page a number of the machines of this composite type as now built by prominent companies. The presentation is, however, by no means complete, and should include the General Electric Co. and the Westinghouse Machine Co., if not other American builders. The builders of the turbines, sections of which are shown, are as follows:

1. Bergmann, Berlin.
2. British Westinghouse, Manchester.
3. Melms & Pfenninger, Berlin and Munich.
4. Terry, Hartford, Conn.
5. Gutehoffnungshütte, Oberhausen.
6. Brush, London.
7. Allgemeine Elektricitäts Gesellschaft, Berlin.
8. Brown Boveri, Baden.

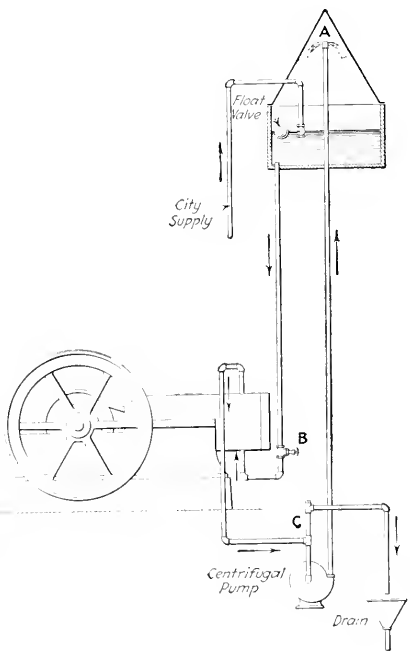


Examples of Steam Turbines of the Composite Type

Gas-Engine Cooling Water

By G. A. Field

The temperature of the jacket water should be controlled to suit the individual case. For instance, large engines require cooler cylinders than smaller ones, and oil engines often require slightly higher temperatures than those burning gas or gasoline, because of the tendency of the oil to condense on the cylinder walls. In automobile engines the jacket water often reaches the boiling point without any serious results. Under average conditions the temperature of the cooling medium on entering the cylinder jacket will not exceed 60 deg. F. and on leaving should not exceed 160 deg., 150 deg. being better practice. Should the temperature of the cooling water exceed 185 deg., there is danger of deposit in the jacket.



Arrangement of Cooling System

As a safeguard against incrustation of the water jacket soda may be introduced, about a pound a month being used for every 17 cu.ft. of reservoir capacity. The jacket should be flushed out frequently. Another method is to fill the jacket space with one part sulphuric acid and ten parts water and allow it to remain over night.

For small engines, not hopper cooled, but using the thermo-siphon system, ordinary tanks or reservoirs are used. In this case the bottom of the reservoir should not be below the water outlet of the cylinder jacket, as the circulation is maintained solely by the difference in the density of the water due to the difference in temperature at the inlet and the outlet. The height of the water in the reservoir should not be less than four inches above the discharge of the return pipe. The capacities of reservoirs of this type are, of course, dependent upon the size of the engine and should be from 50 to 60 gal. per hp.

Water injection in various quantities directly into the combustion chamber is also used, but has not as yet displaced the water jacket to any great extent. A very small quantity of water is commonly injected with the fuel of oil engines to prevent preignition and also, by lowering the temperature of the burning charge, to prevent the decomposition of the fine particles of oil before evaporation is fully attained. This results in a decrease in the amount of carbon deposited in the combustion space.

It is estimated that about one-third the total heat supplied to the engine is carried away in the cooling water. Manufacturers guarantee a heat consumption of from 11,000 B.t.u. per b.hp.-hr. for full load, to 19,000 or 20,000 B.t.u. for one-quarter load. Therefore, with a safe allowance for ordinary working conditions of 12,000 B.t.u. per b.hp.-hr., based upon full-load rating, it will be seen that about 4000 B.t.u. per b.hp.-hr. must be carried away by the cooling medium.

As one B.t.u. is required to raise 1 lb. of water 1 deg. F., for an average range of 90 deg. it will require $4000 \div 90 = 44.5$ lb. of water, which is equivalent to approximately 5.35 gal. per b.hp.-hr.

Practical experience shows that small hopper-cooled engines require from 0.3 to 0.6 gal. of cooling water per b.hp.-hr., while larger engines using forced circulation should have a pump capacity of from 10 to 15 gal. per b.hp.-hr.

An economical and efficient arrangement for recooling the jacket water, and also providing for loss due to evaporation or danger of the pump failing to operate, is shown in the attached sketch. The cooling tower may be placed on the roof at some elevation above the engine, and it should be in the open air. The hot water is delivered along the under side of the ridge at *A* and is sprayed outward on each side against the sloping sides through holes drilled in the pipe. The sides are made of fine woven wire, which permits free passage of the air and carries the water down to the open tank below. Water enters the tank from the city supply pipe until the level reaches a sufficient height to close the float valve.

After starting the engine, the valve *B* is opened and the centrifugal pump is started. The pump, being at the lowest point in the line, is always primed and the cooling water immediately takes the circuit downward from the tank through the water jacket of the engine, into the pump, and upward to the spray and back to the tank.

Should the pump fail to operate properly or stop altogether, the circulation will still be maintained; the water being constantly replenished by the city-supply pipe through the automatic float valve. After passing through the cylinder jacket the water, instead of passing through the pump, will flow upward through the pipe *C* and into the drain. By means of the float valve, all losses due to evaporation are replenished, making the system automatic.

The pump should, if possible, be belted to the engine, but may be run by an electric motor. In shutting down the engine the valve *B* is, of course, closed and the pump stopped.

Manual Training Schools in the United States numbered 279 in 1913, with 65,699 students.

A Large Wooden Flywheel

Engine wheels of large size, especially those designed for high rim speed, are, in many instances, being built up with wooden rims, and many old-style cast-iron wheels on large engines are being replaced with the modern wood-rimmed wheel. Such a change has recently been made at the large cotton mill operated by the Berkeley Co., at Berkeley, R. I. The two independent Corliss engines at this plant, each having a separate flywheel and shaft, are operated together as a cross-compound, in conjunction with an independent condensing apparatus. The cylinder of one is 26 and of the other 52 in. in diameter, each having a 72-in. stroke. The wheel of the high-pressure engine, 25 ft. in diameter and 88 in. width of face, was originally of cast iron, the centers being in two pieces forced upon the shaft, and the arms and segments, eight of each, being cast separately.

the pad on the rim segment, to prevent further development of the cracks. Such repairs as could be made between a Saturday night and the following Monday morning were attended to, and the wheel was operated with the mill load the greater part of the following Monday morning, when it was thought wise to shut down and note conditions. It was found that the pad at both ends of the segment adjoining the one originally cracked had developed fractures, and special steel patches had to be made up and applied to those segments before the engine could be again operated. Meanwhile, it had been determined that the wheel, cracked as described, was not safe to run, no matter how well repaired and patched up, and an order was placed for a modern wheel of such design as would permit the engine to be operated at any desired speed and still have a greater factor of safety than could be had with an all cast-iron wheel.

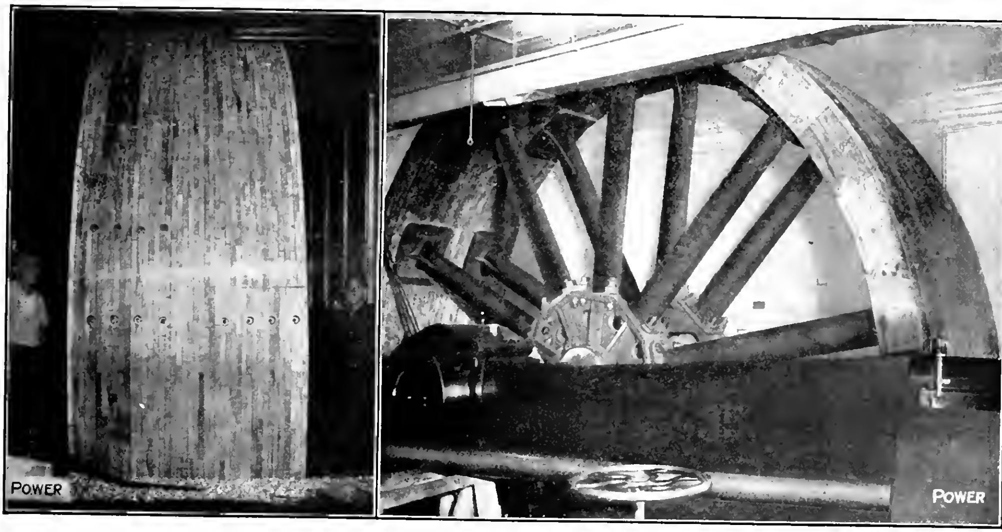


Fig. 1. Twenty-Five-Foot Flywheel with Wooden Rim at Berkeley (R. I.) Cotton Mills

This wheel was designed for about 50 r.p.m., and at the time of its installation so large a wheel, with only eight arms and eight rim segments, was considered to have an ample factor of safety when running, as this ran, with a rim speed of 65.45 ft. per sec. Later, the speed of the engine was increased to 60 r.p.m., giving it a rim speed of 78.54 ft. per sec., and as a matter of insurance, the built-up iron wheel was stayed for additional strength by applying wrought-iron bands on the shaft on each side of the wheel hub and having steel stays reach therefrom to the bolts securing the joints of the rim segments; these stays being 16 in number, twice as many as there were arms in the wheel.

In this manner the wheel was operated for a considerable time and was carefully inspected at given periods. Some months ago, during such a week-end inspection, cracks were noticed in the pad of one rim segment at the point where the wheel arm was bolted to the rim, and while the cracks found were not such as would indicate any necessity for condemning the wheel, it was thought wise to apply special wrought-steel patches to strengthen

The new wheel was designed, built and installed by the William A. Harris Steam Engine Co., of Providence, R. I., and is of the same size as the one replaced, but the hubs are in two pieces, designed for a clamping fit to the shaft instead of being forced into place, and the arms, which are cast separately, are 20 in number, of oval cross-section and hollow, there being two sets of these arms, 10 in each set. The rim is 14 in. thick, built up of white pine, and while the new wheel is superior in every particular to the old type of wheel and has a greater factor of safety, it weighs only about the same as the iron one which it replaces, and does not, therefore, bring any greater weight on the main bearing, the original shaft being re-employed. The total weight of the new wheel is about 80,000 lb., of which 60,000 are in the iron work of the hubs and arms, and 20,000 in the wooden rim. The patched-up and repaired iron wheel was operated until the new one could be made ready, and then, during one week's shutdown, the old wheel was removed and the new one installed without removing the main shaft from the engine.

It will be noticed from the accompanying illustration that the new wheel center, while being in only two pieces, has double faces to accept two sets of arms, as described. This center complete weighs not far from 10 tons in itself, while the 20 arms weigh about a ton apiece.

The work of removing the old wheel and installing the new one was carried on under pressure, so to speak, and in cramped quarters, and the accomplishment of the complete job in one week's time was considered quite remarkable. The wood rim was built onto the arms, piece by piece, at the mill, each piece being securely spiked and

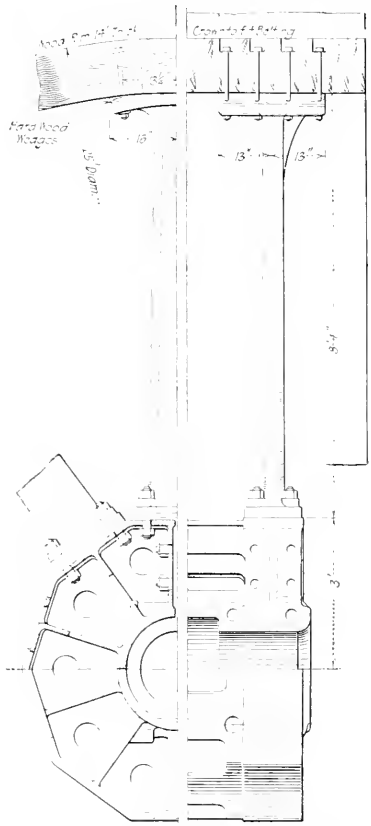

Fig. 2. Showing Construction of Large Wooden Flywheel

glued, and then the completed rim was turned up true and faced off with three independent crowns for as many belts of unequal width.

The builders of this wheel have installed a number of such wheels at various places throughout the country, and make a specialty of their design and construction. They have recently converted two 15-ft. by 25-in. iron wheels into one wheel of 16½ ft. diameter by 51 in. face, by building a wood rim onto the faces of the old iron wheels, giving them greater strength, permitting higher rotative speed than that for which they were designed, and allowing the operation of one belt where two had previously been employed, while the cost of converting the old wheels into one was much less than would have been the cost of a new iron wheel to accomplish the desired purpose, and the time required was really not so great as would have been needed if the old wheels had been removed and a cast-iron one substituted.

Just for Fun

[*More stories of stupidity and ignorance competing with "Some Original Ideas," as printed Jan. 19, 1915.*]

In one of the mills of this city there are two 72-in. by 16-ft. return-tubular boilers carrying 110 lb. steam pressure. The average load is about 176 i.hp. The boilers are kept reasonably clean and oil is used for fuel. One of the mill owners thinks he needs more capacity for steam generation because the engineer reports that the shell of the boiler becomes almost white-hot. After turning off the oil it gradually cools down to a cherry-red. —*A. L. Harris, McPherson, Kan.*

A few years ago I read in an article, "To stop knocking give your valve more lead." Very simple, thought I, although it had been my belief that the knock was in the piston and not in the valve. Besides, I had always thought that babbitt metal was better than lead. However, being a believer in following directions to the last letter, I took the valve, valve rod, and eccentric off, melted out the babbitt and substituted lead. I was firm in my conviction that it would be impossible to give the valve more lead than that. The knock did not stop at all; the article, therefore, was wrong. Nevertheless, lead is necessary and it does stop knocking.—*W. F. Schaphorst, New York City.*

A prize "bone-head" trick was pulled off on a new Corliss engine built by one of our largest concerns and erected by one of their shop men, but evidently changed afterward. At any rate complaint was made that the engine would not carry the load, in fact would "lay down" with about quarter load. One of the best shop men was rushed to the scene, arriving just before noon. On entering the engine room the very first thing he noticed was that the eccentric connecting-rod was connected to the upper pin on the rocker and the reach-rod connected to the center pin—in other words the two rods were reversed in position. The motion being so reduced, the valves were not given sufficient opening, hence the lack of power.

Taking in the situation at a glance, the shop man suggested going to dinner before beginning the task of putting the engine right, to which the engineer agreed. They started out together, but the shop man suddenly remembered having left his gloves, told the engineer to go ahead and order the dinner and he would go back after them. While in the engine room alone, he quickly reversed the connections, then hastened to join the engineer in a good dinner and "trimmings." On their return to the engine room he suggested that the engine be started up so that he might judge of its ailment. It, of course, behaved all right; then he suggested putting on the load, and to the wonder of the engineer it carried it with ease. The engineer was kept guessing to the full satisfaction of the shop man before being told what had happened.

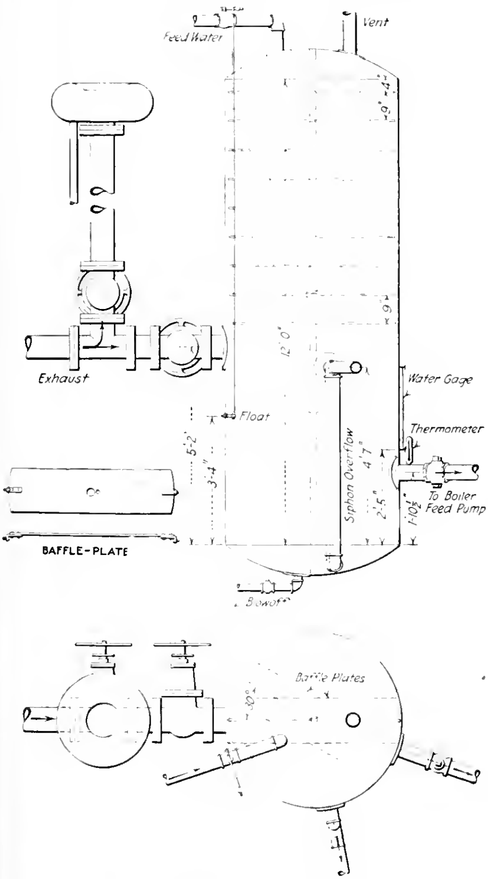
This is a "sure enough," "honest injun" true story.—*F. R. Compton, New York City.*

An Open Feed-Water Heater

By F. F. Jorgensen

The illustration is of a home-made open feed-water heater used at a coal-washing plant. It heats all of the feed water for four 150 (rated) horsepower boilers. Exhaust steam is taken from a 13x16-in. double engine, a 12x14-in. single engine, a 13x12-in. single engine, the boiler-feed pump and a small coal-drag engine.

Nearly 9000 lb. of exhaust steam per hour is available. The back pressure is but little above atmospheric,



Details of Heater Construction

so that if all the steam were condensed 970.4 B.t.u. per lb. of steam would be obtained, or 8,733,600 B.t.u. in all.

About 15,000 lb. of feed water per hour is required and its temperature on entering the heater is very little above 32 deg. during the cold weather. The temperature leaving the heater remains practically constant at 212 deg. In raising the temperature of the water from 32 to 212 deg., 180 B.t.u. per lb. is required.

The heater was made from a discarded compressed-air receiver and it has been in service for a year, giving excellent results.

Variation in Coal Constituents for Similar B.t.u. Values

By Henry D. Jackson

The recent and persistent agitation of the subject of purchasing coal on the B.t.u. basis is of value to both the buyer and the seller, but if coal were bought on the B.t.u. basis alone, it would be likely to prove an expensive method to the purchaser, for all coals having a high B.t.u. content are not necessarily good for use under the boilers of the plant for which the coal is being purchased.

Coal varies widely in ash, moisture, fixed carbon and volatile matter. The ash is, of course, a waste, and a low ash content is advisable because it means that less coal has to be fired and less waste material handled for a given evaporation. Moisture is a detriment because it must be evaporated and the heat to do this must come from the coal, and therefore, considerable moisture means a large waste of heat. Volatile matter may or may not be of value, depending upon what it consists of, as well as whether it can be burned to advantage under the boiler.

The table shows the range of constituents found in coals having the same B.t.u. value. Take the two top rows

TABLE SHOWING WIDE RANGE IN COAL CONSTITUENTS FOR APPROXIMATELY THE SAME B.T.U. VALUES

Value in B.t.u.	Moisture	Volatile Matter	Fixed Carbon	Ash
10,001	8.93	36.53	33.76	20.78
10,264	3.53	20.75	47.85	27.87
10,816	10.83	36.24	39.75	13.18
11,142	9.04	29.65	45.57	15.74
12,195	3.12	35.75	47.67	13.96
11,906	5.59	25.07	53.28	16.08
12,958	4.49	40.55	47.43	7.53
13,129	3.24	17.46	66.69	12.61
14,107	1.75	36.77	55.14	6.34
14,024	2.14	16.83	71.91	9.12

of figures, for instance; the moisture varies between 8.93 and 3.53 per cent., the volatile matter between 36.53 and 20.75; fixed carbon between 33.76 and 47.85, and the ash between 20.79 and 27.87, yet the B.t.u. content is practically the same.

For most boilers as set at the present time, the second coal shown on this list would probably be more satisfactory as regards evaporation than the first, although its ash content is higher. This is due to the higher fixed carbon and lower moisture. Following these figures right through, one can readily see that there is a wide variation in coals. Therefore, the buyer should take into account more than the B.t.u., and in order to be sure that the coal purchased is the best for the purpose, it is advisable to burn it under the boilers and to determine the evaporation, and then buy by specification that coal which gives the best evaporation for the lowest price. Test every car of coal and see that it comes up to specification. Put a bonus and forfeiture clause in the specification, which will give a bonus for an increase in the fixed carbon or decrease in the volatile, ash or moisture, and exact a forfeiture or a decrease in price for excess of ash, moisture, or volatile matter or decrease in fixed carbon, the object being to obtain a coal having a maximum of B.t.u. with a minimum of waste material. The specification should limit the minimum amount of fixed carbon as well as the maximum amount of ash and moisture acceptable.

A New Organization called the Institute of Industry and Commerce has been formed in London. The institute hopes, among other things, to stimulate and encourage standardization in methods of production, organization and distribution, to bring about closer coöperation between science and management and labor in industry, and to consider all legislation which may affect industry.—Foreign Exchange.

Test of Turbo Air Pump

SYNOPSIS—A pump which apparently produces over 100 per cent. vacuum, the absolute pressure in the chamber being less than that of water vapor present at the observed temperature.

The editor was privileged to see recently, at the works of the Wheeler Condenser & Engineering Co. at Carteret, N. J., a turbo air pump under test. This pump is of the type in which the air is expelled by a succession of rapidly moving water pistons. Fig. 1 shows the action diagrammatically, the rotating impeller throwing off streams of water at a high velocity, which are broken up by the pointed divisions of the compression channels into plugs which continue their course through the channels, pushing the air and noncondensable vapors before them. The pump in this form was developed by the Allgemeine Elektricitäts Gesellschaft, the General Electric Co. of Germany, and is built by the Wheeler Condenser & Engineering Co. Fig. 2 shows the exterior of the impeller and the renewable entry piece at the commencement of the compression channels, and Fig. 3 the pump in section.

The pump under test had a capacity suitable for about a 20,000-kw. condenser. The purpose was to determine how nearly it would come to maintaining a theoretical vacuum when different amounts of air were allowed to enter. The pump was arranged for testing, as shown in Fig. 4. The plugs at *A A A* controlled carefully calibrated openings through which known amounts of air were admitted. The temperature of the incoming and outgoing hurling water was measured by the thermometers at *B* and *C*, respectively. The mercury column at *D* indicated the vacuum, and the V-notch weir *E* enabled the amount of hurling water used to be determined.

The temperature of the hurling water as measured by the thermometer at *B* was 93 deg. F., and one would naturally say that the absolute pressure in the chamber *F* could not be less than 1.556 in., the pressure of water vapor at 93 deg. As a fact, however, the mercury gage *D* connected with this chamber showed a vacuum of 28.8 in.

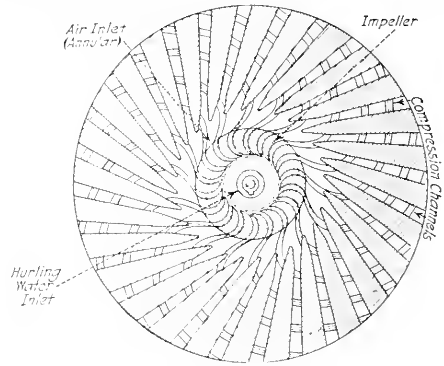

FIG. 1. DIAGRAMMATIC SECTION OF PUMP

The barometer at the time read 30.02 in. If these were right the absolute pressure in the chamber was 30.02 — 28.80 = 1.22 in., or only 0.784 of the tension of water vapor at 93 deg. with which it was supposed to be in con-

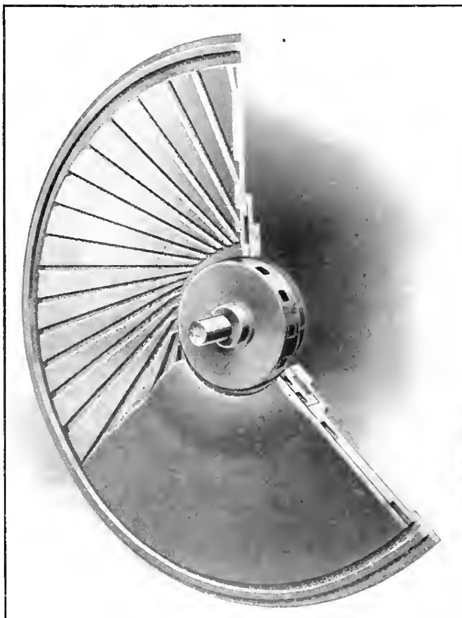

FIG. 2. IMPELLER AND COMPRESSION CHANNELS

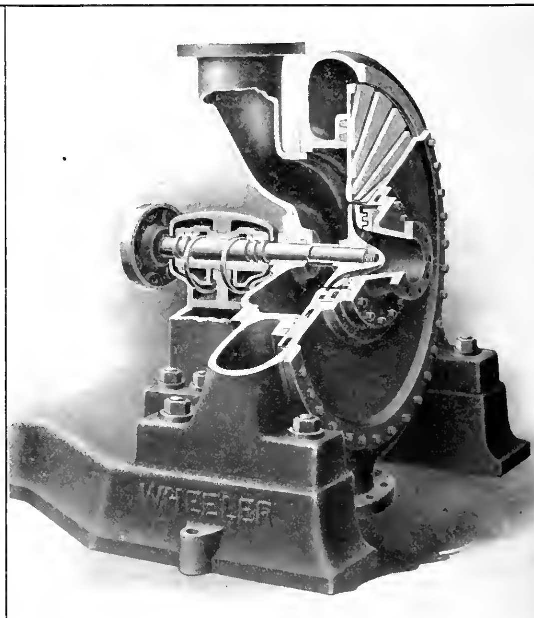

FIG. 3. SHOWING IMPELLER IN SECTION AND IN SITU

tact. It was not until just after the fourth observation, as shown in the fifth column of Table 1, when the air was being admitted at the rate of 32 cu.ft. per min., that the pressure in the air inlet became greater than that due to

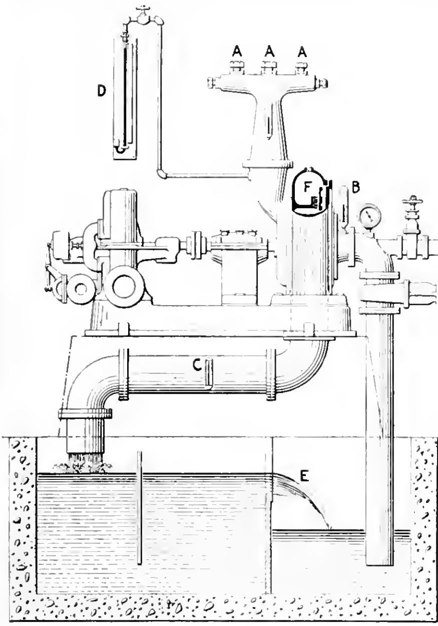

Fig. 4. Pump Arranged for Testing

the temperature of the hurling water. An explanation suggested by the engineers of the condenser company is, that as the water is subjected to the action of the vacuum a small amount evaporates under the reduced pressure and a cooling effect occurs, resulting in a lower temperature and vapor tension, or higher vacuum, in the immediate vicinity of the surface of the water.

It is customary at the Wheeler works to refer all vacuums to a 30-in. barometer. This is done in the sixth column of the table, and the ratio of the vacuums so found to the vacuum (28.144 in.) corresponding to the tension of aqueous vapor at 93 deg. and a 30-in. barometer is given in the eighth column. This ratio would, however, be different for each barometric pressure taken as a base.

In Table II are given the results of a test of a pump of the same type, but of relatively small size, connected to a surface condenser and with cooler water, the condenser working at about half of its rated capacity. Notice the close agreement between the exhaust-steam temperature corresponding to the vacuum (Col. 3) and as observed (Col. 4).

TABLE I

Barometer Reading In. Mer		Observed Vacuum In. Mer		Absolute Pressure at Air Inlet In. Mer.		Pressure of Aqueous Vapor at 93 Deg. F In. Mer.		Ratio of Condenser Pressure to Vapor Pressure at 93 Deg. Steam Piping

While the work of planning and erecting steam piping seems of minor importance, its proper execution affects the economy and continuity of the plant's operation to a greater degree than an equivalent expenditure on any other feature of the average power plant. The factor of safety usually employed for pipes and fittings is from six to ten times the working pressure they are intended for, yet constant annoyance and even disaster follow their improper erection or later neglect. Among the chief causes of failures of pipe systems are water-hammer, expansion and contraction, which produce distortion, vibration, misalignment, poor workmanship at joints, and corrosion.

Water-hammer may be produced by a great variety of

TABLE II

Time	Vacuum Referred to a 30-In Bar	Temp. Corresponding	Temp. of Exhaust by Thermometer	Temp Hurling Water In	Temp Hurling Water Out	Temp. Circulating Water In	Temp. Circulating Water Out	Temp Condensate
12:30	29.64	50	50	37	39	37	44	46
1:	29.64	50	52	38	40	38	43	47
1:30	29.59	53.5	54	38	40	38	44	48
2:	29.59	53.5	54	38	40	38	44	48
2:30	29.59	53.5	54	38	40	38	44	48
3:	29.54	56.5	58	37	40	37	46	46
3:30	29.79	53.5	54	37	40	37	46	47
4	29.64	50	52	36	38	36	44	45

conditions, some of which are difficult to forestall or identify, but the effect is usually the same—broken fittings or at least loosened joints, resulting in more or less serious damage. Any depression, or pocket, below the drainage level of the pipe line may, under certain conditions, accumulate condensate or water enough to produce water-hammer, therefore such pockets should be avoided. A valve so placed that water may accumulate above it when closed, constitutes one of the most frequent sources of water-hammer. When such a location is unavoidable a drain should be tapped in immediately above the valve, with the small drain valve easily accessible to the operator when at the main valve. A short open-end drain pipe is usually best, so that the operator may be sure the drain is not obstructed and that the steam is reasonably free from moisture, before opening the main valve. This is intended to be independent of and in addition to the regular drainage system. Reducing tittings on horizontal runs are frequently responsible for water pockets. Owing to the rapid rate of condensation, water-hammer may occur if steam is too rapidly turned on long lines when cold, even though sufficiently graded and drained for ordinary duty. It should be borne in mind that disastrous water-hammer may occur at low pressure—even below that of the atmosphere.

Expansion and contraction, when no adequate allowance has been made to relieve the strain so produced, always tend to loosen joints and often distort valves and cause fittings to break. Allowance should be made for elongation with an increase of temperature to which the pipe is subjected, equal to the difference in degrees multiplied by the length in inches and divided by the constant 150,000, or 0.6 in. for each 100 deg. per 100 ft. of pipe. The most commonly used form of expansion absorber is the ordinary, long-radius bent pipe. So called swing joints are also used, consisting of screw fittings so placed that expansion or contraction will cause them to change their relative positions by turning on the thread. Two pairs of elbows connected by short lengths of pipe are usually necessary. The threads for such work should be well formed and ground in with emery and oil to make as perfect a ground joint as possible, and after wiping off the emery they should be well lubricated and not made up too tightly. The extra resistance to the flow of steam caused by the elbows is an objectionable feature in addition to the difficulty of maintaining a steam-tight joint. The slip joint, consisting of a sleeve, smooth and true, attached to one section of the pipe and sliding in a stuffing-box attached to the other section, is quite commonly used and has advantages and uses peculiar to itself. Another form is made of a pair of large circular flexible diaphragms of steel, copper or other metal bolted to the flanges of the two sections of pipe and bolted together at their periphery with a flange of large diameter between. This forms an expansion joint of considerable merit. A corrugated copper sleeve, with supporting rings and having a flange attached at each end, is used where the expansion is not too great. Care should be taken not to tax this joint beyond the limits recommended by the manufacturer. Ball-and-socket joints and sometimes unions are utilized to avoid excessive expansion strains.

Vibration is usually caused by motion of the engine or other machinery to which the pipe is attached and the pulsating of the steam in the pipe. If this motion, or vibration, is rapid and violent the life of the pipe line will be uncertain. In cases where there are several high-speed engines which cause the pipes to vibrate in unison part of the time and out of step at other times, the strain becomes particularly severe at intervals. Lines should be free to expand lengthwise, but their motion in other directions should be carefully limited.

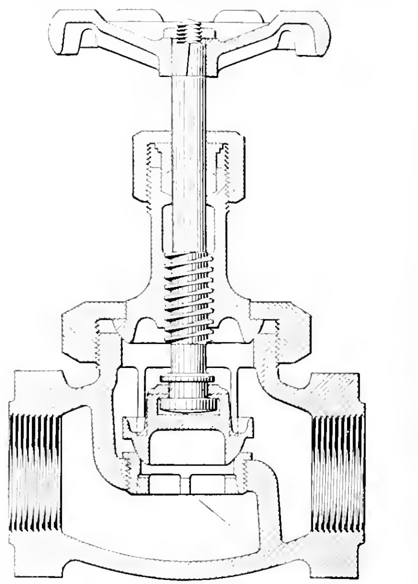
Misalignment puts severe strain on the pipe and fittings, either in connection with expansion and contraction or independently. If the pipe line is not straight, because of crooked threads or flanges, the difficulty will usually increase under heat changes, although joints that have to be forced out of their natural positions or strained when cold may sometimes take an easier position when heated; but such strain should be carefully avoided.

Poor workmanship will soon manifest itself when the pipe system is subjected to the foregoing conditions in addition to the pressure sustained. Work poorly done through carelessness or ignorance is scarcely less criminal than if so done with intent to do injury. Ignorance is no excuse and carelessness is less than none—it is a confession.

External corrosion is sometimes serious when a combination of heat and moisture is augmented by a trace of acid or other corrosive element in the pipe covering. This condition is more frequently met with in underground construction where, incidentally, it is the more serious on account of the inaccessibility of the line. It can usually be avoided by a protective coating applied to the pipe before the insulating covering is put on. Internal corrosion is more common in boiler-feed lines and return lines from steam-heating systems and is sometimes due to the action of warm distilled or nearly chemically pure water, which readily attacks wrought iron or steel. Water not over 80 per cent. pure is not likely to attack the piping seriously, but if air is admitted with warm water containing a trace of acid there is likely to be corrosion. Cast-iron or brass pipe will usually withstand indefinitely the action of water fit for boiler feed.

Powell "Irenew" Valve

The Powell "Irenew" valve, a sectional view of which is shown, has recently been developed by the William Powell Co., Cincinnati, Ohio. The main feature is the removable horseshoe disk, which is arranged to slide over the head of the stem into a socket, thus permitting it to swivel freely. When it is desired to remove the disk from the stem for regrinding or renewing, it is merely slipped from the socket. Should it become needful to regrind the valve, it is not necessary to disconnect it from the pipe, but by simply releasing the bonnet and unscrewing the large hexagonal nut the valve bonnet may be withdrawn and a pin fitted through a hole in the valve-stem head to lock the disk.



"Irenew" Valve in Section

The removable disk is made of a noncorrosive metal applicable to most temperatures of superheated steam. To remove the seat, a screwdriver or other flat tool is used, which engages with the lug projecting from the inner circle; the seat is screwed out of the valve and a new one inserted.

Municipal Plant Lowers Rate—The City Council of Two Harbors, Minn., has ordered the rate charged by the municipal lighting plant reduced to 6c. per kw.-hr. for lighting instead of 8c., as heretofore, and a new rate of 3c. per kw.-hr. for power. Consumers who take the power rate will be obliged to install a separate meter. The municipal power plant is a paying proposition, and the city officials feel that they can afford to make the reduction in rates.

Editorials

Depreciation as a Practical Problem

To many engineers the word depreciation visualizes difficult and wearisome arguments upon the present and past values of power-plant equipment by theorists before commissions passing upon the right of corporations to issue more stock, maintain existing prices for service, or consolidate with others of their kind. To others depreciation means the underlying reason why the company had to buy a new condenser or feed pump last week, after getting a good many years of satisfactory service out of the equipment. To still others it means the cause of getting eight hundred dollars for a compound engine in perfectly workable condition, which cost originally six thousand dollars, but which has been obliged to make way for a turbo-unit that will generate more horsepower-hours per cubic foot of space in a day than the faithful old cross-compound could produce in a fortnight.

In technical literature there is hardly a subject on which more purely speculative matter has been written than on depreciation. Hundreds of pages in court and commission cases have been devoted to mere definitions of the word, and assumptions by the thousands have been made and will be made as to values and percentages to be allowed for depreciation in one form or another, in trying to prove some administrative policy just or some existing set of charges proper. Probably depreciation will never be reduced to a plain "two-and-two-make-four" basis while progress continues in equipment and plant design, but men closely associated with such plant and equipment can do much toward ridding the subject of some of its most glaring uncertainties if they attack the problem systematically and are accorded the coöperation of their employers.

Depreciation is, finally, a matter of plant life. How it shall be offset is a problem for the statisticians, but the basis upon which the men behind the gratings and wired-glass windows are to proceed has a direct and inescapable origin in the work of the engineer. How little we really know about this life question and how much we assume! Surely, it is time for the engineer to begin to contribute his observations and judgment in a broader way upon this important problem, which is always the unknown coefficient of the manager's equation of probable cost. Where can the engineer lay hold of the matter effectively enough to help his employer, to add some specific solvent to the mass of undigested and hypothetical data which is congesting the modern industrial library?

There is only one way to go about this task and that is by keeping a record of the installation, repairs, replacements, failures, and final disposition of every piece of apparatus affecting an estimate of the probable life of similar equipment at any future time; of studying the influence of performance and of idleness upon wear and tear and upon fitness for the service of today and of day after tomorrow; and by maintaining sufficiently complete records to enable the owner of the apparatus at practically any time to determine with least delay the total outlay of money upon it to date compared with the initial cost. It is not too late to begin to collect such material in many plants where the original equipment still handles the daily service. Every time a piece of machinery goes into commission fresh from the factory, the operating engineer should be permitted to acquaint himself, if he will, with its initial cost in as much detail as necessary; and the dates on which spare parts are substituted, with the cost of so doing, should be set down as part of a definite record which will enable the expert ultimately to judge the probable life of such equipment without guessing.

True, the mere cost of repairs and spare parts inserted may not throw light on the life of a machine as a whole, but here is exactly where definite data are useful in marking off life zones which will at least indicate where money must be spent to make good the aging of equipment and where enough durability can be anticipated to reduce the annual sinking-fund allowances for final replacement. There has been too much temptation in the past to assume all-around depreciation rates on aggregations of apparatus having enormous differences in life—a policy justified by the need of doing something constructive to establish a fund capable ultimately of putting in the equivalent in capacity of the depreciated equipment, but none the less a policy which must sooner or later give way to the more scientific plan of basing life and total cost estimates on data gathered in plant and field. There is room for real research in this department of engineering economy.

Placing the Blame

If there is complaint that water powers in the public domain in the West are being withheld from use, the blame must rest with the men and interests responsible for the legislative methods which made impossible the passage of the Adamson and the Ferris bills, urged by the Secretary of the Interior, approved by the President, and indorsed by the leading conservationists of the country. Under cover of specious arguments for states' rights, filibusters on buffer bills, and senatorial courtesy, the same senators and the same interests which defeated water-power legislation seven years ago have again made it impossible this year.

The remaining water-power sites in the public domain are of enormous value, controlling as they do the key to the development and use of the vast water powers in Western cañons and streams. Many other valuable power sites once owned by the nation have been acquired by speculative and monopolistic private interests in the past for little or no return to the Government, and have been capitalized at large values on which power users have been required to pay interest in the form of power rates. Other sites are being held unused by private owners who paid nothing, or next to nothing, for them, in anticipation of the needs of communities not yet developed, or for the purpose of maintaining rates for power supplied from plants already in operation. While independent interests concerned in hydro-electric development have generally expressed willingness to accept the terms of the bills before the late Congress, some of the larger and politically more influential interests refused even to consider the terms.

President Roosevelt withdrew the power sites which continue in the ownership of the people to prevent them from being gobbled up by the water-power trust. The "interests" at that time were powerful enough in Congress to prevent enactment of legislation that would allow use of these withdrawn sites under government control and with limited terms of occupancy and use. These same interests have so far blocked and defeated the efforts of the present Administration to secure legislation of the same nature. It is apparent that their purpose is to tire out the Government, in the hope that eventually these valuable sites may be given away, as have others in the past. It so happens, however, that the nation is fairly well informed nowadays of the value of these remaining national assets, and there is little probability of public opinion ever agreeing to turn them over as a free gift to any individuals. Fortunately for the country, delay in water-power legislation means nothing worse than delay in development. It is a big stake for which the trust is playing, but it has a forlorn hope of winning, and the longer obstructionists block legislation that would make regulated development possible, the stronger the growing sentiment for public development and operation is likely to become.

Efficiency Engineering

Many engineers are beginning to see a lucrative field in applying the principles of efficiency to engineering, particularly to factory power plants. Many have already gained considerable success, which has tempted others to follow their lead.

Efficiency applied to power plants means actually the elimination of wastes, these wastes being usually the result of faulty engineering when the plants were designed. The owner of an inefficient plant is often the victim of an inefficient or an unfit engineer. This is a reflection on both the owner and the profession.

No engineer worthy of the name is really anything else than an efficiency engineer; his whole course of study and practice is to adapt nature's law to practical needs economically. No standard textbook teaches us to design otherwise than economically. The laws relating to the transformation of heat energy have been known for years. The heating of feed water, economical sizes and covering of steam piping, the heating value of exhaust steam, etc., are not new. Certain refinements in the apparatus used in power work have been made, and special equipment has been devised, much of which enables improvements to be made, looking to the saving of both labor and coal. At the same time, many of the new appliances are got up to sell. The uninitiated owner frequently falls for the expert salesmanship employed to sell these devices. Some salesmen call themselves, and really believe they are, efficiency engineers, owing, no doubt, to the ease with which they are able to dispose of their goods. This practice has given the engineer considerable trouble in the work he is now undertaking, as owners and superintendents have become somewhat skeptical.

The engineer who often meets with scant tolerance at the hands of the owners also has himself to blame, outside of the bad effect caused by the exploiting of bad appliances. Looking at the matter a little deeper, we find that almost anybody can hang out his shingle and practice engineering. If plausible enough, he can and does secure work which afterward needs considerable attention and expense to make it perform economically. Then again, there is almost a department-store variety of competition among some engineers, in price cutting, resulting in the job being a repetition of this practice.

We are inclined to believe that these methods have called attention to the need for the efficiency engineer far more than the so called recent discovery of efficiency, or the availability of new apparatus to secure economy, the principles of which are old and well understood.

Other professions, such as the medical and legal, require their members to pass examinations and meet certain requirements before permission is given them to practice. The profession of engineering, although really the oldest of them all, puts no restrictions on its followers. Would it not be best for all concerned if consulting as well as operating engineers were prohibited from practicing without a license?

Skepticism as an Asset

Orthodoxy has little place in science. Skepticism—the insistent desire to be "shown," unwillingness to take things for granted—is a real asset to the engineer. It makes him uncomfortable enough, as everyone knows, but it helps him master his profession and makes him of increasing value to his employer.

It is unsafe to assume that a thing cannot be done merely because someone says so. Reports that a certain policy or practice is impossible must be checked before they are accepted. Suppose, in a large plant, a subordinate engineer investigates heat losses in certain piping and reports that nothing further can be done to remedy the situation. If the chief accepts such a report without checking its reasoning and conclusions, is he much better than a rubber stamp?

Coöperation and dependence upon the work of others are absolutely necessary today in engineering as well as in commercial activities, but a certain class of problems needs to be handled by direct methods, with routine thrown out of the window. All jobs which look impossible are of this class. Plenty of them *are* impossible, financially or physically, but the point is not to make any assumptions. If it is a report to the "boss," let it carry the convincing facts and arguments, so that it can be checked at the first reading. If it is a job handed down to the engineer from his superiors, let it be analyzed from every possible viewpoint before the answer is sent back that it is not feasible to carry out the plan.

These are more than generalities. They fit into daily experience. They teach that merely glancing over a report or a drawing and putting on the "O.K." with one's initials without a real check of the work, is largely wasted energy, economically unjustified. Question every proposition; make it prove its right to live; and by so doing cultivate the true scientific spirit which, combined with a sense of financial proportion, keeps the engineer high among the intellectual and constructive workers of the world.

Correspondence

Relative Water Required by Refrigerating Systems

Referring to G. B.'s question, page 311, Mar. 2 issue, I should judge that he wished to know the difference in quantity of water required for cooling, regardless of the kind of prime mover used. If both systems were motor-driven the absorption system would require three times the amount required for a compression system of equal capacity.

The quantity of water needed in the ammonia condenser would be the same in either system. To overcome the heat of absorption we need about twice the amount required in the condenser, making about three times the quantity for the absorption system that is needed when the compression system is used. When the strong-liquor pump to the absorption system is steam-driven its exhaust and other exhaust steam available can be used in the ammonia still, the condensate from the still can be returned to the boilers, and makeup water for the boilers can be taken from the water that has passed the condenser in either system.

In small absorption systems where closed ammonia condensers are used, it is usual to pipe the discharge from the condenser through the cooling coils in the absorber. When this is done there will be a slight rise in the temperature of the water after passing the condenser, but there will be a rise of about 30 deg. F. after leaving the absorption cooling coil. I have used this water to advantage in supplying a hot-water boiler when there was a demand for hot water about the place.

Boilers for Isolated Plants

The following criticism is directed at errors, as they appear to the writer, in C. L. Hubbard's article on "Boilers for Isolated Plants" in the Feb. 16 issue.

1. About the middle of the first column, page 233, we read: "The heat absorbed by the water in the boiler per pound of coal burned =

$$\frac{970.4 \times W \times q \times f}{w}$$

where

W = Apparent weight of water evaporated in pounds per hour.
q = Quality of the steam.
f = Factor of evaporation.
w = Weight of coal burned, in pounds per hour.

It is theoretically incorrect to introduce the quality of the steam into the computations at this point. It should have been taken into account in figuring the factor of evaporation.

The total heat of dry saturated steam is made up of two parts, the sensible heat of the liquid and the latent heat of vaporization. If we are dealing with wet steam of quality q, we have for its heat content all of the heat of the liquid plus q per cent. of the latent heat of vaporization. Obviously, it is incorrect to take q per cent. of the sum of both parts when we should have used one part in its entirety and q per cent. of the other part.

2. Near the bottom of the same page, is stated: "W.R. = Water rate of the engine under given conditions of *feed-water temperature and* steam pressure . . . ." The steam consumption of the engine is independent of the feed-water temperature and the words in italics should be omitted.

3. The last sentence of the article, near the top of page 234 reads: "All heating requirements are reduced to pounds of steam per hour and the result divided by 34.5 to find the boiler horsepower." This should read: "the result multiplied by the factor of evaporation and divided by 34.5 to obtain the boiler horsepower."

Calculating Pump Slippage

The letter on the subject of calculating pump slippage, by George L. Sullivan in the Dec. 29, 1914, issue, page 928, indicates a practical, though somewhat inaccurate way of determining pump slippage.

The slippage of a pump depends not only on the amount of the fluid slipping by the piston, but a great deal of it is due to the fluid running back before the valves close. Therefore, at medium speeds, the cylinder is not quite filled to its capacity at each stroke of the piston. Thus, it is evident that unless the slippage is determined by a calibrated flow meter, or by weighing the water, the result will be inaccurate.

For small and medium-sized pumps it is practical to connect a number of barrels or other receptacles in series, so that by connecting the discharge with one of the barrels, the water will run over and flow into the next barrel.

Knowing the capacity of the barrels, the slippage may be determined by subtracting the number of gallons of water in the barrels from the theoretical capacity of the pump, or,

$$S = \frac{aln}{231} - Q$$

where

S = Pump slippage;
Q = Quantity of water in the barrels in gallons;
a = Area of the cylinder in square inches;
l = Length of stroke in inches;
n = Number of discharge or working strokes required to fill the barrels.

The pump should be allowed to make a few strokes before discharging into the barrels. Care should be taken to get the pump up to the normal working speed and pressure as soon as possible.

For large pumps this method is not practical, as the barrels will be filled too quickly.

Providence, R. I. Samuel L. Robinson.

Auxiliary Exhaust Valves on Uniflow Engines

The writer, having read the article by Professor Stumpf in the Mar. 23 issue of POWER, entitled "Recent Development in the Construction of the Uniflow Engine," must take issue with the author on several points, especially the paragraph reading as follows:

> It is wrong in principle to build uniflow engines for condensing service with auxiliary exhaust valves. The short compression is wrong, and just as wrong is the increase of clearance space and surface connected with these valves. Even when used for noncondensing service with steam pressures as used in modern power plants, auxiliary exhaust valves show no gain

The reason for the adoption of the auxiliary exhaust valve, as applied to uniflow engines by the Skinner Engine Co., is to allow them to be operated noncondensing without the addition of wasteful clearance spaces which would otherwise be indispensable. It will be of interest to the reader to learn what these valves accomplish.

When the engine is running condensing, these valves are not in operation; but their function on a condensing engine is to relieve the cylinder of dangerous compression if the vacuum should suddenly break. In this event they operate automatically, and the engine continues to run noncondensing and with high economy.

The reader will understand that, with compression extending during 90 per cent. of the stroke and with atmospheric pressure in the cylinder at commencement, as would be the case in a uniflow engine without auxiliary exhaust valves, operating noncondensing, the compression would become so great as to endanger the cylinder. The greatest prejudice against the uniflow engine that European builders have had to overcome was the fact that so many cylinders had been cracked through the central exhaust ports, owing to this excessive compression when the vacuum broke

Two cylinders were thus wrecked at the plant of Vivian & Sons, Hafod Copper Works, Swansea. South Wales; and many other wrecks in Europe have been reported. The writer's understanding is that several cracked cylinders have occurred in this country on condensing uniflow engines not equipped with the auxiliary exhaust valves. Such accidents prove that cylinder relief valves cannot effectually relieve this compression; and in no case that has come under the writer's observation did the compression lift the steam valves a sufficient amount to relieve the cylinder of the excessive pressure.

The clearance volume required for these auxiliary exhaust valves is less than 1 per cent., even on small engines, and about ½ per cent. on large engines. Therefore, the uneconomical effect of these clearances is negligible.

The last statement in the paragraph quoted, "Even when used for noncondensing service with steam pressures as used in modern power plants, auxiliary exhaust valves show no gain," is incorrect.

The professor condemns the use of auxiliary exhaust valves, on account of an increase in the clearance of less than 1 per cent. which is made necessary by their employment, when, if they are eliminated on a noncondensing engine, it is necessary to employ a clearance space amounting to 14.2 per cent. for an engine operating under 120 lb. steam pressure at throttle, with atmospheric exhaust, and 17.3 per cent. if the back pressure at the cylinder is 3 lb. above atmosphere. Still greater clearance must be allowed if superheat is added or if the boiler pressure is lowered.

There are two methods of obtaining this clearance—one by employing separate clearance pockets arranged to be placed in communication with the cylinder when the engine is operating noncondensing, as shown in Fig. 1, and the other by concaving the ends of the trunk piston.

The former method is especially disadvantageous on account of the large additional surfaces introduced. In fact, published economy curves of noncondensing uniflow engines having these clearance pockets show that they are not as economical as many counterflow engines

By the second method, besides having the handicap of additional clearance, the engine cannot be operated condensing with even fair economy without substituting a flush piston and thereby reducing the clearance.

With either method the clearance volume is fixed for noncondensing operation and, in an existing engine, cannot be varied to suit the changes of steam pressures, steam temperatures or exhaust pressures.

Fig. 2 is a noncondensing indicator diagram from a cylinder of the construction shown in Fig. 1. The amount of clearance required for noncondensing operation with a predetermined steam pressure is shown at the left, in proportion to the stroke of the engine.

That Professor Stumpf realizes this point is proven by the following excerpts from his well known work "The Una-Flow Steam-Engine." Speaking of the uniflow cylinder as applied to locomotive practice, where his own curves show that for a boiler pressure of 242 lb. (which is, of course, much greater than is employed in stationary plants) a clearance of 8 per cent. must be employed for saturated steam and 10 per cent. for superheated steam, and where for 154 lb. pressure he admits that 13.2 per

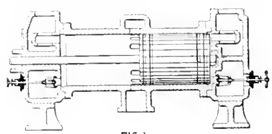

FIG 1

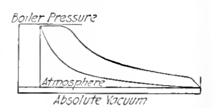

FIG.2

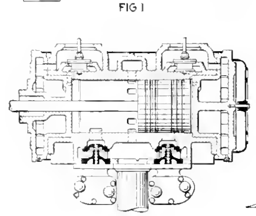

FIG 3

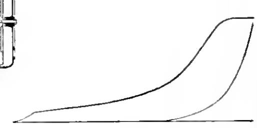

FIG.4

cent. clearance must be employed for saturated steam and 16.1 per cent. for superheated steam—all on the basis of atmospheric exhaust—he says:

> 1. The volume of clearance space should be kept as small as possible.
> 2. The amount of clearance losses depends upon the volume of the clearance.
> 3. The volume of clearance space is dependent upon the pressure and temperature of admission steam.
> 4. In all cases the pressure at the end of compression must not exceed the initial pressure.
> 5. Possible lines of development would be to employ saturated steam, introduced into the cylinder in as dry a state as possible, and superheated only a few degrees, and at a pressure that is at present usual in compound locomotives, so that the clearance space and the loss entailed thereby may be reduced.

In other words, he practically condemns superheat for noncondensing uniflow locomotives, because it makes necessary still greater clearance. The reader should bear in mind the fact that the pressures carried in modern locomotives are much higher than those employed in stationary plants, and that the clearance, therefore, may be less, but the professor wishes to reduce this clearance still further by employing saturated steam.

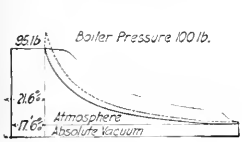

FIG 5

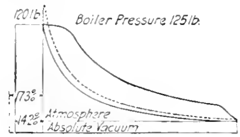

FIG. 6

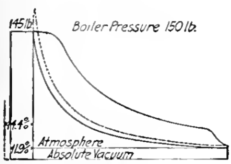

FIG 7

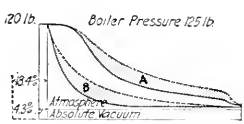

FIG 8

6. Other means for improving the action of the uniflow engine for locomotive work are to increase the boiler pressures and, consequently, the compression, so that the clearance volume may be reduced.

In other words, pressures from 235 to 260 lb. are not high enough for the economical operation of a large-clearance noncondensing uniflow engine.

7. Comparative tests with uniflow and counterflow engines, working with superheated steam of 11 atmospheres (161 lb. gage), have shown that the advantage rests with the uniflow engine for light and medium loads, but for heavy and overloads the advantage rests with the counterflow engine.

Here he admits that the large-clearance two-valve uniflow engine is not as economical on heavy loads as the counterflow type. Such is not the case with the small-clearance Universal Unaflow engine employing auxiliary exhaust valves which require the small clearance of less than 1 per cent. which Professor Stumpf objects to, as is proven by the reproduced performance curve of a Universal Unaflow engine operating noncondensing, with saturated steam at 136 lb. initial pressure.

Fig. 3 shows the Universal Unaflow construction, with auxiliary exhaust valves, which have the effect of delaying the compression to that point where it is usual to start the compression in a noncondensing counterflow engine. This construction allows the use of small clearances, even when operating noncondensing, which is not practical with the two-valve uniflow engine. Fig. 4 shows the diagram which it makes.

As a further proof that Professor Stumpf realizes the disadvantages of large clearances, it is only necessary to call attention to the fact that he sought to employ small clearance in a uniflow engine when operating noncondensing, by providing an auxiliary exhaust valve in the piston, which had the effect of delaying the compression beyond the point where the piston covered the central exhaust ports.

The European uniflow engine is, primarily, a condensing engine, for the reason that except in isolated cases all power plants in Europe operate with vacuum. In America, however, the great majority of plants operate noncondensing, and it is due to this fact that the necessity of adapting the uniflow engine to noncondensing work, which meant the employment of auxiliary exhaust valves to delay the compression, appealed to American engine builders before it was seriously considered abroad.

This principle, however, has now been adopted by a prominent German builder, and a description of this engine has been published in the European mechanical press.

One American builder, after having built and thoroughly tested a noncondensing uniflow engine having no auxiliary exhaust valves, now refuses to bid on the uniflow engine for noncondensing service.

The Skinner Engine Co., to determine the relative values of the two types under discussion, has made elaborate tests on both, having built a two-valve uniflow engine for this purpose. The results of these tests were greatly in favor of the engine with the auxiliary exhaust valves, especially when the steam pressure was changed from that for which the clearance in the two-valve uniflow engine was designed.

It was also demonstrated that the capacity of the cylinder was reduced owing to the long duration of compression, namely, 90 per cent. of the stroke; and this reduction of cylinder capacity compelled the employment of a larger cylinder. This in turn would impose greater stresses on the engine and decrease its mechanical efficiency.

The Universal Unaflow engine, which has auxiliary exhaust valves, has obtained mechanical efficiencies in excess of 97.5 per cent., proving the correctness of the principle from a mechanical standpoint.

Professor Stumpf has admitted that, with a noncondensing uniflow engine having no auxiliary exhaust valves, the volume of clearance is dependent upon the steam and exhaust pressures, and that it should be greater for superheated than for saturated steam.

Figs. 5, 6 and 7 show the different clearances required for two-valve large-clearance uniflow engines operating noncondensing, under different steam- and exhaust-pressure conditions. The full vertical line at the left of the diagram indicates the amount of clearance required in proportion to the stroke for different pressures of saturated steam. The dotted vertical line at the left shows the additional clearance required if the engine is to operate against 3 lb. back pressure above atmosphere.

In many plants the steam pressure fluctuates considerably and heating requirements render it advisable to employ a greater back pressure on a noncondensing engine during the cold months; and, inasmuch as it is impossible to vary the clearance in an existing two-valve noncondensing uniflow engine for the changes in steam and exhaust pressures, the engine is not as flexible or as efficient under these variable conditions as one employing auxiliary exhaust valves in connection with small cylinder clearances.

Fig. 8 is a double indicator diagram of a noncondensing Universal Unaflow engine (full line), superimposed on the diagram (dotted line) from a large-clearance uniflow engine having no auxiliary exhaust valves, both engines exhausting against a slight back pressure. The Universal Unaflow engine has 4.3 per cent. clearance, whereas the large-clearance uniflow engine must have 18.4 per cent. clearance for saturated steam.

With the large-clearance uniflow engine, the shaded section *A* must be added to the diagram to offset the loss in area *B* caused by early compression. This loss in area is compensated for only by the addition of more steam, a later cutoff, a higher release and less expansion.

The writer, however, readily agrees with Professor Stumpf on one point, namely, the necessity for the employment of steam-tight valves. Valve leakage in a noncondensing two-valve uniflow engine would be of more serious consequence than with a noncondensing uniflow engine having auxiliary exhaust ports located between the ends of the cylinder and the central exhaust ports, for the reason that the effect of this valve leakage would be in evidence during 90 per cent. of the compression stroke, and such effect would be to increase greatly the final compression pressure. With the same amount of valve leakage on a uniflow engine having auxiliary exhaust valves, the effect of leakage operates to increase compression during only 25 or 30 per cent. of the stroke.

Nevertheless, it is well to eliminate even this valve leakage, and this has been accomplished in the case of the Universal Unaflow engine by the adoption of a self-expanding poppet valve.

Convex and Concave Drum Heads

The discussions during the past year in Power, with regard to the allowable pressure on convex drum heads, were of a purely technical nature, in which the aim was to discover the proper factor of safety, having in view explosions due to failure of convex heads near the root of the flange, by the tearing out of a circular section. It was pointed out by one writer that the factor of safety, 5, assumed in all rules in this country was entirely too low and that a higher factor, at least 8.33, should be used. F. G. Gasche, in discussing the subject advocated a factor of safety of 15.2, based on a thorough analysis of the stresses set up on such heads. Since that time another disastrous failure has occurred, resulting in heavy property damages and personal injuries, that also adds to the proofs of the fallacy of the factor of safety of 5.

In this connection I would mention recent tests to destruction of two concave heads that failed under hydrostatic tests. The vessels were tanks or drums, having the following dimensions: Diameter, 114 in.; shell plate, 1 in.; long seams, butt, double-strapped, triple-riveted, with an efficiency of 80 per cent.; tensile strength of heads and shell, 55,000 lb.; thickness of heads, 1⅛ in.; heads bumped to 114-in. radius and single-riveted to the shell. The required pressure was 150 lb., which gave a factor of safety of 5 in the shell. The sketch shows how the heads were put in, one being concave and the other convex. The heads were from the same block, being duplicates in each case. Moreover, the drums were new and were tested where built.

The first drum failed at about 210 lb., the failure occurring in the B head near the flange and also by tearing the shell near the head seam. The second drum failed by two ruptures in the head, the shell developing no defects, but the failure took place at 150 lb.

Commenting on this, I am of the opinion that the head in the first tank was harder or stiffer than in the second, inasmuch as the shell was injured. In other words, in the second case the head sprung in the center enough to cause it to rupture at a point relatively near the flange, and in the first one the head was strong enough to force a rupture in the shell adjacent to the head.

It seems to the writer that tests to destruction must be accepted as conclusive practical results on which to base deductions to determine the safe working pressure. To this end let us compare the results with the present rule as follows:

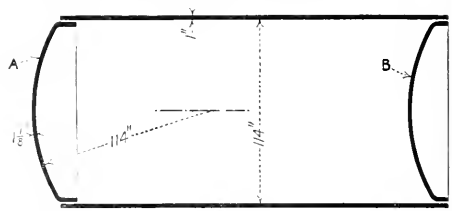
P = Working pressure allowed;
t = Thickness;
$T.S.$ = Tensile strength;
R = Radius, or ½ diameter of drum;
5 = Factor of safety.

Then

$$P = \frac{t \times T.S.}{R \times 5} = \frac{1\frac{1}{8} \times 55{,}000}{57 \times 5} = 217 \text{ lb.}$$

as respects the A head, and 0.6 of this, or 130 lb. on B. Using the factor 8.33, the pressure allowed on A would be 130 lb., and on B, 79.8 lb. This gives a real factor of about 2, based on the 150 lb. at which failure occurred.

By Mr. Gasche's factor, A would be allowed 71.4 lb. and B 42.8 lb., making the real factor about 3 on the concave head. In all the above calculations the tensile strength is taken at 55,000 lb. per sq.in.



Section through Drum That Was Tested to Failure

Granted a test to destruction is accepted as a practical method in determining the safe allowable pressure, and assuming that there should be a factor of 5 to safeguard against accident during the presumed life of a vessel, then the pressure allowed would be one-fifth the bursting pressure, or 30 lb.; as regards the weakest part, namely, the concave head.

In discussing these failures of concave heads we have the empirical rule of allowing six-tenths the pressure allowed on convex heads, but one can readily see that the stresses set up are vastly different from those on convex heads, especially when it is considered that a vessel subjected to internal pressure tends to assume a spherical shape, and an inquiry as to the foundation of this rule is in order.

Along this line it seems to the writer that our technical colleges might well take up the matter of convex and concave heads and make a thorough inquiry and give the results to the public. They have facilities for doing research work of this sort that are beyond the practical man in the field. Surely the situation warrants investigation, where the factors of safety vary from 5 to 15, and only in the latter is the efficiency of the (usually) single-riveted joint taken care of, and such joints are only about 50 per cent. as strong as the plate.

New York City.

Practical Pump Slippage Test

In a large pumping station the amount of slippage was based upon the difference between the calculated displacement and the meter reading. At one time the station slippage recorded was abnormally high. As the combined output of all the pumps entered the same main, some test was necessary to locate the responsible pump.

To do this the station was operated for a specified time with each pump shut down in turn. The pump that was out of service when the best slippage record was made, was identified for special test. The suction side manhole plates were removed, and water was then bypassed to the discharge chamber and allowed to accumulate a pressure there. Large quantities of water rushed from the suction manholes. This indicated that no mistake had been made and resulted in a decision to revalve the pump.

EDWARD T. BINNS.

Philadelphia, Penn.

Explosion of Hot-Water Tank

Power plants are not the only scenes of disastrous explosions. On Oct. 20, 1914, at about 10:30 p.m. on the premises at 18 McCann St., Ilion, N. Y. a hot-water tank exploded, with the results shown in the reproduction of photograph taken the morning after (Fig. 1).

An investigation showed that a system of installing a pressure-reducing valve between the street main and the dwelling is in vogue in the village, as shown in the sketch,

FIG. 1. CONDITION OF PREMISES AFTER EXPLOSION

Fig. 2. The reason for this is that the pressure in the mains is upward of 150 lb. per square inch at many points. Houses on the slopes or tops of hills do not have extraordinary pressure, but the majority of dwellings and business places have this system with a reducing valve, as shown in Fig. 3.

As such valves are absolutely nonreturn, when one is placed in a dwelling without a safety valve of some kind on the house side, there is no automatic means of relieving the pressure if it goes beyond that for which the reducing valve is adjusted. The only means of release is opening some of the various taps by hand.

The family in this case left home to spend the evening with friends, leaving the gas jet burning under the heating coil attached to the hot-water storage tank. This allowed the pressure at the weakest spot to reach the bursting point. Without the reducing valve in the system the pressure would have relieved itself into the city main. That the stop-cock next to the street was open was proved by the fact that the first man to arrive on the scene after the explosion closed it to prevent further flooding of the premises.

In this case the weakest point was the lapwelded type hot-water tank in common use, which let go along the longtitudinal seam from end to end. The force was great enough to tear the seam apart, turn the sheet out flat and double it over from end to end as usually happens in such cases.

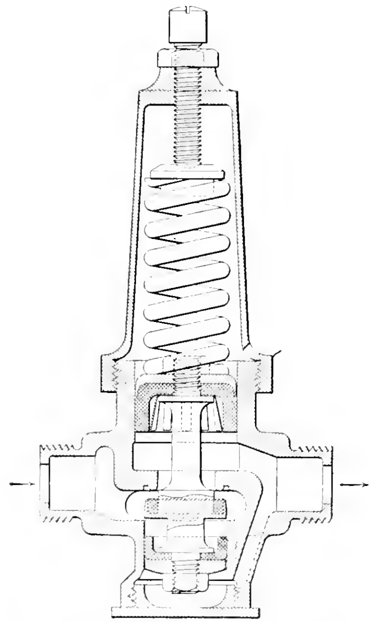

FIG. 3. TYPE OF REDUCING VALVE USED

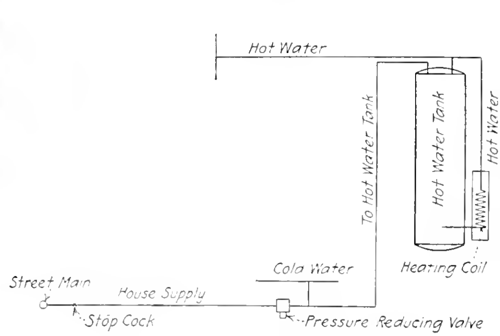

FIG. 2. DIAGRAM OF PIPING SYSTEM

This accident shows that the authorities should insist on the use of safety valves where reducing valves are installed or should not allow the use of the latter at all.

The wrecked dwelling has been rebuilt and the water system installed in this same place without the reducing valve. There are many other places where the old system is in use, and no attempt has been made to correct the fault in such installations. Other municipalities have the same conditions, and other explosions have occurred from the same cause. All should take warning, for the continuation of this system will mean more loss of property and possibly loss of life, which will amount to criminal negligence on the part of those who have the power to correct this condition and fail to do so.

Testing for Open Circuit

In the Feb. 9 issue, page 195, there was described a practical method of testing for an open circuit in a starting resistance. This is to close the line switch, throw the starting-box arm on the first contact, and then bridge between the contact buttons with a piece of metal, such as a screwdriver. Of course, the motor will start if the metal bridges across the open-circuited part of the resistance.

The scheme is possible and no doubt has been used safely by the writer of the article. Nevertheless, it seems dangerous. An open circuit means full line voltage at the break, under the conditions specified. Would one use a screwdriver to close a 550-volt circuit? When the test is made, practically the resistance is in circuit, but should the screwdriver slip and bridge across the contacts at opposite ends of the box, injury to the operator's eyes might result.

Oil Separator Failed to Work

An article in the Nov. 3, 1914, issue of POWER, page 650, by T. W. Reynolds, under the above heading, is faulty in the application of the figures arrived at as a solution for the failure of the separator drain to work.

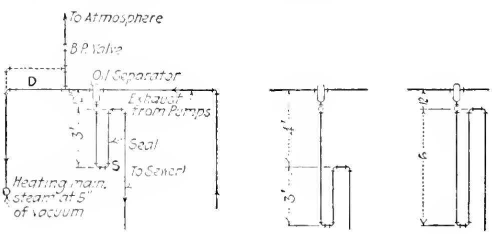

FIG 1 FIG 2 FIG 3

SEAL FOR OIL SEPARATOR

Mr. Reynolds has treated his problem as though the vertical drain pipe from the bottom of the separator dipped directly under the surface of water and oil in a cistern open to the atmosphere. His solutions are correct for this condition, and the dimensions given will work out in practice.

For the arrangement shown in the diagrams, however, the dimensions given are incorrect, for the following reason: With the siphon type of seal (this is the type shown in the sketches) the liquid discharged from the separator must all pass over the crest of the siphon, and the limiting height for proper discharge will be the distance between the crest of the siphon and the allowed height of the liquid in the separator, not, as Mr. Reynolds has erroneously assumed, the sum of the distances from the crest of the siphon to the level of the liquid in the separator and the length of the riser leg of the siphon. This being the case, it is evident that the arrangement shown in Fig. 3 is no better than that shown in Fig. 1 for removing drips from the separator under a vacuum of 5 in.

To fulfill the conditions given in Mr. Reynolds' article the distance between the crest of the siphon and the bottom of the separator would need to be about six feet instead of four feet as shown in Fig. 2. This gives a column of liquid above the crest of the siphon equal to 6 times 0.434 lb. per sq.in., or 2.604 lb. per sq.in., which is slightly in excess of 5 in. of vacuum, which equals 2.46 lb. per sq.in.

With the six-foot dimension instead of the four-foot dimension shown in Fig. 2 of Mr. Reynolds' article, the siphon seal will properly remove all the condensation and drips collected by the separator, and if the riser leg of the siphon were made six feet also (keeping the crest of the siphon six feet from the bottom of the separator, as before outlined) the seal would properly take care of the drips collected by the separator under all conditions of pressure in the heating system from 5 in. vacuum to about $2\frac{1}{2}$ lb. back pressure, that is, pressure above the atmosphere.

E. N. ROBERTSON.

Denver, Colo.

The only thing that is wrong with Mr. Reynolds' proposed remedies is that they are no better than the original, and besides, the figures he uses are for water at 39 deg. F., and not for cylinder oil, although water of condensation will be caught by the separator also.

The original layout has two faults. One is that the top of the seal is too near the same level as the bottom of the separator. Another is that the seal is not deep enough. As the pressure in the main will sometimes be atmospheric, the depth of the seal should be such as to make it safe at atmospheric pressure.

Cylinder oil weighs about 0.39 lb. per square inch per foot of column. I would make the height of the seal rather more than

$$\frac{2.46}{0.39} \times \frac{1}{2} = 3.15\ ft.$$

After being in operation for a few minutes the discharge side of the seal will be full of water and this column of water 3.15 ft. in height will counterbalance about 3.5 ft. of oil. I would therefore place the top of the seal

$$\frac{2.46}{0.39} + (3.5 - 3.15) = 6.65\ ft.$$

below the bottom of the separator.

His sketch No. 3 would not do for any degree of vacuum.

R. MCLAREN.

Will Quizz, Jr.

SYNOPSIS—Will Quizz, Jr., has a lot of questions to ask Chief Teller about the hydrometer and the various graduations on it.

"Have you tested the brine in the cooling tank lately, Will?"

"Yes, Chief, the specific-gravity age shows 1.206. I took along the other gage, the Baumé, and that showed 26. What do these figures mean?"

"To begin with, get the object of the test clearly in mind. What do you test the brine for, anyway?"

"To find out whether it has enough salt or calcium chloride in it or not."

"Yes, but couldn't you tell that in some other way? Tell me how."

"I could take a graduated flask and draw off a certain amount of the liquid, evaporate the water out of it and weigh the salt it contained, but that would be a lot of bother."

"Suppose, then, you put the same amount of salt into the same quantity of water and weigh the mixture carefully, you would find that for a certain degree of saltness the weight would be the same every time and for a greater or less degree the weight would vary accordingly. This method would not be convenient, either, because care must be taken to get just the correct quantity each time and weigh it carefully. By the way, did you ever think of why they always use those peculiar-shaped bottles or flasks, with long slender necks on which there are graduations, in the laboratories? The idea is to fill to a certain mark in a slender part for accuracy, because a few drops more or less will change the level in a slender tube a lot, while if the mark were on the large body of the flask a difference of considerable magnitude would hardly be noticeable. This same feature applies to the hydrometer, which will be referred to later.

"Now, suppose you used the same flask, but instead of putting the fluid into it, you put certain weights inside of it and put the flask into the brine. It would sink to a certain depth, displacing an amount (measure) of liquid exactly equal to the volume or measure of that part of the flask which was submerged and in weight equal to the total weight of the flask and contents. The level to which it settled could then be marked on its neck so that it might be used again as a test gage for other brine of the same density into which it would settle to the same mark. (This is where the long slender neck of the hydrometer enters in, as referred to before. As the part is slender, it would have to be submerged to a greater extent to displace a small amount of liquid, and the graduations would be farther apart and more easily read.) This method would be more convenient than measuring out a given quantity and weighing it, or evaporating it in the way you just spoke of. Then by a series of tests you might construct a scale on the neck of the flask, so that you would know the density or saltness of the fluid by the depth to which the flask settled and would know by that scale how much salt there was to a cubic foot just as well as if you had gone to the trouble of evaporating the water out. If, after getting your flask nicely graduated for brine, you should put it into pure distilled water it would be likely to sink 'head over heels' unless the neck was very long. This is because the fresh water is less dense and the same vessel would sink deeper or entirely."

"Yes, Chief, I have always understood that objects which will sink in fresh-water streams or lakes will sometimes float in the ocean. So this is the same thing, is it?"

"That's the idea, Will. Then if you were making a hydrometer you would want a fresh-water mark on it as a means of comparison. That's just what Baumé, Twaddell, Beck and others did in constructing an arbitrary scale. The way Baumé first arrived at his scale was, the instrument was submerged in water, by means of the mercury placed in the bottom of the glass, to a certain point which was marked zero. If the instrument was to be used to determine the density or specific gravity of fluids heavier than water, it would be loaded so that it would sink in distilled water almost to the top of the tube, because with the same amount of weight it would not sink so far into the heavier fluid, therefore the graduation was downward from the zero mark made at the surface of the water. The instrument was then put into a solution of 15 parts of salt and 85 parts of water. The point to which it would sink in this solution was marked 15, the distance between these two points was then divided into 15 equal parts, and the graduation was continued beyond 15 in equal divisions. This constitutes the Baumé scale for liquids of greater specific gravity than water. On the other hand, if the instrument was to be used for fluids lighter than water a different scale was used. Baumé used for the zero point the position of the instrument in a solution of 10 parts of salt and 90 parts of water, and for 10 its position in distilled water, and divided this distance into 10 deg., and continued the graduation to the top of the scale.

"There is a tendency now to discard all arbitrary scales in favor of those which read in terms of specific gravity without the necessity of interpolation. The Baumé scale in its time was a very important development, but since the specific gravity of the common fluids has now been established so that the instruments marked with a scale showing the specific gravity by direct reading are preferable. It will be interesting for you to look up a table showing by comparison the Baumé scale and the specific-gravity scale."

"Yes, Chief, such a scale does not mean much, to me at least."

"The specific-gravity scale shows by direct reading the weight of the fluid as compared with the same volume of pure distilled water at 65 deg. That is, the brine in this case is 1.206 times as heavy as water (62.35 per cubic foot), the brine would be $62.35 \times 1.206 = 75.194$ lb. per cubic foot. Any reading of specific gravity multiplied by the weight of water per cubic foot will give the weight per cubic foot of the fluid in question. The reading on the Baumé scale in so called degrees must be transposed by reference to a table to become intelligible."

"The term specific gravity gets me twisted somehow, Chief. See if I have it right. Gravity, or weight, refers to the action of the law of gravitation acting on a given substance. Then the word specific added makes the weight refer to and compare specifically with some other recognized substance, so that the specific gravity of a substance is its weight compared with distilled water, bulk for bulk. Is that right, Chief?"

"Yes. The weight of an object as shown by the scales is independent of its bulk or volume. Its density is its weight per unit of volume (1 cu.ft. for example). Its relative density, or specific gravity, is its weight per unit of volume (as before) specifically compared to the weight of the same volume of a predetermined standard (pure distilled water at maximum density for heavy things is generally used and hydrogen for gases)."

"Another thing puzzles me, Chief. If a body which sinks is put into water it will displace a certain amount of the water which, if allowed to overflow and is measured, will occupy the same space as the body which has been put into the water, but they do not weigh the same. In the other case if the body placed in the water floats, the water which is displaced by it will be of the same weight, while the volume of water displaced will be equal to only that part of the body which was immersed, yet the specific gravity of each is given in the table. How is that determined?"

"The specific gravity of the body heavier or more dense than water is obtained by sustaining some of its weight, or that part of its weight greater than the weight of the water displaced by it, by means of scales with the proper weights on the opposite side; then in every case the weights so required plus the weight of the water displaced will equal the weight of the body being tested, while the ratio of the weight of the body in air and in the water is its specific gravity.

"Density is defined as 'the ratio of mass to volume.' It was considered worth while by the International Congress of Physicists at Paris in 1900 to pass a resolution defining this quality as stated above, because the term is so frequently misused by writers on scientific subjects. Density and specific gravity are by no means the same, although one is proportional to the other. The specific gravity of any substance is defined as the ratio of its density to the density of water.

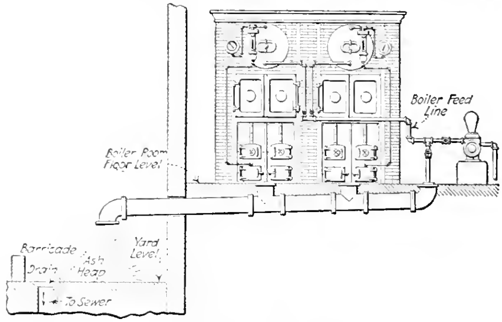
"This old problem may interest you, as it is along the same lines: A canal aqueduct is capable of sustaining ten tons per running foot, the structure filled with water weighs seven tons per foot, and a boat weighing four tons per foot is to pass through the canal. The question is, will the structure sustain the weight when the boat is in the canal?"

Ash Handling by Flushing

An interesting way of handling ashes was observed during a visit among some small plants where the number of boilers did not warrant the use of conveying machinery.

In one plant, a part of which is shown in the sketch, the yard level was below the boiler-room floor. To convey the ashes to this level 6-in. terra cotta soil pipe was laid as shown. The elbow at the extreme right was blanked off and a 2-in. pipe inserted. Water for flushing the ashes out of the pipe is admitted through this line. In this plant water from the feed-pump discharge was used.

The large pipe should be inclined considerably and large clinkers should be broken before entering the tees.



How the Ashes Are Flushed to the Yard

Centrifugal Crude-Oil Pump

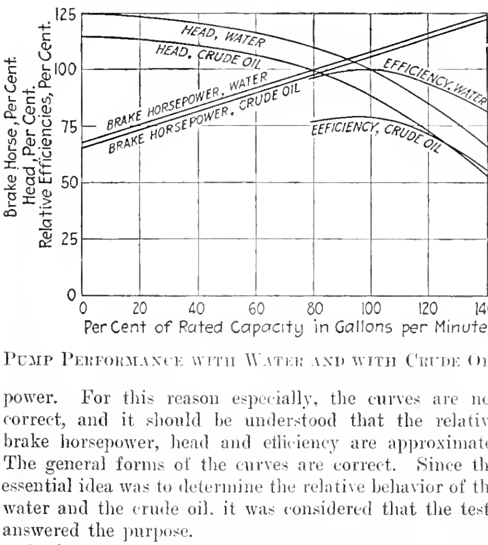
By A. B. Morrison, Jr.

In handling liquids other than water with a centrifugal pump it is necessary to study closely the characteristics of the liquid to be pumped and its behavior under similar operating conditions in order to estimate even approximately what can be expected in the way of power and speeds to produce certain results. A centrifugal pump was used for handling crude oil, replacing a direct-acting steam pump which had been used for the same service. The results obtained were so much at variance with what had been expected that some further tests were made to ascertain wherein the difference lay, and as a result some interesting data were obtained.

The centrifugal pump was designed to deliver 1600 gal. per min. against a head of approximately 60 lb., the head being due almost entirely to the friction in a long line of pipe, the static elevation being slight. The pump was of the single-stage, horizontal split-casing type, direct connected to a steam turbine running at approximately 2000 r.p.m. The guarantees as to head, capacity and steam consumption were made on the basis of pumping clear water. On the basis of such data as were available to the customer, it was assumed that the friction of the crude oil through the discharge pipe would be approximately the same as that of an equal amount of water. It was, therefore, considered that the pump should show the same efficiency, approximately, pumping oil as water. The crude oil had a specific gravity compared to water of 0.865 to 1.

A test was run on the outfit as installed, by measuring the steam to the turbine with a steam-flow meter, the oil by measuring the total amount taken from the tank and dividing by the total minutes run to get the average quantity pumped per minute, and the pressure by means of gages on the suction and discharge, correcting for the difference in level between these gages and the center line of the pump. The speed was recorded at frequent intervals, so that a good record of the pump performance was obtained. Allowing for possible errors in the readings and giving the outfit the benefit of every doubt, the steam consumption, as shown by two different tests, was so much greater than that guaranteed that it was evident something was wrong. A test of the turbine and pump separately, the latter pumping water, showed that both met their respective guarantees as to capacity and efficiency, so there was no apparent reason why the combined outfit should not give the results anticipated if the assumption as to the power required for handling crude oil were correct.

To determine how much difference existed between pumping crude oil and water a series of tests was run on a smaller motor-driven pump, as it was not possible to run the turbine outfit on anything but oil. The pump available for the tests was a small single-stage side-suction one direct-connected to a three-phase motor. It was old and not in good condition. The suction was under a slight pressure and the discharge was into a tank, the pressure on the discharge being varied by manipulating a valve. By means of a float on the tank the average quantity pumped in gallons per minute was determined for five-minute intervals. Gages on the suction and discharge gave the pressures. The gages on the suction were, apparently, not accurate, so that the readings were not wholly reliable. At the time the test was made no wattmeter was available, so it was necessary to read the current and voltage in one phase only and assume an arbitrary constant for efficiency and power factor in calculating the horsepower.



PUMP PERFORMANCE WITH WATER AND WITH CRUDE OIL

For this reason especially, the curves are not correct, and it should be understood that the relative brake horsepower, head and efficiency are approximate. The general forms of the curves are correct. Since the essential idea was to determine the relative behavior of the water and the crude oil, it was considered that the tests answered the purpose.

An inspection of the curves shows the marked increase in the efficiency of the pump when handling water. The brake horsepower was approximately the same in both cases, though the weight of the oil pumped was considerably less and the head generated by the pump less. Through the pump the velocity was very high as compared with that in an ordinary line of pipe, and this high velocity of the oil caused, on account of the viscosity of the latter, the loss in efficiency. This is shown by the head curve. Theoretically, the head in feet should be the same regardless of the liquid pumped, but part of the head generated is lost in the pump because of the greater work required to get the oil through the impeller and casing.

One fact not shown in the curves, but brought out in the operation of the large pump, is that the assumption that the pipe friction is about the same for crude oil and water at the usual pipe velocities is quite correct. The crude oil was pumped through the pipe line in the calculated and desired quantity, and while the required pressure, measured in feet, was slightly greater than that for water, it did not differ from that estimated enough to occasion any trouble. When the velocity is as high, however, as is necessary to get the liquid through a centrifugal pump, the greater viscosity of the oil causes the very marked increase in the friction and power required.

In view of the results obtained with the outfit described, it is a question whether it would not have been better to install a compound direct-acting steam pump. The conditions were not favorable for a steam turbine, as the steam pressure was only 70 lb. gage and the exhaust was to the atmosphere. The pump also ran somewhat slower than the most economical point of the turbine. There is, of course, the argument for greater simplicity in the turbine-driven outfit, both in prime mover and pump, but the ordinary direct-acting steam pump is not likely to give trouble and in the present case the steam consumption would have been no greater and the first cost probably less.

Steam-Turbine Drive for Steel Mills*

The Carpenter Steel Co., of Reading, Penn., furnishes an interesting example of how increased power can be obtained, while reducing the fuel bill and the number of boilers in service. This plant is, moreover, notable as being the first in America, and the second in the world, to apply the steam turbine to the driving of rolling mills through the medium of mechanical speed-reducing gears.

The company does a general merchant trade, consisting of high-grade tool steels, projectiles and special steels for such uses as safety-razor blades, springs, and the like. The two-stand, 18-in., three-high roughing mill now driven by turbine was formerly driven by a 36x36-in. simple slide-valve engine, operated condensing, while the 10-in. and 8-in. finishing mills were driven by belt from a cross-compound, 22&40x48-in. engine, exhausting into a jet condenser, which gave a vacuum varying from 18 to 24 in.

Besides the main power units for the mill, there were in the immediate vicinity several service and boiler-feed pumps and air compressors, the exhaust of which was partially utilized in an open feed-water heater, the surplus escaping to the atmosphere. While no data were obtained regarding the steam consumption when using this equipment, it was necessary that five boilers of a nominal total rating of 1000 hp. be operated continuously.

With a view to reducing power costs, several alternatives were considered. The simple engine driving the roughing mill could have been replaced by a modern compound engine and a modern high-vacuum central condensing plant for the two engines put in. But because of the fluctuations of load on the engines and the small average horsepower required, also because of the first cost of the equipment and the moderate economy, this scheme was not adopted.

The second alternative was the installation of a low-pressure turbo-generator operating on the exhaust of the compound engine to supply current to a motor driving the roughing mill. This did not appear attractive, as it involved a large investment in turbine, generator, switchboard, transmission lines, motor, starters etc., and nearly all the current produced would have been consumed by the roughing mill.

The third plan considered, and the one ultimately adopted, was the installation of a low-pressure turbine to drive the roughing mill. This proposal involved the use of speed-reducing gears, a new expedient for this work, but one which had already been satisfactorily used by James Dunlap & Co., Calderbank Steel Works, near Glasgow, Scotland, where a mixed-pressure turbine, developing 750 hp., drives a three-high, 28-in. plate mill. The speed reduction of the Calderbank mill is made in two steps—first from 2000 to 375 r.p.m. and then to 70, by means of double-helical gears of the rigid-frame type.

As compared to the 15 to 20 per cent. loss of energy in

*From a booklet issued by the De Laval Steam Turbine Co.

the electrical method of driving, the gear loss is not more than 1½ to 2 per cent., besides which it costs less, occupies much less space, is simpler and requires less attention.

For the operation of the roughing rolls at the Carpenter steel plant, an average of about 350 hp. was required, at a speed varying from 60 to 100 r.p.m., while for the greatest efficiency and simplicity of construction a turbine of this capacity should run at about 5000 r.p.m. To secure the reduction of 50 to 1, a two-step reduction gear was adopted, the gear and turbine being mounted on one base plate and the complete unit so located that the shaft of the slow-speed gear is in line with the shaft of the engine which the turbine replaces. The 26-ft. engine flywheel, weighing 47,600 lb. and the engine shaft and bearings were left in place. In order to avoid interruption of work while making the change and also to provide against any possible interruption of service thereafter, the engine was left intact and only the connecting-rod removed, a distance piece, which serves also as one of the flanges of the flexible coupling on the low-speed gear shaft, being bolted onto the crank disk. After the turbine was installed it was thus possible to operate it without load in order to try out the installation, during which period the engine continued to drive the mill and practically no time was lost in changing from engine to turbine drive.

The turbine, which is of the mixed-flow type, was built by the De Laval Steam Turbine Co., and contains eight pressure stages, the first pressure stage consisting of two velocity stages. The low-pressure steam, that is, the exhaust steam from the engine, is admitted at the third pressure stage and expands through the remaining stages to exhaust pressure.

The turbine is designed to operate under four different steam conditions: When receiving engine exhaust at a pressure of 3-lb. gage, and when exhausting into a vacuum of 27 in., it is to develop 350 hp. at speeds corresponding to 70 to 100 r.p.m. of the mill shaft, under which condition it is guaranteed to take not more than 26 lb. of steam per brake horsepower per hour, as measured at the end of the second gear reduction. It is also to be able to carry the normal load of 350 hp. when using steam at 120 lb. pressure gage and exhausting to a 27-in. vacuum, under which conditions it is guaranteed to take not more than 17½ lb. of steam per brake horsepower per hour. When receiving both high- and low-pressure steam and exhausting to vacuum, the turbine is to be able to carry 600 b.hp. continuously. It is also to be able to carry a load of 600 hp. on high-pressure steam only, as when the compound engine is not running. Under these conditions it is guaranteed to take not more than 15.7 lb. of steam per brake horsepower per hour.

The turbine is also to be able to carry normal load noncondensing when receiving steam at 120 lb. and exhausting to atmosphere, making it possible to inspect or repair the condenser or circulating pump without interfering with the operation of the mill.

The roughing mill is three-high and consists of two stands of 18-in. rolls. It is manually operated, two men being employed on each stand. The reduction of a 4x4-in. billet, 17.6 in. long, weighing 80 lb., to an oval 1¾ in. wide is performed in thirteen passes, occupying 41⅗ seconds.

Owing to the fact that the finishing mill cannot take high-carbon steel as fast as the roughing mill can supply it, only one billet is usually in the latter at one time, but when rolling low-carbon steel, two billets are in at once. When handling one billet no speed variation is perceptible on the tachometer, which is permanently attached to the 600-r.p.m. shaft, while when handling two billets the speed drops about 2 per cent. The fact that there is no drop of speed with one billet in the mill shows that the heavy flywheel is not required for power storage under such conditions. By setting the governor for a greater drop in speed before the high-pressure valve opens, the power-storage capacity of the flywheel can be utilized and unnecessary use of high-pressure steam avoided.

The compound engine, operating noncondensing, ordinarily supplies steam to the turbine under 3 to 3½ lb. back pressure, the pressure being regulated by a multiport safety exhaust outlet valve. The roughing mill, however, is not required at certain times, the steel being taken directly to the finishing mill, at which times the valves between the engine exhaust and the turbine, and between the turbine exhaust and the condenser can be closed and the valve between the engine exhaust and the condenser opened, permitting the engine to operate condensing.

In the low-pressure supply line to the turbine is placed a receiver steam separator. To insure dry steam, a coil of 1-in. copper pipe, inserted in the 12 ft. of 10-in. pipe between the separator and the turbine, is kept filled with live steam and drained by a steam trap. Adjacent to the low-pressure throttle valve of the turbine is a multiport flow valve, designed to prevent the vacuum from backing up from the condenser through the turbine into the engine exhaust line. Without this valve there is always a possibility of air being drawn in through leaks in the exhaust line and through piston-rod and valve-stem packings of the engine at times when there is little or no exhaust steam available. Such air would interfere with the operation of the condenser.

The condenser, which is of the multijet type, is located just outside of the engine room and is protected by a 10-in. multiport atmospheric relief valve. With a water temperature of 72 deg. F., the condenser maintains a vacuum of 28.2 in. with the barometer at 29.78 in. As there was a surplus of exhaust steam for operating the circulating pumps, and also because of the desirability of a simple, reliable condenser, this type was considered best.

The circulating water for the condenser is supplied by a centrifugal pump driven by a mixed-flow geared turbine of the velocity-stage type with two sets of nozzles and designed to operate either with steam at 120-lb. gage or with steam at 3-lb. gage, exhausting to a 27-in. vacuum. It exhausts through a 10-in. pipe to the same condenser that serves the main unit. The speed-reducing gears permit both turbine and pump to run at the best speeds for economy, viz., 5000 r.p.m. for the former and 1500 r.p.m. for the latter. The turbine can be started noncondensing and will carry full load with high-pressure steam alone, thus providing both for starting the pump before the condenser is in operation and for carrying its full load without taking low-pressure steam. Surplus exhaust steam not used by either turbine passes to the open-feed water heater, which also receive the exhaust from pumps, air compressors, etc.

The cost of the installation, consisting of the turbine, reduction gear, condenser, piping, circulating pump, valves, etc., erected complete, was not far from $25,000, and owing to the better economy secured through its use, it has been possible to reduce the boilers in operation from 1000 hp. to about 600 hp. This indicates a saving approaching $15,000 per year.

Cause of the "San Diego" Explosion

The cause of the low water which allowed the boiler aboard the U. S. armored cruiser "San Diego" to become overheated and explode on Jan. 21, it is learned, was the top of a bucket strainer in the feed tank came off, dropping to the bottom of the strainer, partly closing the opening of the suction pipe to the feed pumps. One-half of the supply of feed water was thus shut off and as water was being carried rather low and the engines running at full power, it was impossible to get sufficient water to all the boilers, with the result that five boilers were badly overheated, when the explosion occurred.

The "San Diego" (originally the "California," built in 1907) is the flagship of the Pacific fleet that had just completed a four-hour speed trial. Her triple-expansion engines indicate 30,000 hp., and are capable of developing a speed of 22.5 knots. The boilers are of the B. & W. marine type (forced draft), with 1592 sq.ft. of grate surface, and 70,000 sq.ft. of heating surface. She carried a crew of 822 men, nine of whom were killed as a result of the explosion.—A. P. Connor, Washington, D. C.

Recent Court Decisions

Digested by A. L. H. STREET

Fires Set By Traction Engines—One operating a steam roller or traction engine along a street or highway must use that degree of care to avoid setting fire to adjoining property which an ordinarily careful person would use under the same circumstances. And if a law or ordinance requires such engines to be equipped with spark arresters, the owner is liable for loss directly attributable to failure to comply with the requirement. These rules were lately announced by the Delaware Superior Court in the case of Cecil vs. Mundy, 92 "Atlantic Reporter" 850.

Classification of Fuel-Gas Rates—A public-service corporation engaged in furnishing gas for heating, lighting and power purposes may lawfully classify its rates according to the nature of the service afforded, as well as the quantity of gas furnished, if the classification is not unfair or discriminatory against other classes of consumers. The West Virginia Supreme Court of Appeals has just handed down this decision in the case of Elk Hotel Co. vs. United Fuel Gas Co., 80 "Southeastern Reporter," 922. But the court holds that the same rate and service must be offered alike to all consumers similarly situated and provided with the same character of equipment.

Impairment of Franchise Rights—After a power company has acquired a right to use streets and highways for the maintenance of transmission lines under existing constitutional and statutory provisions, the right cannot be impaired by a subsequent constitutional amendment. Hence, the provision incorporated into the Michigan constitution in 1909, to the effect that public-service corporations shall not be permitted to use the streets of a city without obtaining a franchise from the city, cannot be deemed to impair a previously acquired right to maintain a line along certain streets. (Michigan Supreme Court, City of Lansing vs. Michigan Power Co., 150 "Northwestern Reporter," 250).

Washroom Law Sustained—In 1913 the Illinois Legislature enacted a law which, in effect, requires that owners and operators of coal mines, steel mills, foundries, machine shops, etc., provide adequate washroom facilities to enable employees whose work in such employments causes their persons or clothing to be covered with grime, dirt or perspiration to such an extent as to render their remaining in that condition unhealthful or offensive to persons with whom they come in contact in leaving their work, to change their clothing and wash before leaving. In the case of People vs. Solomon, which was recently before the Illinois Supreme Court, the validity of this regulation is upheld. (106 "Northeastern Reporter," 458.) Doubtless it will be construed as extending to the employment of stationary engineers and firemen in the employments covered by the law. In fact, the decision seems to hold that it covers all employments where "employees become covered with grease, smoke, dust, grime and perspiration" to the extent that their remaining in that condition would be unhealthful or offensive to the public.

The Engineer as an Expert Witness—The qualifications of an engineer to testify as to the availability of means to prevent injury to adjoining property in the cleaning of locomotive boilers were under consideration recently before the Pennsylvania Supreme Court in the case of Vile vs. Pennsylvania R.R. Co. (91 "Atlantic Reporter," 1049). In this case the plaintiff, an occupant of land adjacent to the defendant's premises, recovered judgment for injury to the land through the fact that smoke, soot, ashes, etc., were cast upon it in the defendant's process of cleaning its locomotive boilers by means of compressed air. A consulting engineer, who testified in the plaintiff's behalf, admitted that he had had no experience with locomotive boilers, but that they presented no problems with respect to such processes that do not equally apply to other boilers, and that he had made a special study of power and combustion, and had had experience in doing away with the evils of smoke, etc. The Supreme Court holds that he sufficiently qualified himself as an expert to enable him to testify that in such cases as this one, deposits of soot on premises near those upon which boilers are cleaned can be avoided by using brushes instead of blowers and by washing the smoke to remove injurious impurities. The court finds that this method has been found to have been effectively used by railroads and in stationary plants for 70 years, and that the compressed-air method was adopted merely to save time and expense. And it is further found that the damage which the plaintiff sustained could have been avoided by the defendant's discharging the noxious fumes through a high chimney, and that it is no defense to such a suit that the compressed-air method is in common use.

PERSONALS

Edward Wegmann and A. G. Hillberg have taken offices in the South Ferry Building, New York City, to engage as consulting hydraulic engineers on water-works, water-power developments, sewer systems, irrigation and drainage projects. Mr. Wegmann was for more than 30 years connected with the construction of the Croton Water-Works. He was the last chief engineer of the Aqueduct Commissioners and subsequently for four years consulting engineer of the Department of Water Supply, Gas and Electricity. He is well known through his books—"Design and Construction of Dams" and "The Water Supply of the City of New York." Mr. Hillberg has been connected with large hydro-electric developments, notably the Mississippi River Power Co.'s plant at Keokuk, Iowa. For the past two years he has been associate editor of "Engineering Record," in charge of hydraulics.

ENGINEERING AFFAIRS

The Illinois Section of the American Water Works Association, succeeding the Illinois Water Supply Association, held its seventh annual meeting at the University of Illinois, Champaign-Urbana, Ill., Mar. 9 to 11. The program included the following papers: "The Design and Operation of Intermittently Operated Water Purification Plants," E. B. Black, consulting engineer, Kansas City, Mo.; "Wash Water Salvage at Champaign and Urbana," H. E. Babbitt, instructor in University of Illinois; "Relation Between Bacteriological Standards and Vital Statistics at Hannibal, Mo.," W. F. Monfort, consulting chemist, St. Louis, Mo.; "Loss of Head on Strainers of Water Filters," Langdon Pearse, division engineer, sanitary district of Chicago; "Experiences in Rebuilding and Reinforcing a Water Works System," O. T. Smith, superintendent and manager, Water Works Co., Freeport, Ill.; "The New Harrisburg (Ill.) Filter Plant," L. F. Payne and Glen W. Bass, Central Illinois Public Service Co.; "Soft Water" (Illustrated), Cass L. Kennicott, vice-president and general manager, The Kennicott Co., Chicago; "Water Works Improvements at Springfield, Ill." (Illustrated), W. J. Spaulding, commissioner of public property, Springfield, Ill.; "Coal Mining Operations" (Moving Pictures), R. Y. Williams, director Miners' and Mechanics' Institute, University of Illinois; "Coal Resources of the Danville Area," F. H. Kay, assistant state geologist, Illinois; "Investigation of Artesian Water Supplies in the Chicago Area" (Illustrated), Frank De Wolf, director Illinois State Geological Survey; "The New Filtration Plant at Decatur, Ill." (Illustrated), Harry Ruthrauff, commissioner of public property, Decatur, Ill.; "The New Filtration Plant at Quincy, Ill. (Illustrated), W. R. Gelston, superintendent Citizens Water Works Co., Quincy, Ill.; "Kinks in the Control of Hypochlorite at Denver," W. W. DeBerard, western editor, "Engineering Record," Chicago; "River Sand as a Filter Medium," L. A. Fritze, city chemist, Moline, Ill.; "Choice of Alloys in Connection with Water Works Equipment," Horace Carpenter, engineer, Sanitary District of Chicago; "The Practical Value of Publicity to the Water Works Man," S. C. Hadden, associate editor, "Engineering and Contracting," Chicago; "Treatment of Water for Locomotive Use," W. A. Pownall, water engineer, Wabash Railway, Decatur, Ill.; "The Possibilities of Improved Water from Deep Wells in Northern Illinois," C. B Williams, hydraulic and sanitary engineer, Chicago; "Water Supply of Longview, Texas," Paul E. Green, civil and sanitary engineer, Chicago; "Arsenic in Filter Alum," Edward Barton and A. N. Bennett, state water survey, University of Illinois; "Some Features of the Ontario Statutes and their Administration Affecting Water Supply and Sewerage," F. A. Dallyn, provincial sanitary engineer, Toronto, Canada; "The State Public Utilities Commission of Illinois and Water Works," W. A. Shaw, member Public Utilities Commission, Springfield, Ill.; "State Regulation of Municipally Owned Plants," C. M. Larson, chief engineer, Railroad Commission of Wisconsin; "The Illinois Utilities Commission and the Water Works Companies," C. G. Bennett, mechanical engineer, Illinois Utilities Commission, Springfield; "The Application of the Theories of Regulation to the Management of Utilities," Douglas A. Graham, principal assistant engineer, Dabney H Maury, Chicago; "Economic Waste Aspects of Water Works

Operation," Ralph E. Heilman, assistant professor of Economics, University of Illinois; "Ancient and Modern Accounting for Utilities," Edward A. Pratt, president Edward A. Pratt Audit Co., Peoria, Ill.; "Water Waste Prevention by Individual Meter vs. District Meters," R. O. Wynne-Roberts, consulting engineer, Regina, Sask., Canada. The exhibits of the Associates were shown in Engineering Hall.

NEW PUBLICATIONS

COX'S COMMERCIAL CALCULATOR. By Edward L. Cox. Published by Funk & Wagnalls Co., New York. 7x11 in.; 203 pages; cloth. Price, $10.

A collection of tables, from which the product of any two numbers whose sum does not exceed 202,000 can be found. The use of the tables is briefly explained and illustrated. Two key numbers must be obtained from the numbers to be multiplied, by the use of a simple formula. Each key number forms an unusual index to the table numbers required, in that the digits must be taken in order from right to left to find the correct page, column, section and line. The product desired is the difference of these two table numbers. The tables themselves are conveniently arranged and the book is valuable for commercial and scientific purposes in which products up to ten billion, accurate to the smallest unit, are essential.

GEARING. By A. E. Ingham. Published by D. Van Nostrand Co., New York. 5½x8½ in.; 181 pages; cloth. Price, $2.50

To the outsider the acquiring of practical gearing knowledge has been somewhat of a task. In one book he may find a complicated discussion of gearing principles; another may give him the manufacturing methods, while he must consult a third to find practical methods of design. Mr. Ingham has endeavored in the one book to cover the whole broad field of gearing. Nearly half of the 181 pages relate to spur gears, but in this section is stated the theory of the involute and cycloidal curves, which is later applied to the bevel, worm, spiral and helical gears.

The reader is given methods of drawing gear-teeth curves, such as the Brown & Sharpe single curve and the Grant odontograph; is shown how to calculate speed ratios for simple and compound gearing; and is informed regarding the materials and proportions of gears for the efficient transmission of power. The diametral, circular and metric systems of gear pitches are described. Numerous working drawings, cross-sections as a rule, accompany the design directions, while the manufacture and application of the various gears are illustrated by photographs. Formulas are given so that the reader may understand and pass through all the steps necessary to obtain the complete dimensions, but the numerous curves and tables, demonstrated by numerical examples, afford many short cuts. In general, Mr. Ingham's work offers a simple and adequate presentation of the information required in the design and application of gearing.

BOOKS RECEIVED

OXY-ACETYLENE WELDING AND CUTTING. By Calvin F. Swingle. Frederick J. Drake & Co., Chicago, Ill. Cloth; 190 pages, 4¼x6¾ in.; 76 illustrations. Price, $1.

HANDBOOK OF MACHINE SHOP MANAGEMENT. By John H. Van Deventer. McGraw-Hill Book Co., Inc., New York. Leather; 374 pages, 4x7 in.; 244 illustrations. Price, $2.50.

ELEMENTARY ELECTRICITY AND MAGNETISM. By W. S. Franklin and Barry MacNutt. The Macmillan Co., New York. Cloth; 174 pages, 4¾x7¾ in.; 152 illustrations. Price, $1.25.

ADVANCED THEORY OF ELECTRICITY AND MAGNETISM. By W. S. Franklin and Barry MacNutt. The Macmillan Co., New York. Cloth; 300 pages, 5¾x8¾ in.; 217 illustrations. Price, $2.

SANITARY REFRIGERATION AND ICE MAKING. By J. J. Cosgrove. Technical Book Publishing Co., Philadelphia, Penn. Cloth; 331 pages, 5½x8½ in.; 103 illustrations; tables. Price, $3.50

PREVENTING LOSSES IN FACTORY POWER PLANTS. By David Moffat Myers. The Engineering Magazine, New York. Cloth; 560 pages, 5x7½ in.; 68 illustrations, including several plates. Price, $3.

Antimold and Antibug Varnish for Books—The following ingredients make a varnish that has been found very useful in protecting books from mold and from roaches: Bichloride of mercury, 2 parts; orange shellac, 20 parts; oil of turpentine, 250 parts, and the balance up to 1000 parts, 95 per cent. ethyl alcohol.—"The Canal Record," Dec. 16, 1914.

Charles T. Main, engineer, Boston, Mass., is distributing a handsomely printed volume of halftone illustrations of industrial plants of his design. This follows a similar work issued some time since, and is inscribed "Industrial Plants, Vol. 2." Prospective builders of anything from cotton mills to central stations will find in it worth-while suggestions.

BUSINESS ITEMS

The New River Co., equipment sales department, Macdonald, West Virginia, is sending out a list of second-hand power plant equipment, quoting prices and terms.

Harry J. Ernst, advertising manager of the D. T. Williams Valve Co., Cincinnati, Ohio, has been elected treasurer of the company, succeeding R. E. Mullane, recently elected president.

The Link Belt Co., Chicago, Ill., is sending out bulletins descriptive of the Wendell centrifugal coal drier, and the Link-Belt electric hoist. Both bulletins show illustrations of the equipment and go into details of construction. Copies are sent on request.

The Chicago office of the Terry Steam Turbine Co., Hartford, Conn., is now in charge of A. W. de Revere, located in the Peoples Gas Building. This company has also opened an office in the Michigan Trust Bldg., Grand Rapids, Mich., in charge of A. L. Searles.

The Sprague Electric Works of General Electric Co. has recently opened a branch sales office in Cleveland, Ohio. It will be in charge of Frank H. Hill, manager, who also has charge of the Pittsburgh office. The Cleveland office will be located in the Illuminating Building.

The sales of Sarco steam traps, Sarco vacuum valves, and Sarco temperature regulators have shown such substantial continued increases during the past half year, that the Sarco Engineering Co. of New York has moved its offices into larger quarters in the new South Ferry Building, 1 State St.

A very interesting booklet has just been published by the Murray Specialty Mfg. Co., 55 West Woodbridge St., Detroit, on "Boiler Feed—How To Regulate It." It's a 32 page booklet describing the apparatus in detail and containing many clear and instructive illustrations. Testimonial letters and installation details are also given. A request brings a copy.

The Harvard Medical School has recently given an order to the Builders Iron Foundry, Providence, R. I., for two extra heavy meter tubes for boiler feed service. This institution already has two Venturi meters on its heater conservation system and six Venturi meters for brine measurement. M. L. Bayard & Co., of Philadelphia, have recently placed an order for 36 double dial indicating instruments to be used in connection with effluent controllers at the Cleveland filtration plant.

The Southwark Foundry & Machine Co., Philadelphia, Penn., has secured the exclusive United States license to manufacture the Harris valveless engine, Diesel principle, which will hereafter be known as the Southwark-Harris valveless engine. The engine will be built in sizes from 75 b.hp. to 1000 b.hp. Leonard B. Harris, the inventor of the Harris valveless engine will be with the company as consulting engineer and naval architect, and J. P. Johnston will be in charge of oil engine sales.

Heating and Ventilating System of American Cigar Co.'s Plant

By W. L. Durand

SYNOPSIS—Modern demands for comfort and convenience in the heating and ventilation of factory buildings have far outrun the relatively simple requirements of former years. An interesting example of modern tendencies is found in the equipment of a new factory erected for the American Cigar Co.

The new building of the American Cigar Co., Garfield, N. J., covers an area of 15,000 sq.ft.; it is five stories high and has a floor area of 50,000 sq.ft. It is used exclusively for the manufacture of cigars and about 1000 persons are employed.

The power plant, Fig. 1, is located in the basement, with natural light for the engine room and a convenient arrangement for handling the coal and ashes.

The boiler room is equipped with two 75-hp. horizontal return-tubular boilers arranged in a battery. While 125 lb. pressure is carried, the boilers are built to withstand 150 lb. The boiler furnaces are equipped with bridge-wall dampers and ducts leading to the rear of the setting, so that if it is desired later to increase the output by the addition of forced draft, no changes to the setting will be necessary.

The water for the boilers is taken from a driven well in the pump room. Two 4½x2¾x4-in. duplex, outside-packed plunger pumps are so connected that either one can be used to pump water from the well to the feed-water heater, to the boilers direct, or from the feed-water heater to the boilers. The steam piping is arranged to control the pumps by throttle valves when pumping from the feed-water heater to the boilers, or by means of a float in the feed-water heater when pumping from the well to the heater. This arrangement permits of one pump being used to handle makeup water to the feed-water heater under automatic control, the other to be used as a boiler-feed pump; in case of a breakdown to either pump, water can be fed direct to the boilers by the other.

A hydraulic damper regulator is used in connection with a balanced damper in the main smoke flue. If forced draft is installed this will also be used to operate a balanced valve in the steam connection to the forced-draft fan, permitting automatic control.

Bituminous coal is burned in the boilers. It is stored in a pocket adjacent to the boiler room, the coal being supplied from a driveway overhead. The ashes are removed by an overhead trolley which discharges directly to the driveway.

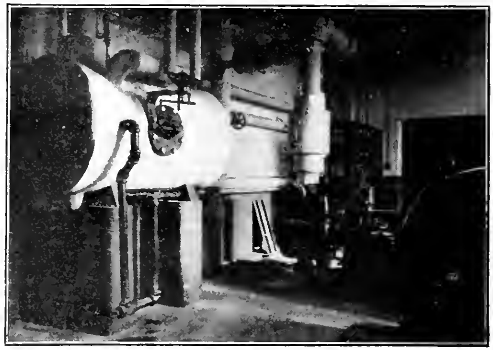

Fig. 1. Partial View of the Engine Room

The engine room is equipped with a 10x12-in. high-speed engine directly connected to a three-wire, direct-current 110-volt generator. It was the first intention to use a four-valve engine, but after going into the situation it was found that engine economy was of value only during the summer months when the load was the lightest, and that the saving would not be sufficient to warrant the increased cost of both engine and generator. The increased cost of the generator would be almost as much as that of the engine, due to the lower speed of this type of engine. No breakdown service or extra unit was installed,

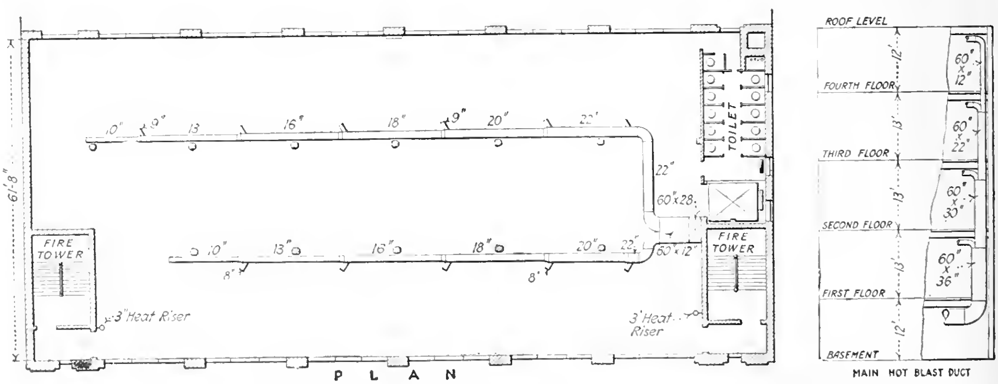

Fig. 2. Plan and Elevation of the Hot-Air Ducts

since the character of this factory did not seem to warrant the extra expenditure.

Exhaust steam from the engine and pumps passes to a feed-water heater and is then used for heating hot-blast coils, with provision for using live steam from the boilers through a double set of reducing valves.

The building is heated by means of a hot-blast system supplemented by a few coils and radiators. The air in entering passes first through a tempering coil, an air washer, and a reheater to the intake of the supply fan. From the supply fan it is distributed by a main riser with two branch ducts on each floor. Fig. 2 is a plan and elevation of the hot-air ducts. Fig. 3 is a plan view of the engine, boiler and air-washing rooms.

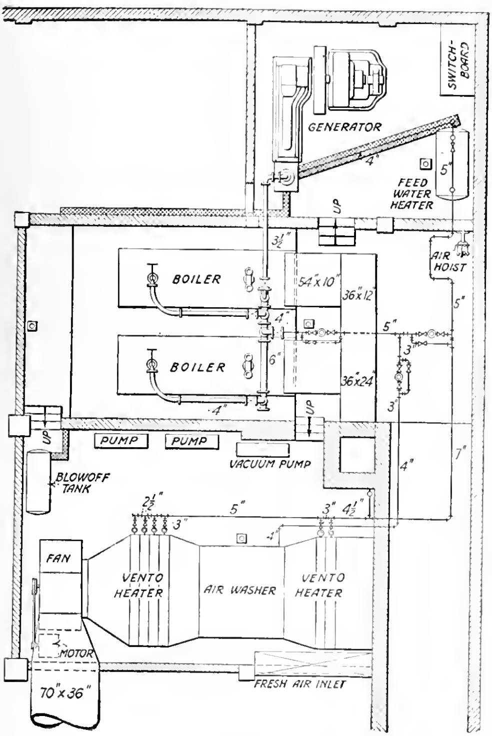

FIG. 3. PLAN OF ENGINE, BOILER AND AIR-WASHING ROOMS

The tempering coil consists of two groups of 60-in. cast-iron heaters set on 5-in. centers. Each group contains 20 sections, making a total of 640 sq.ft. The coils raise the air to a certain necessary minimum temperature, as later described, before passing to the air washer.

The air washer consists of a metal spray chamber through which the air is drawn. Under the chamber is a tank which is kept filled with water. A centrifugal pump driven by a directly connected motor draws water from this tank and forces it through the spray nozzles. The nozzles, of which there are approximately seventy, are uniformly distributed over the cross-section of the washer, so that this chamber is filled with a fine mist so dense that it is impossible for the air to carry any dirt through it without the latter becoming wet and heavy. At the end through which the air leaves the spray chamber is placed a set of eliminator plates, which extract all the water and dirt. These plates are kept flooded, so that dirt is washed into the settling tank.

This apparatus is provided with an arrangement for automatically controlling the humidity. The spray water is heated when the humidity is too low, in order to increase the evaporation; this heating is controlled by a

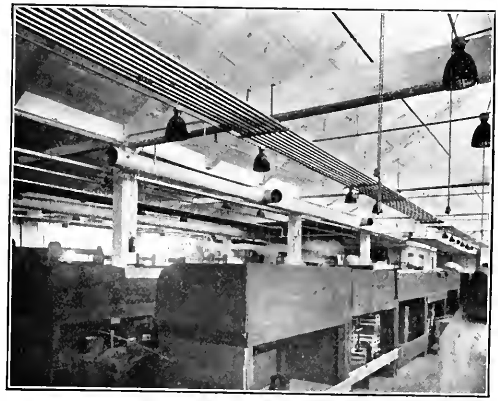

FIG. 4. SHOWING AIR DUCTS AND STEAM COILS ON THE TOP FLOOR

thermostat placed in the air duct leading away from the apparatus. While one of the functions of an air washer s to remove dust and floating solid matter from the air before entering the rooms to be heated, the principal reason for installing one in this factory is for humidifying the air, and in order to give the best possible conditions for the manufacture of cigars it was decided to maintain a humidity of at least 65 per cent. at all times.

For the proper operation of this apparatus the temperature of the entering air should fulfill two conditions—it must be not less than 32 deg. F. to avoid danger of freezing the water in the washer, and it should have such a temperature that when saturated, as it is when leaving the washer, it will carry such a moisture content as will give it, at the desired room temperature, a relative humidity of 65 per cent.

The heating stacks consist of four groups of 60-in. cast-iron heaters. Each group contains 22 sections, making a total of 1408 sq.ft.

The fan is a 54-in. diameter multivane, and it has a capacity of 25,000 cu.ft. of air per minute against a pressure of 1 in. of water. It is driven by a directly connected 10-hp. engine. The reason for using an engine in preference to a motor is that in case of a breakdown to the engine generator set the building could still be kept warm and work would not have to be entirely suspended.

The factor determining the amount of air circulated was the number of occupants. This being fixed, the heat losses were computed, and the required temperature of air from the reheater for extreme conditions was found to be 120 deg. F., which temperature is given by the arrangement outlined above.

On the first floor, which has an extended wing, and on the top floor, Fig. 4, steam coils are installed to offset the heat losses through the roof. This is necessary to prevent an excess of air on these floors, which would occur if these losses were taken care of by the hot-blast system. The arrangement of the air ducts and outlets on the other floors is shown in Fig. 5.

The entire heating apparatus is governed by an automatic temperature-controlling system. One thermostat is located between the primary heater and the air washer, controlling supply valves on both sections. The valves are fitted with differential springs, the outer section being the last to close, so as to maintain temperatures from 45 to 55 deg. F., as desired. One thermostat is located in the air washer, as previously described. One thermostat of the two-relay pattern, adjustable from 65 to 125 deg., is located in the duct beyond the reheater and controls the four valves on the steam supply to the reheater. Two thermostats on the first floor, and three on the top floor control the ceiling coils.

Fig. 5. Arrangement of Air Ducts and Outlets on the Center Floors

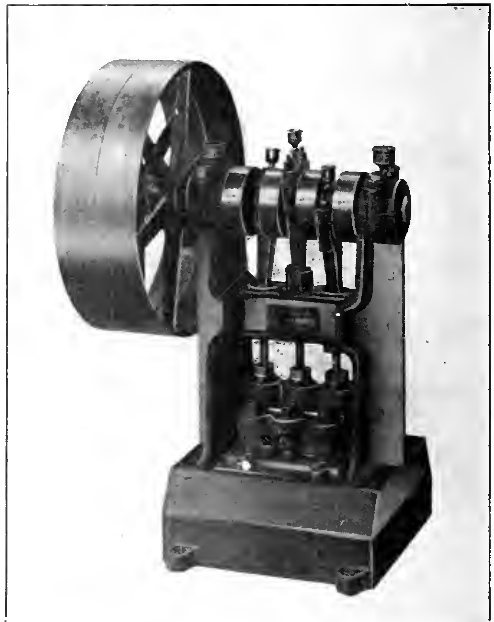
A vacuum system is used in connection with all coils, radiators and stacks. The condensation is carried to a 6x7x8-in. vacuum pump with suction strainer and vacuum governor. The discharge on the pump is carried to a standpipe with a vent to the atmosphere, instead of the customary air-separating tank. From there it flows to the feed-water heater. With a heating system of this character it is possible to carry a vacuum of 1 to 2 in. of mercury on the steam side of the system and 7 to 8 in. on the return side.

The covering is 85 per cent. magnesia for all steam pipes in the basement, being 2 in. thick on the high-pressure and 1 in. on the low-pressure. The exhaust pipe, which is in a chase, is covered to the fourth floor, where the last connection is taken off. No vacuum return pipes are covered.

As this is one of the first buildings in this country used exclusively for the manufacture of cigars to install an air washer and is in the nature of an experiment, the comparison of the results obtained at this factory with similar factories owned by the same company, but heated by steam with no ventilation and humidity control, will be watched with interest.

Single-Acting Hydraulic Pump

This pump fills the requirements where a uniform flow of a small quantity of water under high pressure is required. When motor-driven it may be mounted on a truck and used as a portable outfit. It is provided with a knockout attachment that automatically cuts off the delivery of water, but holds the pressure when the predetermined maximum is reached. A slight drop in the pressure automatically starts the flow, which continues until the maximum is again reached. The base of the pump forms a reservoir for the liquid used in the operation.



Single-Acting Triplex Hydraulic Pump

PRINCIPAL EQUIPMENT OF THE AMERICAN CIGAR CO.'S NEW PLANT, GARFIELD, N. J.

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
2	Boilers	Return-tubular	75-hp	Steam generators	Hand-fired, 125 lb. steam, natural draft	E. Keeler Co.
1	Engine	Ide	10x12-in.	Main units	125 lb. steam-saturated	A. L. Ide & Sons
2	Pumps	Duplex	6x4x6-in.	Boiler feed and makeup water	Automatic and hand regulated	Henry R. Worthington
1	Generator	Direct-current	50-kw.	Main unit	110-220-volt, 3-wire system	Westinghouse Elec. & Mfg. Co.
1	Heater	Combination	150-hp.	Heating feed water	Using exhaust steam	Linton Machine Co.
1	Fan	Sirocco	54-in., 25,000 cu ft. per min.	Hot-blast system	230 r.p.m.	American Blower Co.
1	Engine	Vertical, high-speed	10-hp., 6x6-in. cyl	Driving fan	230 r.p.m., 125 lb. steam	American Blower Co.
1	Air washer	Wet	70-nozzle	Washing ventilating air		American Blower Co.
1	Pump	Centrifugal	2-in.	Water for spray nozzles	1200 r.p.m. capacity, 120 gal. per hr	American Well Works
1	Motor	Direct-current	5-hp	Driving cen. pump	1200 r.p.m., 220-volt	Westinghouse Elec. & Mfg. Co.
2	Heater groups	Vento, 60-in.	20 sections each, total 640x sq.ft.	Tempering air	0 to 50 deg.	American Radiator Co.
4	Heater groups	Vento, 60-in.	20 sections each, total 1408 sq. ft.	Heating air	50 to 120 deg.	American Radiator Co.
1	Control system	Thermostat		Heating system	Automatic	Power Regulator Co.
1	Vacuum system	Donnelly		Heating system	Automatic	Jenkins Brothers
1	Pump	Simplex	6x7x8-in.	Handles condensate	10-in. vacuum	International Steam Pump Co.

The pump is built for either gear, chain or belt drive. The design is such that any one of twelve different-sized plungers may be furnished, ranging from $\frac{3}{16}$- to 1-in. diameter, advancing by increments of $\frac{1}{16}$ in. They are capable of exerting a maximum pressure ranging from 750 to 8000 lb. per sq.in. The three plungers are of the same diameter and work to the same maximum pressure. The stroke is 2¾ in. Each has a speed of 35 ft. per min. at 150 strokes, which is the rated speed, and gives the pump a total capacity of 0.11 to 1.20 gal. per min., depending upon the diameter of the plungers. The suction and discharge valves are located in the pump cylinder.

The plungers are bronze, except on the $\frac{5}{16}$- and ⅜-in. sizes, where steel is used to withstand the high pressure. The cylinders are cast *en bloc*. With the $\frac{5}{16}$-in. and the ⅜-in. plungers cylinders of forged steel are used, and for the pumps having larger plunger diameters a special bronze is used. The height over all is 35 in. and the floor space required is 16x18 in. The weight is 500 lb.

This pump is manufactured by the Hydraulic Press Manufacturing Co., Mount Gilead, Ohio.

Piping and Supports in Municipal Plant

By A. D. Williams

SYNOPSIS—Some unusual features found in the steam piping at the East Fifty-third St. Station, Cleveland Municipal Electric-Light Plant.

The East Fifty-third St. Station at Cleveland is designed to operate at 225 to 250 lb. steam pressure with a superheat of 125 to 150 deg. F., steam temperatures of 525 to 600 deg. F. being obtained when the plant was tested. The boilers are of the Stirling "Delray" type with two superheaters each, from which the steam is taken off through nonreturn valves and 8-in. steam lines to a main header divided in three sections, from each of which one of the main units is supplied.

One of the features of the steam piping is the use of flanges welded to the pipes and welded steel nozzles on the header and manifold, pipe bends being used for all changes of direction; the only castings used in connection with the live steam piping are the valves. Like most modern plants, this station is designed upon the unit system and may be operated as though it consisted of three separate plants. In one way, however, it departs from the unit design, namely, in the use of a large main steam header instead of cross-connection loops between units. This header is placed in the basement, near the wall between the boiler and turbine rooms, and is the lowest point in the steam line. It is divided in two sections by an expansion loop (Figs. 1 and 4), each section ending with a manifold tee having four side outlets from which 6-in. inverted "U" pipe bends are taken off and connect with the other section. The combined area of the bends is slightly less than the area of the header. The two manifold tees are dead-ended next to the wall by forged-steel bumped heads welded on, the opposite end being closed by a blind flange. Each section of the header is anchored midway between its ends and is supported elsewhere by rollers, as shown in Figs. 2 and 5. At each anchor point the pipe rests in a heavy cast saddle, to which it is secured by clamping rings, and bands welded to the pipe at these points assist in preventing any slipping of the rings. Each section of the header contains one Venturi Hopkinson-Ferranti stop valve by means of which the plant can be separated into three operating units.

This header, being the lowest point of the steam piping, is provided with drain outlets piped to a trap set in a pit below the floor; this provision is necessary, even with superheated steam. A stop valve is placed in each of the turbine steam leads next to the header, with the valve stem set at a 30-deg. angle (Fig. 2). Each boiler lead

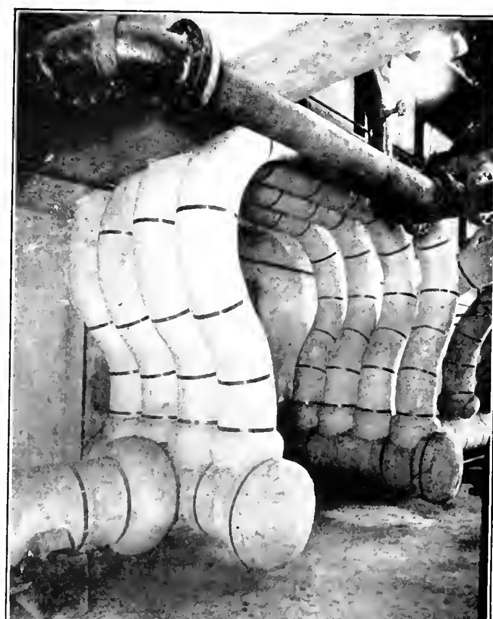


Fig. 1. Expansion Bend in Main Steam Header

is also provided with a stop valve just beyond the bend to the header, and the leads to the far side of the boiler room are supported at the boiler-floor level by floor-plates and supporting rings designed to permit free expansion in the long lead below the floor. These sliding floor-plates are shown in Fig. 6.

Fig. 7 shows the construction of two supports for the feed-water pipes—one a steel bracket anchor built up of angles and plates, the other a cast-iron saddle anchor with

a steel clamping plate to hold the pipe. Both of these supports are secured to the masonry by expansion bolts.

Figs. 3 and 8 show the arrangement of the boiler-feed pumps and the piping at this point. Three five-stage centrifugal pumps are installed, all being designed to operate at 1750 r.p.m. against a pressure head of 720 ft. One pump, for emergency service, is driven by a 125-hp. steam turbine and has a capacity of 350 gal. per min. The center pump has a capacity of 750 gal. per min. and is driven by a 250-hp., 440-volt, three-phase induction motor. The third pump is driven by a 125-hp. induction motor and has a capacity of 350 gal. per min. The feed-water supply is drawn from the hotwell into which the condensate from the surface condensers is discharged, a sufficient head being maintained to cause the water to flow to the V-notch meter through a 12-in. supply line. All of the pumps draw on a suction header to which the water from the meter flows through an 8-in. line, and an 8-in. bypass is provided around the meter. From the pumps the water enters a pressure header from which lines run to both economizers. Two bypass risers are provided which connect to the boiler-feed loop. The pressure end of the boiler-feed system is arranged so that there are two possible routes for either hot or cold feed water between the pumps and the boilers.

The use of electrically driven auxiliaries for the condensers, induced draft and forced draft, and for the stoker drive and boiler feed, eliminates a large amount of small steam piping and exhaust lines. All of the piping under high pressure is extra strong lap-welded medium-steel with cast-steel fittings. The low-pressure piping is of standard-weight wrought iron, cast iron or, as in the case of the free exhaust line, spiral riveted pipe. Each turbine is connected to the free exhaust line by a 24-in.

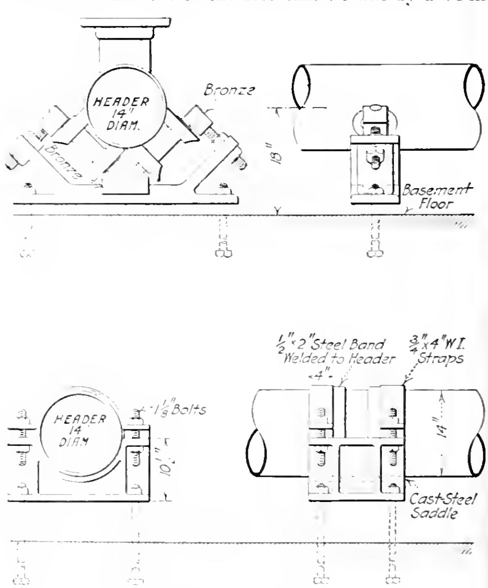

FIG. 5. ROLLER SUPPORT AND ANCHOR BLOCKS FOR MAIN STEAM HEADER

free exhaust valve on the condenser. A 24-in. header is located in the turbine-room basement, just below the floor, and a riser at the center of this header passes up through the floor, then diagonally through the wall into the boiler room and ends just above the roof. This riser,

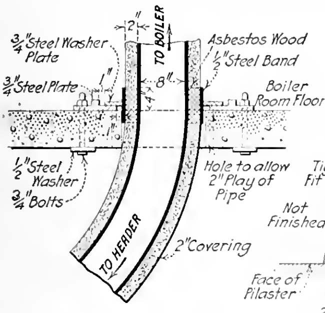

FIG. 6. SLIDING FLOOR PLATES FOR BENDS LEADING TO BOILERS NOS. 1, 3 AND 5

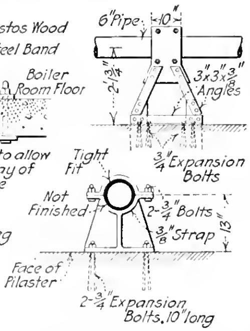

FIG. 7. CAST-IRON AND STEEL ANCHORS FOR 6-IN. PIPES

which may be called upon to carry the exhaust from three 5000-kw. turbines, is the same size as the header and the free exhaust valves.

The nominal overload steam requirements of the turbines is about 70,000 lb. per hour. This is brought to the turbine through an 8-in. pipe, the velocity of flow being about 117 ft. per second. In the exhaust line this amount

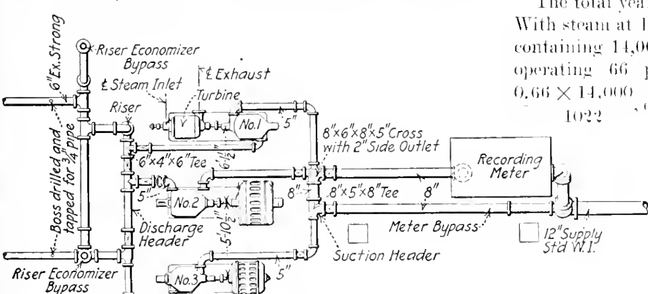

FIG. 8. PLAN OF PIPING AT BOILER-FEED PUMPS

of steam could be carried with a velocity of about 110 ft. per second, at 17 lb. absolute pressure. The reduction in cost of the pipe and covering for small sizes is considerable, so that for economic reasons the pipe should be the smallest size that will pass the steam with the maximum permissible friction and radiation losses.

⁂

TYPICAL CONDENSER DATA AND PERFORMANCE

Horsepower	Steam, Lb. per Hr.	Cooling Surface, Sq.Ft.	Condensation Rate in Lb. per Sq.Ft.	Actual Vacuum 30-in. Bar	Circulating Water, Deg. F.	Hot-well Temp., Deg. F.

Costs in Small Industrial Power Plant

By C. W. THAYER

When an isolated power plant can be operated at a profit in a district where the hydro-electric interests are well developed, the figures should prove important.

In the present instance, the plant consists of two horizontal return-tubular boilers, with an aggregate rating of 225 boiler horsepower, two steam pumps, one power pump, an open feed-water heater, a draft regulator and the usual small accessories. The total value of this equipment is $4100. The building is valued at $3000, the 110-ft. chimney at $1200, the boiler and accessories foundations at $150, and the land at $1000.

The fixed charges on the boiler plant are as follows:

Interest at 5 per cent. on total investment of $9450..	$472.50
Taxes at 1 per cent. on total investment of $9450....	94.50
Insurance on building and equipment..............	15.00
Special boiler insurance...........................	36.00
Depreciation on building and chimney (1.5 per cent. on $4200)	63.00
Depreciation on equipment (6 per cent. on $4250)....	255.00
Repairs on building and chimney (1.5 per cent. on $4200)	63.00
Repairs on equipment (6 per cent. on $4250)........	255.00
	$1254.00

The operating charges are as follows:

Engineer, 70 per cent. of time in boiler plant (70 per cent. of 52 weeks), at $22 per week.............	$800.80
Night fireman, 30 per cent. of time (30 per cent. of 52 weeks), at $18 per week....................	280.80
Sunday man, 52 days at $2.50......................	130.00
	$1211.60
Supplies	70.00
Water	100.00
Coal (1100 tons at $4.20, delivered short tons)......	4620.00
	$4790.00

The total yearly charge for the boiler plant is $7255.60. With steam at 140 lb. gage, feed water at 200 deg. F., coal containing 14,000 B.t.u. per lb., and a boiler and furnace operating 66 per cent. efficiency, the evaporation is

$$\frac{0.66 \times 14,000}{1022}$$

, or approximately 9.04 lb. water per pound of coal. The figure, 1022, is the B.t.u. added to the feed water to produce a pound of steam. The cost of evaporating 1000 lb. of water is 36.5c. which is found as follows:

$$\frac{7255.60}{1100 \times 2000 \times 9.04} \times 1000 = 36.5$$

As the demand for steam increases, the evaporation cost will decrease.

The power plant consists of the following items with their corresponding valuations.

Land valued at	$1000
Building valued at	1150
Engine foundations	450
Slide-valve compound engine, 150 hp., direct-connected to a 125-kw. direct-current generator..........	2800
Generator (125 volts)	1500
Engine piping and separator.....................	700
Switchboard	1000
Apparatus and tools............................	250
Automatic lubricator and filter..................	210
Total	$9060

The engine-plant fixed and operating charges are:

Interest at 5 per cent. on total of $9060..............	$453.00
Taxes at 1 per cent. on total of $9060................	90.60
Insurance on buildings and equipment..............	15.00
Special flywheel insurance.........................	24.40
Depreciation on building, etc. (1.5 per cent. on $1600)	24.00
Depreciation on equipment (4 per cent. on $7460)..	298.40
Repairs on building, etc. (1.5 per cent. on $1600)....	24.00
Repairs on equipment, etc. (4 per cent. on $7460)....	298.40
	$1227.80
Labor (30 per cent. of engineers' 52 weeks at $22)....	343.20
Supplies (oil, waste and fuses).....................	200.00
	$1771.00

The engine is operated 300 days for 9 hr. a day, and switchboard records show the average load to be 140 b.hp. A recording flow meter shows an average of 32 lb. of steam per b.hp.-hr. The steam cost is then

$$\frac{300 \times 9 \times 140 \times 32 \times \$0.365}{1000} = \$4415.04$$

This charge for steam of $4415.04, plus the $1771 for fixed charges, labor and supplies, gives a total charge of $6186.04 for 378,000 hp.-hr., or a cost of 1.63c. per hp.-hr.

In the three winter months all the exhaust steam from the engine is used for heating the plant. As this exhaust will have at least 85 per cent. of the heat units available that are contained in the equivalent weight of saturated high-pressure steam, it is fair to credit this amount to the power plant; hence

$$\frac{\$4415.04}{4} \times 0.85 = \$938.20$$

This reduces the annual cost from $6186.04 to $5247.84 Using this basis, the cost per horsepower-hour is 1.38c.

Eckel Hydrostat Feed-Water Regulator

The Eckel hydrostat for regulating boiler-feed water is illustrated herewith. Fig. 1 shows the device attached to a boiler and piped to a feed pump. The details of construction are shown in Fig. 2. The only moving parts

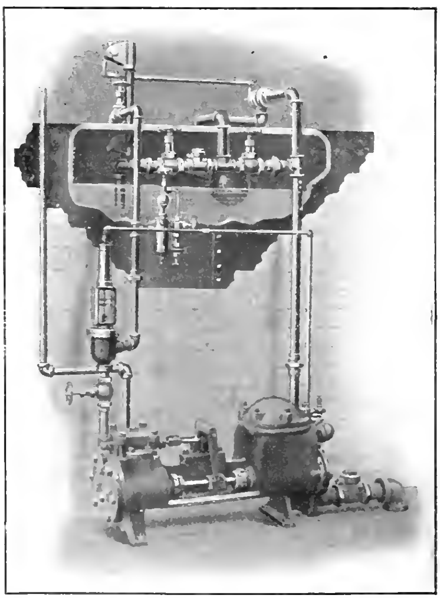

Fig. 1. Pipe Connections of Hydrostat and Pump

in the boiler are the float, tested to 300-lb. pressure, and the rod connection, which is actuated by the float lever as the water level in the boiler rises or falls.

The vertical rod is incased in the upright supporting stand, and its movement is transmitted to a lever in the casing at the top and on the outside of the boiler shell. This lever is attached to a rod which passes through a stuffing-box and by a series of levers operates a control valve in the feed pipe.

The feed pump is fitted with a governor, controlled by the pressure from the water end of the pump. When the valve in the feed line is partly closed, owing to the

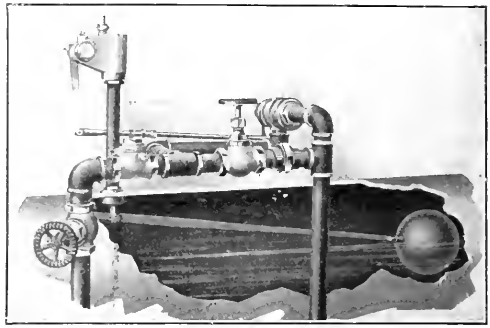

Fig. 2. Hydrostat with Series of Boilers

height of water in the boiler, the pressure in the discharge pipe is increased and this pressure is transmitted to the regulator, partly closing it, and slowing down the pump. Fig. 2 illustrates the type of hydrostat used on boilers set in series, where more than one boiler is fed by the same pump.

The hydrostat used with a single boiler controls the

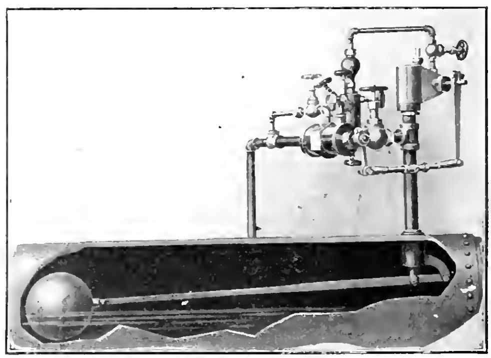

Fig. 3. Hydrostat Used with Single Boiler

pump speed and no pump governor is used in connection with it, as it is a governor as well as a hydrostat.

The control valve is so designed that dirt cannot stop it from closing, and it works like a shear and is supposed to cut off any matter that might lodge between the ports. The valve does not wire-cut by the passage of the water; the valve is sectional and may be easily taken apart.

This regulator, which is made by the Eckel Hydrostat Co., 458 Mt. Elliott Ave., Detroit, Mich., can be used on any steam boiler.

It Is Contended that fuel can be saved by using higher steam velocities in pipes; the limit for safety with reciprocating engines is 82 to 98 ft. per sec. The Berlin Electricity Works Co. carried out experiments and obtained considerable saving in fuel by eliminating pipes which had been put in to reduce the fall of pressure.—Exchange.

Return Traps for Feeding Boilers

By K. M. Gilbert

SYNOPSIS—Advantages and steam consumption of traps. Explanation of the principle of operation.

Steam traps have been known for many years as a means of feeding boilers, but it seems that they have not been used in small power plants as widely for this purpose as their merits would warrant. For small boiler plants up to 300 hp. a steam trap is an economical and satisfactory means of feeding hot water into a boiler. A good trap requires little attention and no lubrication; it has no piston or piston rods to pack, and but few wearing parts.

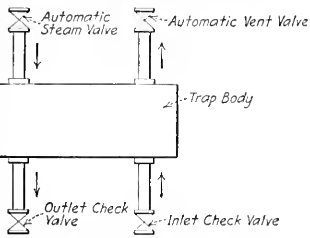

Fig. 1. Diagram of Elementary Trap

For these reasons the repair charges are low—much lower than for a feed pump. For a 100-hp. boiler at full load, a steam trap for boiler feeding would require about twenty pounds of steam per hour; a small duplex steam pump for the same purpose, about one hundred twenty-five pounds. The use of a trap instead of a feed pump would at this rate save 100 lb. per hour, which at an evaporation of 7 to 1 means 14 lb. of coal per hour, or 140 lb. per day for each 100 hp.

There are two general classes of traps, the return and the nonreturn. The return trap is used when it is desired to elevate or discharge the water against a head or pressure equal to or greater than that of the water entering the trap, as for feeding boilers or draining a vacuum system. A return trap has an automatically operated live-steam valve and usually a vent valve, both of which are operated by the action of the trap when sufficient water has entered.

A nonreturn trap has no live-steam connection, and for this reason it cannot discharge its contents against a head any greater than that of the water entering it.

There are several types of traps which, if named according to the method of operating, the valves may be called tilting, bucket, float, expansion, and differential. These various types have their advocates, but from the writer's experience of several years he has found that the tilting trap has given the best service. All of its working parts are accessible and within the sight of the engineer, who can tell at a glance how the trap is working.

While the methods of operating the valves of the several traps vary, the principle of operation is the same for all types and, for the benefit of the young engineer, can be explained by aid of Fig. 1. The drip or feed water for the boiler enters the body of the trap through the inlet check valve. When sufficient water has entered, the operating mechanism of the trap is so arranged that either the weight of the water, a float valve, or a bucket, etc., automatically closes the vent valve and at the same time opens the live-steam valve. The steam pressure then acts on the surface of the water in the trap, the inlet check valve closes and the outlet check valve opens, enabling the steam to force the water out of the trap. When the trap is nearly emptied the steam valve is closed and the vent valve automatically opened. The pressure in the trap body is reduced to atmospheric so that the drip water can enter and again fill the trap. From this explanation it should be readily seen that the steam consumption for each discharge of the trap is about equal in volume to that of the trap reservoir.

Fig. 2 shows the arrangement of piping, traps and feed-pump connections to two return-tubular boilers. The feed pump is for use while examining or repairing the traps. The trap discharging into the boiler must be placed about four feet above the water line in the boiler, then when the steam is admitted to the trap this head is sufficient to overcome the friction of the piping and check valves so that the trap is quickly discharged. In all cases the water must flow into the feed trap for, unlike a pump, it has no power to raise water by suction. When by the pressure in the system the water cannot be raised to the feed trap, another trap must be employed to do this work. The low-pressure trap (Fig. 2) is connected to discharge the low-pressure drips into the feed trap. Its action is the same as the feed trap, and the use of the live-steam connection makes it possible to raise the water.

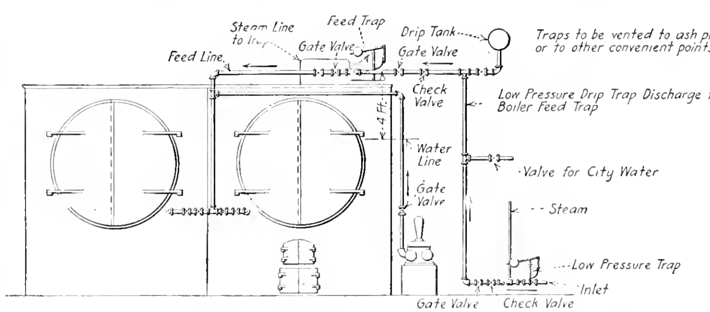

Fig. 2. Piping for Tilting-Trap Boiler-Feed Installation

The pipe connections to and from all traps should be sufficiently large and free from numerous turns. The pipe connections to nearly all traps are too small, and the inlet and discharge pipes should be one or two sizes larger than the trap connections. The inlet pipe line should slope toward the trap, and the outlet should slope downward in the direction of the flow of water to the boiler. An air chamber on the discharge line will prevent the noise and shock which sometimes occurs from water-hammer.

The check valves should be of the swing type and the others of the gate type. The live-steam connection must be made direct to the boiler shell or as close as possible, so as to have the full steam pressure available for operating the trap, as a pound difference in pressure between the trap and the boiler may prevent satisfactory operation and reduce the capacity of the trap. The packing used around the valve stems should be of soft material and well lubricated. Most of the tilting-trap troubles come from using a hard asbestos packing which in a short time becomes hard and binds the stems. The packing should be braided and well lubricated with graphite.

Slippage of Reciprocating Pumps

By T. B. Hyde

SYNOPSIS—In view of the many different expressions relative to pump slippage which have lately appeared in Power, *the following article will be of much interest to the many concerned with the subject. The volume of slippage depends upon the discharge and suction pressures, condition and tightness of valves and plungers or pistons.*

Slip is a "dead" loss of power. The useful work done by a reciprocating pump is measured by the amount of liquid pumped, multiplied by the head pumped against. This is less than the indicated work of the pump cylinder by an amount equal to the slip. Slip is therefore defined as the difference between piston or plunger displacement and the actual volume of pumpage expressed as a percentage of the former.

Where the pumping unit is large slip is usually closely watched and kept at a minimum, but the same cannot be said of many smaller pumps, particularly those used for boiler-feeding purposes. As an example the writer recently noted a feed pump running with 80 per cent. slip; in other words, its displacement was five times its pumpage; its useful horsepower, represented by water delivered to the boilers, 4.20; its actual water horsepower, four times that, say, 17. The steam consumption, or water rate, of these small duplex pumps is seldom less than 120 lb. per water horsepower-hour, and usually higher. Using this conservative figure for an assumption, this pump was using 17 × 120 = 2040 lb. steam per hour, of which 80 per cent., or 1632 lb. (47 boiler hp.), was spent for slip. A feed pump can be handled nicely on 15 per cent. slip, so that there was a clear waste of 38 boiler hp., or in money, roughly, thirty cents per hour. The main units were noncondensing; it was summer and there was an excess of exhaust steam, so there was no justification of this waste.

Slip is greater at low pump speeds than at high. In order to understand this clearly we must differentiate between per cent. slip, or "slip" as it is called, and actual volume of slip. The latter is the difference between displacement and pumpage and is reduced to per cent. slip by dividing by displacement. The volume of slippage depends upon discharge and suction pressures, condition and tightness of valves and plungers or pistons, as the case may be. It may be likened to a leaky globe or throttle valve; the greater the pressure, the greater the amount of leakage; the greater the amount of opening, the greater the amount of leakage. Wherefore, with a given pump, with valves and pistons in a given condition, the actual volume of slip may generally be said to be independent of speed; a function of discharge pressure and time only. But in reducing to per cent. slip, we divide this constant amount by the displacement, which varies directly with speed. Hence, with high pump speed (large displacement) per cent. slip will be low, and *vice versa.*

Slip may be as high as 100 per cent., as is the case of a pump working against a closed discharge valve or a fire pump drifting along at two or three revolutions per minute, maintaining a constant pressure on a sprinkler system. Slip may be as low as zero or even be a negative quantity. In the latter case the pump is actually delivering an amount of water greater in volume than the displacement of the pump itself. When this occurs it is due to the rise in pressure in the suction line when the flow is suddenly checked, forcing water through both suction and discharge valves and into the discharge line. This action is similar to the hydraulic ram, where the velocity of the water being suddenly checked, it is changed into pressure sufficient to force a small quantity of water into the discharge line against a pressure considerably greater than the supply head. This negative slip occurs only under a combination of favorable conditions, among which are high velocity of water in suction pipe with slight suction head, low discharge pressure and tight valves. To produce negative slip the amount of water passed through by this "hydraulic-ram" action must be sufficient to more than balance the normal slippage through the valves.

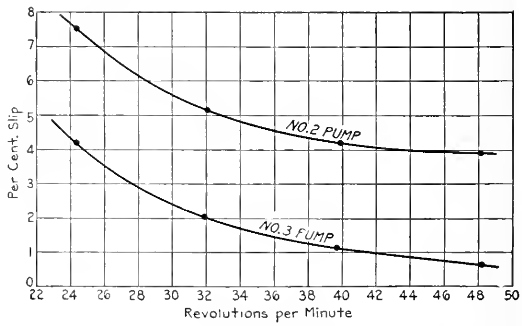

Fig. 1. Slippage-Test Results of Large Pumping Engines

Fig. 1 shows the result of slip tests on two large cross-compound steam-driven flywheel pumping engines. The pump plungers of each unit have a displacement of 306 gal. per revolution. These tests were conducted with considerable accuracy, the water being measured by a venturi meter in the pump discharge line. The discharge pressure was 40 lb. per square inch gage; suction head practically zero. In these pumps, when valves are in good condition negative slip is frequently found at the higher speeds.

Fig. 2 shows a slip test on a 12x7x12-in. steam duplex feed pump. Incidentally, this test was made to calibrate

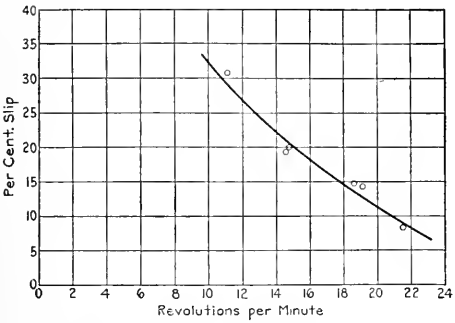

Fig. 2. Slippage Test on 12x7x12-In. Duplex Pump

the pump, so that a revolution counter could be attached and the pump used as a boiler feed-water meter to measure the station boiler load. Such a slip test is simple and can be made by any engineer in the following manner, without any extraordinary apparatus: Blank off the regular discharge line and pipe the discharge to weighing barrels or, as was done in this case, to a large tank that had been previously measured. Old fire hose was used for piping. Put a throttle valve in the discharge line near the pump and place a pressure gage between the pump and this valve. At whatever speed it is desired to run the pump, maintain the discharge pressure, by means of this valve, the same as that against which the pump normally works. Two other conditions—suction head and water temperature—should be maintained the same, although they are of lesser importance than pressure and speed. In the test referred to, these were taken care of by pumping from the regular feed-water heater through the regular suction line. Live steam should be admitted if necessary, to maintain the normal feed-water temperature. The pump may be calibrated at a single speed, which should be that at which it normally runs, or if desired, the calibration may be extended over a range of speeds, but no comparison can be made between test and running conditions unless both pressure and speed are the same. For accuracy suction head and temperature should be the same, although any change in either, sufficient to introduce any serious error in results, would usually make itself noticeable by hammering of the pump, indicating that the pump was getting either vapor or air.

Duplex steam pumps tend to "short-stroke" at low speeds. Strictly, this should not be charged to slip, for it is neither a waste of power nor of steam. In the above test, however, is was charged to slip, in order that the results of the slip test might be applied to the readings of the counter to obtain the amount of boiler feed. This method of measuring boiler feed can be recommended only for places where suitable meters are not available.

Just for Fun

[More stories of stupidity and ignorance competing with "Some Original Ideas," as printed Jan. 19, 1915.]

We are pleased to give you the following, which we believe is good enough to publish in Power

A new salesman was sent out to sell a steam engine. The customer advised him that he would like an engine that would run both over and under. The new salesman explained to him that all he would have to do would be to turn the throttle to the right to make it run over and to the left to make it run under.—*I. N. Beeler, Syracuse, N. Y.*

In a certain felt factory static electricity caused trouble at the cards. I sent an electrician to the plant, instructing him to arrange a "comb" close to the drive belt and connect it by wire to a gas pipe, water pipe, or any conductor that ran to ground. Going to the plant afterward to see if the trouble had been completely removed, I found that instead of being connected to a pipe the wire was run to a pail on the floor, which was partly filled with water. The intention, I was told, was to empty the pail when it became filled with electricity.

In another plant I noticed a pipe with a valve connected to the steam space and running down beside the boiler and through the setting. The engineer opened the valve occasionally. Thinking it might be some new smoke-consuming device, I opened the furnace door to see how it operated and discovered that the pipe was connected to a small bag on the bottom of the boiler. I asked the purpose of the pipe and was told that the mud and scale had a tendency to settle in a bag on the bottom of the boiler and that by means of the pipe he could blow steam into the bag and displace the scale.—*R. McLaren, Medicine Hat, Alta.*

At one time along my trail of bygone experience, I hired out as engineer of a grist mill that was located in a region wherein capable engineers were by no means abundant.

I arrived in the village at supper time on the day before I went to work, and didn't have much of a chance for a preliminary look around. In the morning, when I had everything in readiness, as I thought, for starting the engine and was about to turn on the steam, the colored man who looked after the place at night handed me a stout bludgeon, with the remark: "Heah am yo' stahtah, Boss. Yo' kaint staht dis heah injine 'thout yo' stahtah."

"Starter for what?" I inquired.

"Why, fo' dis heah twadlash," he explained, as he indicated the head-end valve arm.

Sure enough! It wouldn't stay hooked up on the head end at starting, and my predecessor had apparently accepted it as a matter of course that the only thing to do was to keep prying the valve open until the governor rose to a running position. Of course, it was simply a matter of adjusting the safety cam on that end. This I quickly attended to.

At sight of the engine starting off unaided by the hickory stand-by he had offered me, my Senegambian mentor seemed transfixed with the wonder of it, while his ebony visage took on an expression of dumb amazement.

"Laws sakes, Boss!" he exclaimed when he recovered his breath, "yo' sho done chahmed away dat hoodoo, whatevah yo' done!"—*M. D. Conroy, St. Louis, Mo.*

Storage Batteries for Handling Peak Loads

By Everard Brown

SYNOPSIS—Improvement of load factor and plant economy as well as regulation, particularly in the case of hydro-electric generation, where storage batteries are employed to assist on the peaks of the load. Typical load curves show this for different classes of service.

In large central stations for electric power and railway service the use of storage batteries is common. Because of their rather high initial cost, however, this use is somewhat restricted to the larger power plants, although there are some installations among the smaller stations also.

The primary object of a storage battery in electrical-railway service is to relieve the generating apparatus of the larger fluctuations in load by taking care of the peaks that occur at certain periods of the day, and also to act as a reserve in case of a breakdown. By relieving the station of such fluctuations the generating units are free to operate at a steady and, consequently, an economical load. Moreover, storage batteries discharging on the peak loads

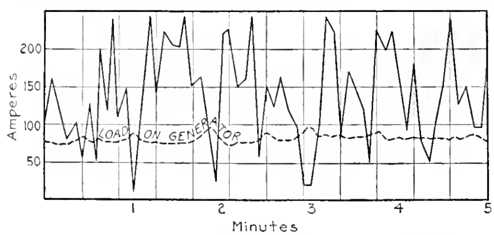

Fig. 1. Battery in Power House—Railway Service

and taking a compensating charge during the period of light load will raise the load factor, thereby improving the economy of the plant; and, by taking slight peaks on an increasing station load, they retard the time of starting additional engines. Figs. 1 and 2 show the fluctuations and peak loads over short periods in railway service as taken care of by a storage battery. In both it will be noticed that the battery is discharging much more than it is being charged. Such a condition occurs, naturally, at times when the traffic begins to increase or lights are put on, but not to such an extent as to warrant the starting up of another generating unit.

Heavy line batteries or battery substations are frequently used on railway and district lighting systems to relieve both the power station and the feeder system, but principally the latter, at times of high peaks. At other times they are used to regulate the voltage and care for the variations in the current. Without batteries the peaks can be taken care of only by extra generating apparatus at the main power station and extra feeders to the center of the load district. The substation battery, being located at or near the point of heavy load, eliminates these requirements and relieves the system of fluctuations, so that the cars or the lights or both, as the case may be, can operate at a steady voltage. The operation of a railway line battery taking fluctuations is indicated by Fig. 3, which shows that current was absorbed and discharged by the battery at very short intervals. In this

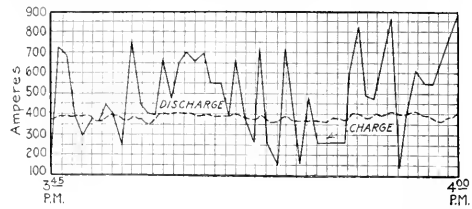

Fig. 2. Battery in Power House—Railway Service

case, however, the discharge is fairly well compensated by the charge.

In rotary-converter substations storage batteries may also be used to advantage. The installation of sufficient storage capacity in such a substation will relieve the converter of current fluctuations, so that the load on the transformers, high-tension transmission lines, and the alternators, engines and boilers in the generating station

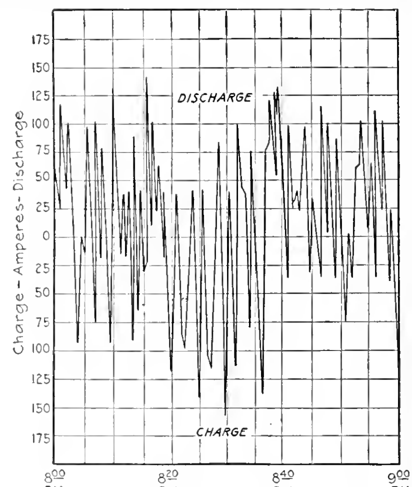

Fig. 3. Railway Line Battery Taking Fluctuations

may be maintained practically constant. An illustration of this may be seen in Fig. 4. The line pressure is maintained between the limits of 450 and 550 volts and is indicated by a nearly straight line. In this curve it will be noticed that the greatest demand upon the substation is between the hours of 6 and 10 in the morning and 5 and 9 in the evening. This is typical of street-railway service. It will be seen that the greatest amount of charging is done between 9 p.m. and 6 a.m., at which time the load is the lightest. Some charging is also done from 10 a.m. to 5 p.m., showing that the power-generating capacity is in excess of the load requirements during this period.

In hydro-electric plants good voltage regulation is often a difficult matter. At full loads a waterwheel usually

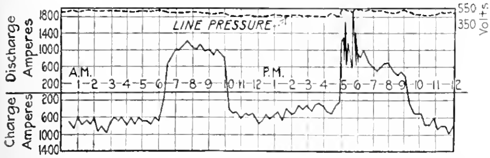

Fig. 4. Railway Line or Substation Battery Taking Fluctuations and Peak Loads and Regulating the Voltage

takes all the effective water that can pass through its opening at a given head, consequently an overload means a drop in speed. The load variation, moreover, is generally so rapid that the inertia of the water in the penstock prevents satisfactory speed regulation, regardless of how sensitive the governor may be or how ample the wheel capacity. These troubles can be largely overcome by

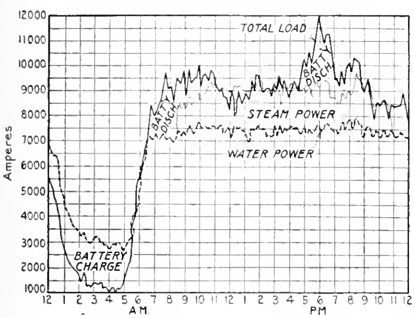

Fig. 5. Battery at Railway Power House Taking Peaks

the use of storage batteries. It might be said, in fact, that the introduction of such a battery is really equivalent to increasing the capacity of the plant in the same ratio that the peak removed bears to the average load. Results of such an installation may be seen in Fig. 5. In this station as much of the power as possible is generated by water and a steam plant in connection with a storage battery helps out on the peak. From midnight till 5 a.m., it will be noticed, the hydraulic generator had a surplus of capacity above the load requirements, so that some charging of the battery takes place. Then from 6:30 to 8:30 a.m. the battery helps the water power and defers starting up the steam plant about two hours.

For small light and power plants of limited output, Figs. 6 and 7 show what the storage battery will do. In such plants the day load is usually light; therefore, a comparatively small battery will supply current for a large part of the time and the battery can be charged in the evening or early morning, when the plant is in operation. In this manner a day service can be maintained at little expense for labor and with a materially decreased operating cost per unit of output. In addition to this there is the advantage, common to all kinds of power stations, of having an extra source of power ready in case of demand, thus insuring good regulation of the voltage.

In considering the installation of storage batteries the room should really be in a separate building, if possible, away from the rest of the equipment, and in order to keep down the temperature and to free the room from acid spray it should be well ventilated. In some instances it may even be necessary to resort to artificial ventilation by means of a fan or blower if the battery does considerable peak-load work and requires almost continuous charging at certain hours. As the gases given off during the charging of a battery form an explosive mixture if confined, this need of proper ventilation is important, as is also the keeping away of any exposed flame at such a time. In cold climates it is sometimes necessary to heat the battery room in order to obtain the maximum capacity.

In charging a battery the rise in voltage is quite gradual except near the beginning and the end of a charge, when it becomes more rapid. When fully charged the

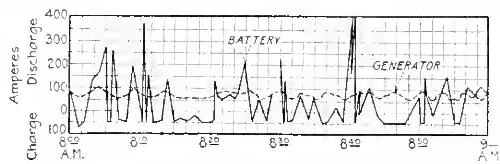

Fig. 6. Battery Taking Fluctuations of Motor Load—Small Plant

color of the positive plates varies from a reddish brown to nearly black and the negative from a pale to a darker slate color. The negative plates, however, are always lighter in color than the positive. Excessive discharging should always be prevented if possible, as it has a tendency to cause excessive heating of the electrolyte and disintegration of the plates. This disintegrating as well as buckling of the plates and sulphating are the most serious troubles incident to the use of a storage battery, but these can be avoided to a large extent by proper attention. Man-

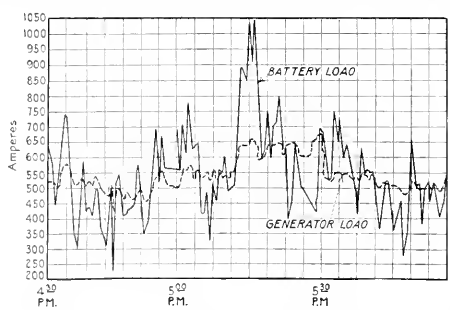

Fig. 7. Battery Taking Fluctuations at Railway Power House of Limited Output

agement of a battery installation requires more experience and care, however, than the handling of electric generators, because of the chemical actions which occur in the former and which are more difficult to determine and correct than mechanical or electrical difficulties encountered in the generator. As for depreciation charges, they are somewhat higher, averaging about 8 to 10 per cent.

Safety-First Water Column

The high- and low-water alarm column, Fig. 1, has the outside appearance of an ordinary safety water column. It differs, however, in that it has no floats. Instead, it has two solid metal weights hung one above the other by bronze rods (Fig. 2) from the opposite ends of two bronze levers which rest on a bronze knife-edge fulcrum.

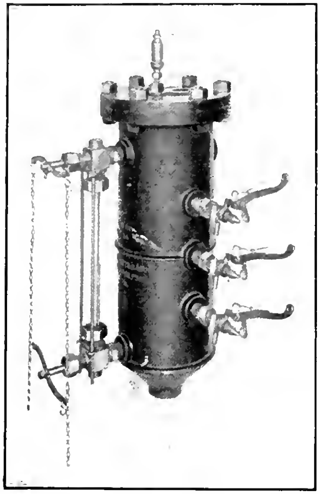

Fig. 1. Safety-First Water Column

The two weights are so designed that the bottom one is the heavier when both weights hang in steam or when both are submerged, as would be the case at extreme low or high water; the top one is the heavier when the bottom one only is submerged, as would be the case when the water level is between the top and bottom gages.

One of the bronze levers is connected to the alarm whistle valve by a knife-edge bearing. The valve and seat are made of monel metal.

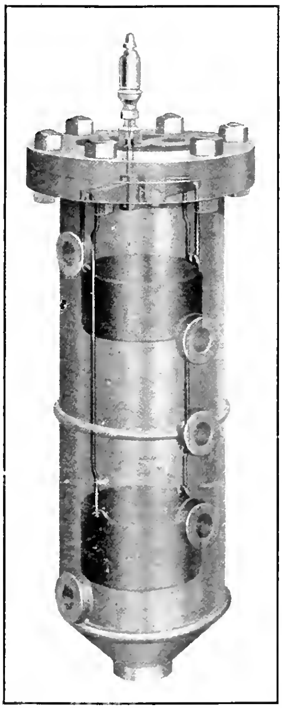

Fig. 2. Arrangement of Weights and Levers

Referring to Fig. 2, it is evident that when the water stands at any level between the top and bottom gages, the bottom weight will be submerged and the top one will hang in the steam space. Under these conditions the upper weight will weigh more than the lower one, and will hold the whistle valve closed.

Should the water fall below the bottom gage, the lower weight will weigh more than the upper one, which will rise and open the whistle valve, thus giving the low-water alarm.

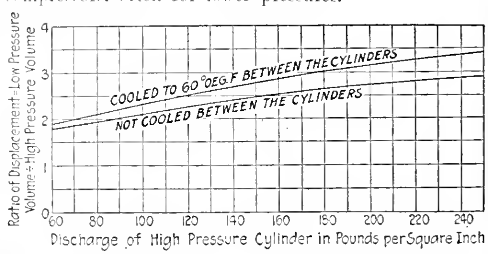
Should the water rise above the top gage, the upper weight will weigh less, and the lower one will overbalance it, which causes it to rise and open the whistle alarm for high water.

This appliance is manufactured by the Engineering Company of Philadelphia, Harrison Building, Philadelphia, Penn.

Cylinder Ratios for Air Compressors

By F. W. Salmon

Many steam-driven air compressors have to operate at speeds differing greatly from hour to hour to suit the demands for air. This makes it desirable to choose the cylinder ratios of the two-stage air ends with great care, so that the machine may operate steadily and smoothly without danger of stopping on a dead center even at the lowest speed, for naturally, a two-stage compressor will be chosen in most cases to secure economy in power for pressures of 80 lb. or higher, and in the case of large compressors, often for lower pressures.



Ratios with and without Intercooling

The curves show the volumetric ratios required for a two-stage air compressor taking dry air at atmospheric pressure at sea level and delivering it from the high-pressure air cylinder at pressures of 60 to 250 lb. gage, both cooled and not cooled between the cylinders. Moreover, they are calculated to give the same power in the high-pressure cylinder as in the low-pressure.

In various books on compressed air, such as that by Frank Richards, Kent's "Mechanical Engineers' Pocket-Book," and Suplee's "Mechanical Engineers' Reference Book," are given tables showing the horsepower required (neglecting friction) to compress and deliver one cubic foot of free dry air per minute at atmospheric pressure, to given discharge pressures, both isothermally (perfectly cooled between the cylinders and during the compression) and adiabatically (not cooled at all). This given horsepower has been divided equally between the two cylinders and the mean effective pressures calculated for each, as well as the resulting intercooler pressure, which may be taken as the initial pressure for the high-pressure cylinder. Hence the volumetric displacement to meet these conditions could be readily calculated for several of the pressures given, including the 60-lb. and the 250-lb., and a smooth curve drawn through the points so obtained on the chart. This covers the range of pressures needed in over 95 per cent. of the air compressors sold, and it can be read close enough for all ordinary work, because in commercial practice air compressors are rarely made to bores of fractions of an inch.

Practically all air compressors operate between the limits shown by the two curves. Even in a single-stage compressor the air is cooled somewhat during compression, and yet in the best two-stage machine it is never quite as perfect as isothermal compression; hence in practice it is wise to choose the nearest commercial cylinder sizes that fall between the curves shown in the chart. Of course, one should consider the actual volume of air displaced from each cylinder rather than the piston displacement, as the cylinder ratio depends upon the volumetric efficiency of each cylinder, which is rarely the same for both the high- and the low-pressure cylinders. This is illustrated in the following example:

Assume, that in order to deliver the air required, a 24-in. low-pressure cylinder will be used having a 30-in. stroke and giving a volumetric efficiency of 0.90 for this stroke with the type of valves used. The size of the high-pressure cylinder is desired that will discharge air at 100 lb. gage, with the same stroke, but with a different type of valve which will probably give a volumetric efficiency of 0.85.

Running up the 100-lb. line the best cylinder ratios are found to be 2.11 not cooled or 2.30 cooled. As both cylinders are to have the same stroke, only the areas have to be considered; hence, if A represents the area of the low-pressure piston in square inches and a the area of the high-pressure piston in square inches, then,

$$a = \frac{A \times 0.90}{constant \times 0.85}$$

or

$$a = \frac{452.4 \times 0.90}{2.30 \times 0.85} = 208\ sq.in.;$$

say 16¼ in. diameter (if fully cooled), and

$$a = \frac{452.4 \times 0.90}{2.11 \times 0.85} = 227\ sq.in.;$$

say 17 in. diameter (if not cooled).

Thus, there is not much difference, and as explained above, actual practice will lie between these two curves. Of course, if the cylinders are of different strokes, their volumes must be considered instead of their piston areas.

Recedence and Pressure Readings from Submerged Pumps

By G. B. Covington

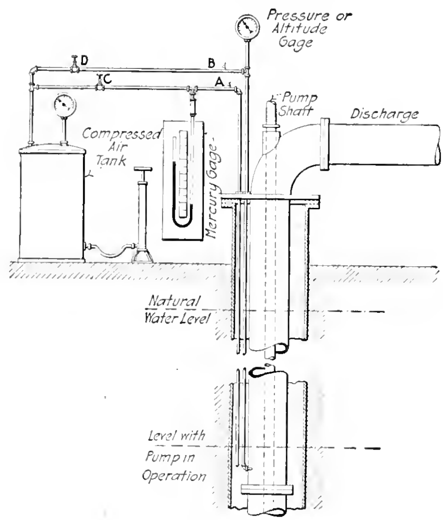
The recedence in level of a deep well, due to its being pumped at various rates, furnishes reliable data as to its capacity. The method of determining the differences in level by an apparatus which may be either constructed as a permanent fixture or made up as a "portable," may be of interest, as in most cases no space is available in the well casing in which to lower a float or other device by which to gage the levels.

For determining the recedence a tube A, shown in the sketch, is let down the well outside the discharge casing, so that the submerged end will be several feet below the natural water level, which, if not known, may be ascertained by experiment.

The tube may be of ¼-in. pipe made up as shown, with valve C for air control and a mercury gage tapped in between it and the submerged tube. Air must first be compressed in the tank (if no service supply is convenient) to a considerable pressure in excess of that due to the submergence of tube A, which may be determined in the following manner: Upon opening the valve C and upon closing the same after a maximum pressure is indicated, the mercury column should recede an amount which will represent the friction of the air in the tube at the rate at which it has been admitted. The static reading is then noted.

Upon starting up the pump or air lift, the operation is repeated, and the difference in the two static readings represents the recedence of the well level. These may be reduced to feet and inches and plotted against "pump delivery."

A similar device for determining the total head under which the pump operates is indicated at B, Fig. 1. The



Method of Determining Recedence and Pressure of Deep Wells

same process of operation will give accurate results with reference to the head under which the pump is working. The friction head without the use of such a device could only be guessed at.

Obviously, all readings must be taken immediately after shutting off the air supply at C or D, otherwise erroneous readings might result, due to a change in temperature of the air confined in the tubes, or slight leakage.

According to the "Electrical World," the main prime mover in the generating station at Independence, Kan., is a double-acting twin-cylinder Strait gas engine, and at one time when this machine was needed to help carry the load an exhaust valve began to give trouble. Shutting off the gas and ignition from the cylinder affected, the men on duty opened the valve chest, took out the defective valve, and replaced it in less than three hours without stopping the engine. The greatest difficulty experienced came from exhaust gases that were discharged up through the manifold from other cylinders. This trouble was overcome by placing a small motor-driven forge blower in such a position that its blast drove these foul gases away from the workmen's faces.

Large Surface Condenser for Commonwealth Edison Co.

The accompanying drawings show the largest Wheeler surface condenser so far built, which is to be installed in connection with a 35,000-kw. turbo-generator at the Northwest Station of the Commonwealth Edison Co., of Chicago.

Looking first at the end elevation, the circulating water entering the station by the inlet tunnel shown at the bottom of the drawing is picked up by the 3½x4½-ft. rectangular suction pipe of the circulating pump. This pipe is in the form of a gooseneck, the top of which is between 11 and 12 ft. above the pump center. The pump is below the water level, but is protected from flooding by this siphon and no valve is needed. A priming pipe shown connects the pump with the water in the riser of the siphon when the small valve is opened, and this enables the pump to pick up its suction and draw the main volume of water over the siphon.

The circulating pump is of the tri-rotor high-speed design for direct-connected drive at 1500 r.p.m. The turbine is a specially designed unit built by the General Electric Co., arranged for driving the circulating pump from one end of the shaft and the air pump from the other, as shown in Fig. 4.

The delivery of the circulating pump is connected through an expansion joint with the water intake of the condenser, and under normal conditions 50,000 gal. of water per minute flows in two passes through the condenser, leaving at the upper left-hand segment in the end elevation, Fig. 1, through a circular discharge main to the outflow tunnel.

Steam is exhausted from the main turbine through a passage about 12x14 ft. in area. The contour of this passage is shown in the plan, Fig. 3.

Upon entering the condenser, the steam first impinges

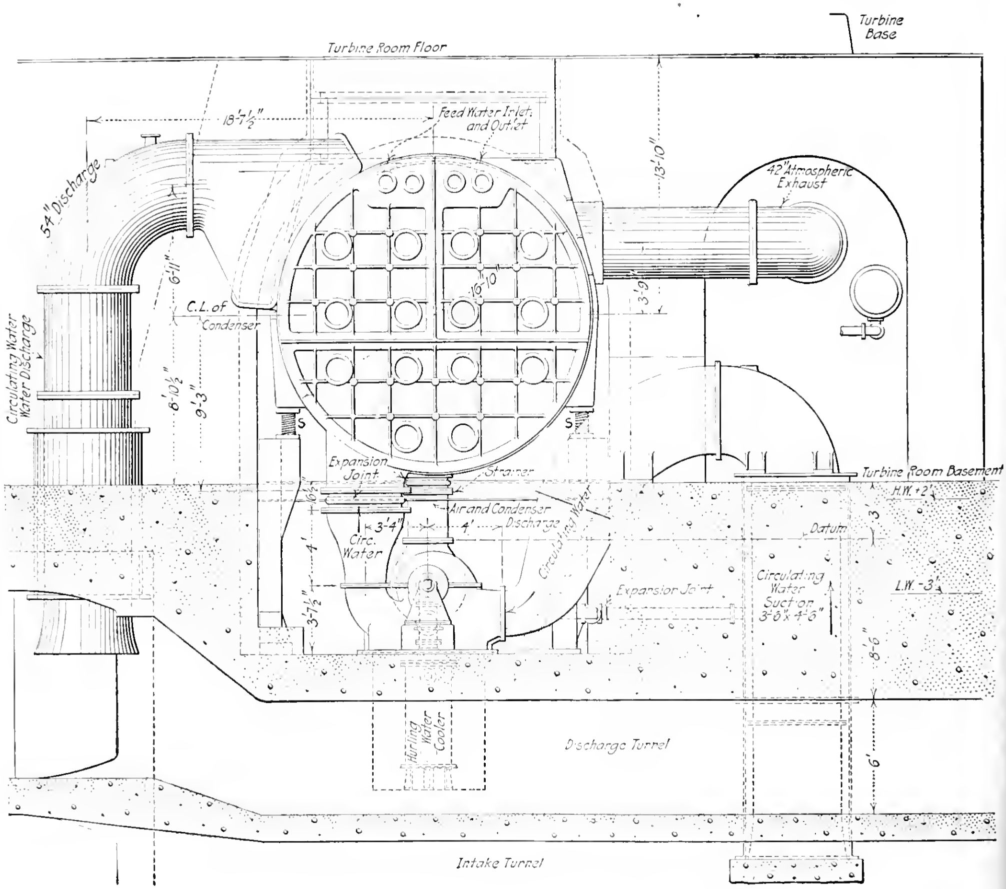


FIG. 1. END ELEVATION OF LARGE WHEELER SURFACE CONDENSER

upon feed-heating tubes arranged at the top of the shell as shown at *AAA* in Fig. 7, through which the condensate is pumped before going to the boiler plant. After giving up part of its heat to these tubes, the steam flows into the condensing space proper, which is arranged with extra wide tube spacing and with the tubes disposed in lines parallel to the flow of the steam. A steam belt extends well below the center of the shell, thus admitting steam well down into the sides of the condenser, all of these features combining to give free flow of steam into and among the tubes. The air is drawn off in the center at the bottom of the condenser through a large outlet pipe, which also carries off the condensate. Baffles *CC* at the sides prevent the short-circuiting of the steam to the outlet.

compression channels; and these plugs, by the momentum due to their high velocity, force the entrapped air before them into the discharge passage against the pressure of the atmosphere. The hurling water enters at *E*, Fig. 5, and is discharged with the air at *C*. In Fig. 2 the combined air and condensate pump is shown at *A*, the hurling water entering at *E* and discharging at *C*, into the well below, the air separating off, the water passing through the cooler alongside, on its way back to the pump. The condensate flows by gravity to the other impeller of the pump at the left in Fig. 5, and is discharged through the pipe *F*, through the heater tubes at the top of the condenser and then to the boiler plant.

The combined Wheeler condensate and turbo air pump

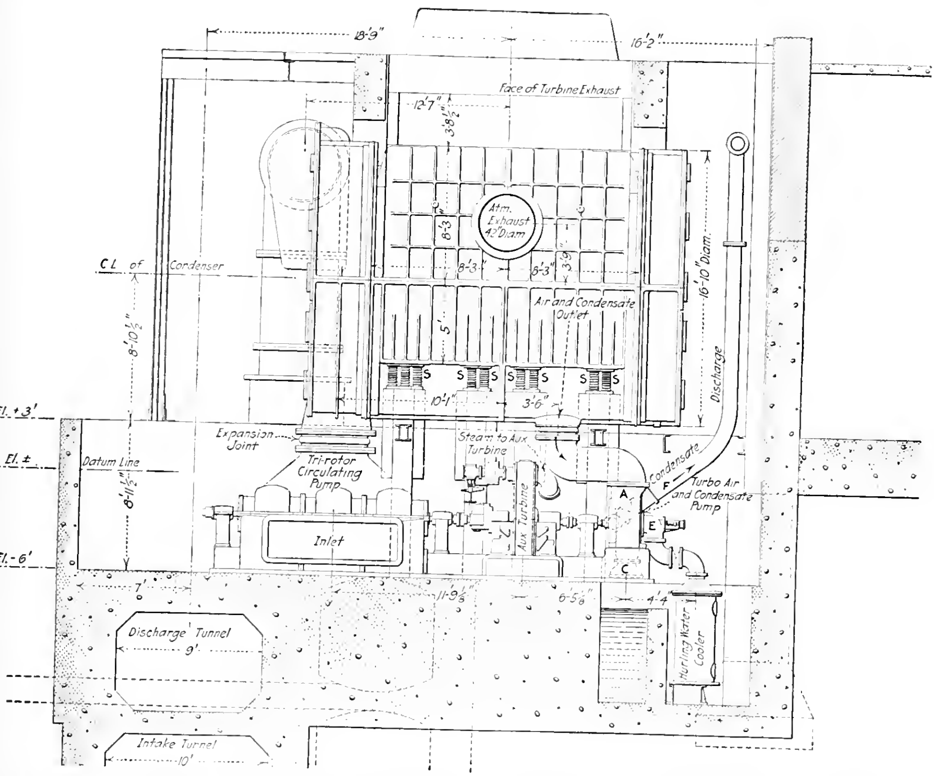

Fig. 2. Longitudinal Elevation of the 50,000-Sq.Ft. Condenser for the Commonwealth Edison Co.

This arrangement of a single outlet for the condensed steam and for the noncondensible vapors is unusual in large condensing units, but was possible in this instance because of the design of air pump which was employed. A section of the pump is shown in Fig. 5. The air and water enter the pump by a common pipe, but are handled separately within the casing. As the condensate enters the chamber *A*, the air turns off from it to the compartment *B*, and is forced out into the chamber *C* by a turbo-air pump impeller shown at *DD*. The action of this pump is shown in Fig. 6. The impeller discharges at high velocity streams of water which are cut into plugs by the sharp edges of the separations of the

is driven by the same auxiliary turbine which drives the tri-rotor circulating pump. Thus the condenser auxiliaries are very much simplified, require less floor space and piping, and less attendance.

In order to allow the condenser free play under varying conditions of vacuum, temperature, etc., its weight is carried upon 18 heavy railroad-type springs, as indicated in Figs. 1 and 2, at *SSS*, the springs resting upon heavy concrete pillars. The shell of the condenser is made of heavily ribbed cast-iron sections, division being horizontally at the center and vertically at the center, making eight sections in all. The weight of shell, tubes, water boxes, piping and contained water will be approximately

200 tons, but this downward force is counterbalanced by an upward force when the vacuum is 29 in., of nearly 170 tons—the upward pressure of the atmosphere on the projected area of the 12x14-ft. opening.

At its maximum capacity this condenser takes care of 400,000 ÷ 50,000 = 8 lb. of steam per sq.ft. of heating surface per hour, which is "some steam" even if it be allowed that 15 or 20 per cent. of it has been already condensed. Imagine an immense pan, 250 ft. long and 200 ft. wide, full of water, over a fire burning with an intensity which would evaporate from every square foot of the water surface over twice as much water as a boiler does at its rated capacity, and you have an

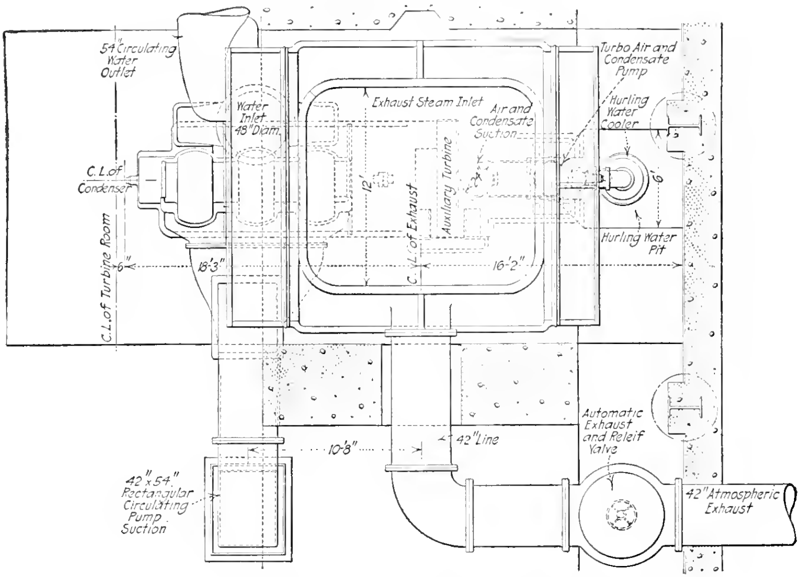

FIG. 3. PLAN OF CONDENSER PIPING AND AUXILIARIES

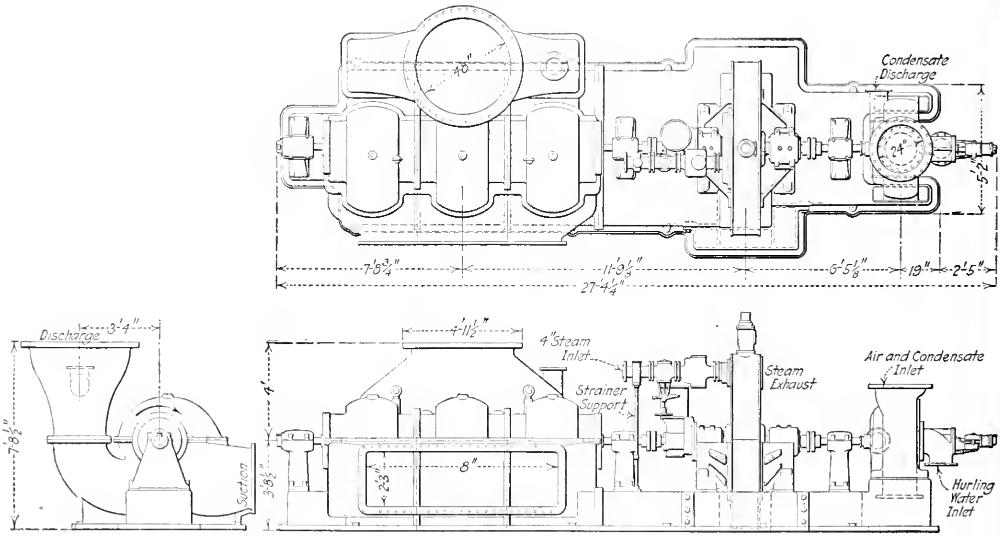

FIG. 4. PLAN, END AND LONGITUDINAL ELEVATION OF TURBINE-DRIVEN PUMPS

There are 50,000 sq.ft. of surface in the condenser, made up of 18 B.w.g. brass tubes. The rated capacity of the condenser is 360,000 lb. of steam with a maximum of 400,000 lb. per hour, and the vacuums to be maintained throughout the year average about 29 in.

idea of the rate of work which this condenser has to undo.

At 75 lb. of condensing water per pound of steam the condenser would require 75 × 400,000 = 30,000,000 lb. of circulating water per hour or over 130 cu.ft. per sec., an amount which with a fall of 10 ft. would develop

$$\frac{30,000,000 \times 10 \times 0.80}{33,000 \times 60} = 121\ hp.$$

and which flowing at the rate of 2 ft. per sec., a rather high rate for a mill race, would make a stream 10 ft. wide and 65 ft. deep. At 29 in. vacuum, or at an average pressure which would support one inch of mercury, the volume of a pound of dry-saturated steam is 654 lb. At its maximum capacity the condenser handles 400,000 lb. per hour or

$$\frac{645 \times 400,000}{3600} = 71,667\ cu.ft.\ per\ sec.$$

which to pass through the 12x14-ft. passage by which the condenser is connected to the turbine would have to have a velocity of 427 ft. per sec. One hundred miles per hour, which is less than 150 ft. per sec., is characterized in the wind tables as an "immense hurricane."

It is true that steam initially at 200-lb. gage, and

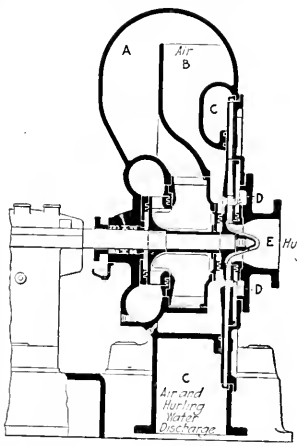

Fig. 5. Combined Condensate and Turbo Air Pump

with 100 deg. of superheat would condense between 20 and 25 per cent. of itself by expanding to 29-in. vacuum, but this is for the academical case of true adiabatic expansion and a 100-per cent. turbine. If the steam rate is 8 lb. per hp.-hr. corresponding to 12 lb. per kw.-hr. and an over all efficiency of 90 per cent. the turbine is converting

$$2546.56 \div 8 = 318\ B.t.u.$$

from each pound of steam into work, 2546.56 being the equivalent in B.t.u. of a horsepower-hour. Steam of 215 lb. absolute pressure superheated 100 deg. contains 1259 B.t.u. per lb. If 318 of these were converted to work there would be

$$1259 - 318 = 941$$

left. The heat of the liquid at 29 in. vacuum, or 1-in. pressure is about 47 B.t.u., which leaves

$$941 - 47 = 894$$

for latent heat. As the latent heat of dry-saturated steam of this pressure is 1047 the quality would be

$$897 \div 1047 = 85\ per\ cent.;$$

that is, for the actual case there would be something like 15 per cent. of the steam already condensed when it came to the condenser instead of the twenty-odd per cent. of the perfect turbine, even including the effect of the heat lost by radiation. It is expected that the condenser will be installed and in operation during the coming summer.

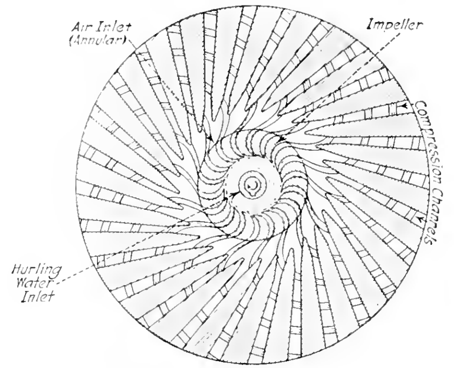

Fig. 6. Showing Action of Turbo Air Pump

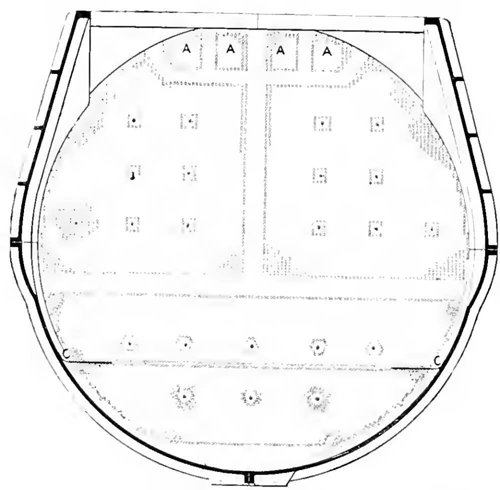

Fig. 7. Showing Arrangement of Tubes and Steam Passages

For the above information and use of engravings we are indebted to Sargent & Lundy, of Chicago, consulting engineers to the Commonwealth Edison Co., and the Wheeler Condenser & Engineering Co., Carteret, N. J., manufacturers of the apparatus.

⁂

How Germans Have Crippled French Industry—Dr. Schrodter claims, in a recent issue of "Stahl und Eisen," that although the French territory occupied by the Germans is less than 4 per cent. of the total area of France, it contains 24.8 per cent. of the steam boilers in number, and 43 per cent. in capacity, for 11 of the principal industries the boilers used by which have been shown in recent official reports.

Synchronous Motor in Low-Pressure Turbine Plant

A POWER contributor has written, asking if there was not something unusual in the manner of controlling the synchronous motor mentioned in the article, "Performance of Low-Pressure Plant," in our Dec. 1, 1914, issue. There is not. However, as many readers may be interested to know how a synchronous motor is controlled when driven by a low-pressure turbo-generator and belted to the same jackshaft as the engines which supply steam to the turbine, the following, from the Jenckes Spinning Co., of Pawtucket, R. I., owners of the plant, will be of interest:

"The synchronous motor is belted to the main jackshaft, which is driven by the reciprocating engines. It also runs in parallel with the low-pressure turbo-generator. The turbine is really of the mixed-pressure type, and when first installed the main or high-pressure valve was left open to be operated by the governor. Much difficulty was experienced with the regulation and it occurred to the owners to shut this valve, so that the turbine would never get anything but low-pressure steam. Now, all the governing is done by the governors on the engines. The synchronous motor floats on the line. When the load on the engines falls off and the turbine is not getting enough steam, the load is made up by the synchronous motor being driven as a generator, which, of course, admits more high-pressure steam to the reciprocating engines and more low-pressure steam to the turbine, and the balance is again restored; if the reverse is true, or the turbine is getting more steam than it can use, it drives the synchronous motor which takes more of the load off the reciprocating engine, which cuts down the supply of high-pressure steam and again restores the balance."

Hose-Clamping Tool

A convenient little contrivance for tightening clamping wire about hose, such as is used around the power plant, is made by the Wieder Manufacturing Co., Warren, Ohio. The tool consists of holder and handle and a slotted pin in which a lever is fitted, Fig. 1. This pin fits in a hole in the main part of the implement, which has a slotted projection at the end for receiving the binding wire.

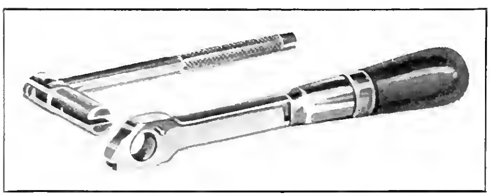

FIG. 1. HOSE-CLAMPING TOOL

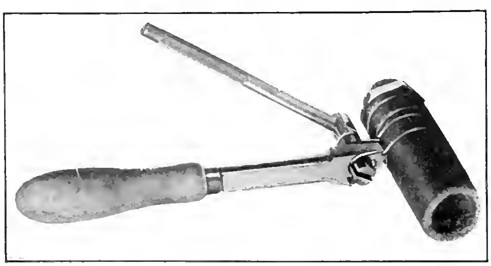

FIG. 2. TIGHTENING THE BINDING WIRE

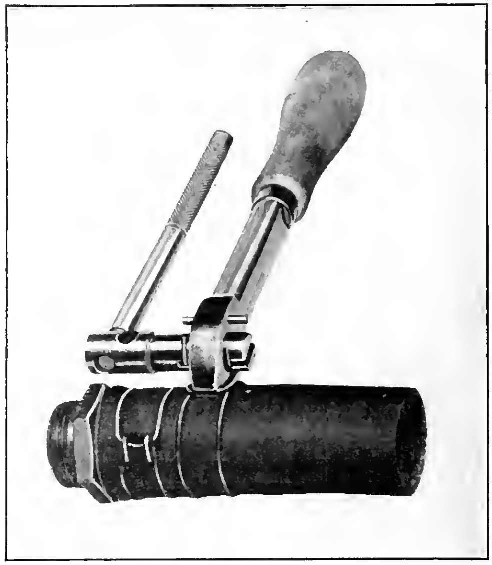

FIG. 3. READY TO TIGHTEN BINDING WIRE

The application is simple. The wire is placed in the slotted end of the tool and bent around, the ends coming about even. The device is then placed against the hose and the loose end wound around the hose and passed through the loop in the wire and the slot in the tightener stud, as shown in Fig. 3. Then it is only necessary to push the lever in the direction to tighten the binding wire, and when tight bring the lever over to bind the loose ends over the end, forming the loop, Fig. 2.

Remarks of the Secretary of Commerce—In passing on the case of an employee who complained that he was required to do work beneath his position in the Department of Commerce, Secretary Redfield said:

You may understand it as my views generally in matters of this kind that I do not know what the kind of work can be which is beneath any man's position. I think there is no work of which I know or have heard that it is beneath my dignity to do, and I am glad to say that I have done the plainest and hardest and, what is sometimes mistakenly called, the most menial work, and am ready to do it again if there is occasion for it. There is no man in the department that ought not be willing to do any kind of decent and honorable work whenever circumstances require it of him, and I know of no work with either hands or head which is not both respectable and honorable if done with the right spirit.

The "Storstad" and the "Empress of Ireland"—The action of the Canadian Pacific Railway Co. against the former owners of the Norwegian collier "Storstad" for the ramming and sinking of the liner "Empress of Ireland" in the St. Lawrence is before the Admiralty Court, Montreal. Originally the claim was for £400,000, but this has now been increased to £600,000, the additional £200,000 being, it is understood, to cover actions for damages by loss of life, either on the part of the relatives of the crew under the Workmen's Compensation Act or otherwise. The "Storstad" was sold for £35,000, which was paid into court, and this amount will be available for, and distributed among, all those who substantiate their claims to it. The Mersey Commission fixed the onus of the blame on Chief Officer Tuftness, of the "Storstad."—Exchange.

Editorials

Another Tribute to Engineers and Firemen

One of the chief lessons thus far taught the world by the European war is the importance of speed in naval activities. More than ever before in history, a difference of a very few knots in the ability of a war vessel to cover a course is counting in the final outcome of conflicts on the sea. Nothing less than speed enabled the now famous "Emden" to pursue her career; speed permitted the "Dresden" to escape so long after the battle off the Falkland Islands; and it was this quality again that so prolonged the destructive mission of the "Karlsruhe." Lack of speed prevented the old-style battleship "Canopus" from joining Sir Christopher Cradock in time to avert the disaster off Coronel, and it was speed primarily that enabled Admiral Sturdee's squadron to crush that of Von Spee immediately after reaching the Falklands.

The value of being able to make twenty-eight knots per hour instead of twenty-four has been demonstrated by the battle cruisers of both Germany and Great Britain in the stirring encounters of the North Sea this winter, and it needs no naval expert to put into words the bearing high speed is likely to have any day upon events of supreme historic interest on the ocean. Only a look beneath the surface is necessary to disclose the importance of faithful performance of duty on the part of the power-plant staff afloat, and it is no discredit to the navigating officers or to the men behind the guns to raise one's hat for a moment in honor of the brave fellows of engine room and stokehole on both sides of the combat whose devotion to throttle and shovel, valve and slice bar, amid fearful and unseen perils, is powerfully helping to decide the issues in the greatest struggle known to history.

Relations of the Consulting and the Operating Engineer

A large part of the work of a consulting engineer consists of analyzing conditions in isolated plants, testing their equipment, and advising their owners what to do to improve the service. Often he is called on the advice of the operating man; more often he is not. To have another step in and tell you how to conduct your own business, especially if he is retained without or against your advice, provokes resentment. But this attitude is becoming less general. Often, the man who protests most about the intrusion of the specialist (in our case the consulting engineer) feels that exposure of his weaknesses is imminent, and of course fights against it.

Consulting engineering, like other professions, has its quacks and fakers. But this kind of man soon gets a reputation that does not help him to do more business or to hold the approbation of his fellow engineers. The work of the consulting engineer brings him in contact with a variety of conditions and things which, together with his technical training, give him opportunities to gain experience that the operating man cannot hope to acquire. It is mainly this difference of training which distinguishes one from the other. If it were possible for operating men to receive such training, there would be need of but few consulting engineers.

The chief cause for the ill feeling that so many operating men have for consulting engineers is not merely because one operates and the other advises and plans. Most power-plant engineers appreciate the professional services of consulting engineers, but are too often suspicious of their presence because of petty things experienced or heard about. For example, a consulting engineer may advise that the present engineer be displaced to make room for a friend of his own. Sometimes, this course is necessary in order that the work which has been done, or is to be done, may be properly carried on.

A man who has been placed in his position by a consulting engineer sometimes feels that his employer is having unnecessary work done on the advice of the consulting man, or that the latter is charging an exorbitant price for his services for certain jobs. He is under obligation to the consulting engineer who got him his job, and rather than incur the displeasure of his benefactor by informing his employer of his suspicions, he drugs his conscience with the conclusion that the employer has money enough to stand it and, after all, no real harm has been done. These cases, we hope, are rare.

It is difficult for most operating engineers to judge of the equity of a charge for consulting work; also, without full knowledge of the work planned, it is not always easy to decide that unnecessary work is being done. The engineer who feels that such conditions exist in his plant should acquaint his consulting engineer with his opinions and thus satisfy himself whether he is right or wrong. Otherwise, a decision arrived at by snap judgment might cause him to lose not only his friend but his job.

A consulting engineer should not make a big ado about reducing the labor force in a plant when the good to follow will soon be offset by losses due to neglect because of a shortage of labor. Little mistakes of this sort sometimes lead to long disputes with labor unions and involve more than a commensurate amount of worry, time and money. Then again, it must be acknowledged that in some plants a reduction of the labor force is justified and often proves a benefit to those laid off, because in new positions they can develop their usefulness to a greater extent than would be possible in positions where time killing was the chief occupation.

Operating men sometimes accuse consulting engineers of playing into the hands of a central station. It is difficult to believe that these alleged acts are numerous enough to warrant as much attention as they receive in some quarters. Usually, when a reputable consulting engineer makes such recommendations, he does so because the condition of the plant, the owner's financial circumstances, and the power consumption all warrant the use of purchased power.

When a plant has been allowed to deteriorate through years of neglect, as some have, and chiefly because those in charge did not sufficiently understand their business, the blame for what eventually happens to it is, first, the owner's, for hiring such poor service, and, second, the engineer's, for not knowing enough of the art of his calling to take care of his own interests.

Granting that consulting engineers are sometimes guilty of malpractice, that some of them stoop to deeds unbecoming a professional man, the conclusion is reached, unwillingly, perhaps, that a great deal of the operating engineer's troubles exist because he does not realize that running a power plant today means more than it did in a past well within the memory of us all. This condition should not exist, for there are many channels open to all for cheaply acquiring the knowledge demanded in modern power-plant practice.

Evils of Low Bidding

In spite of all that has been said and written against these evils, slipshod methods in estimating and underbidding are as common as ever. Nearly every failure can be directly traced to careless bidding and a total disregard of overhead and suitable profit.

Bidding on heating work still seems to be based on so much per square foot of heating surface, and on plumbing, so much per fixture installed. Such methods should never be used except as a check upon a properly made estimate, yet curiously enough, an ever increasing number are still willing to try to make a living by these guesswork methods.

To succeed, every business, great or small, must be operated with a clear conception of overhead expense, or calling it by a better name, the cost of conducting business. This will vary slightly from year to year according to the volume of business done, and should be carefully obtained in percentage upon the cost of the volume done over a given period. Past performance will usually serve as a guide, to be used conservatively in ensuing operations.

Before any article is sold or any work entered upon, the complete cost to the bidder should be known as nearly as possible. First, one should find out just what material is required and its cost, then add the percentage of overhead. The labor required to do the job is the hardest item to estimate accurately; it is usually hard to get away from the allowance of so many hours for fitter and helper per fixture, and if cost cards have been properly kept of previous work, this method is often adopted. It would seem better to analyze each stage of the work and figure on the mean speed of the men, and then check the result by the method mentioned, remembering always that it is safer to over-estimate this item than to under-estimate it. To the labor estimate should be added, as before, the percentage for overhead. The continued difference in bids for the same job and the increasing number of failures show the persistence of careless bidding.

Such ruinous competition works to the moral detriment of the trade as well, inasmuch as the successful low bidder, to come out whole if possible, is tempted to resort to questionable methods in trying to beat the specifications. This reflects on him by the constant disputes, the length of time necessary to collect the final payment, and the knowledge that he will not have a chance to get a repeat order from that customer. Really successful bidders are known better by the number of their old or constant clients, whose good will is the best advertisement possible.

A little missionary work on the part of the technical societies might do something to correct these unfortunate conditions.

The Merit of Individual Effort

The ability to do work above the ordinary is not acquired without special concentration and endeavor. This is what may be called individuality. This characteristic must be developed with several attendant factors if the results are to be what the ambitious worker desires. The expert craftsman of any kind needs that individuality, for he uses his brain as well as his hands. For several reasons this attribute is often highly developed in the man who operates or works in the smaller plant.

There is an abundance of commonplace workers and their position has become precarious, for they are in danger of losing their individuality and power to rise higher than their fellowmen. The man who operates a plant of medium size need not fear being eclipsed by the man who operates the big plant, for in the latter, individuality may be smothered in the volume of work. All depends upon the man himself; he must prove his ability for higher-grade work. If his plant is small and his workers few, he has the greater opportunity to show his individuality. Where resourcefulness and work of the higher grade are sought, one looks to the expert rather than to the utility man.

The man operating a moderate-sized plant is better able to realize his ideals. His operating costs are low, he has only a small force, and his overhead expenses are small. Given these conditions, if his service deserves it, there are not the usual obstacles to his getting sufficient remuneration to more than pay for his seeming limited place in the industrial world. He can give such attention to details that his work will be a source of satisfaction and pride. It should be understood that he must hire only such men as will become an inherent part of his individual operation. This makes the genius, the man who has striven to rise above the ordinary work, an eager worker, and one who can in this way develop his latent powers to excel those who are in the ruts of contentment.

With a limited number of machines and a power that can be supplied at low cost, the operator of the small plant has an opportunity to compel attention. Let him specialize. There never has been a greater demand than exists today for the specially expert. To gain recognition calls for courage, concentration, labor and stability. The man who shows these qualities, no matter how humble his position, is bound to rise.

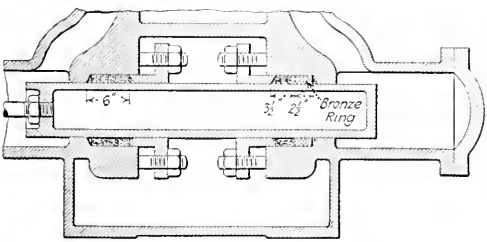
It is greatly to be regretted that Congress failed to approve the two hydro-electric power bills before adjournment. This failure, of course, means that another year of inactivity must pass before anything can be accomplished. Meanwhile the mills are not grinding with the water that is passing.

Correspondence

Depth of Stuffing-Box

The illustration represents the packing-boxes on an outside-packed pump, which was not satisfactory on account of leakage. This pump works on 150 lb. steam and a vacuum of 25 to 26 in. When the packing is tight enough to stop the leak the pump will labor and tremble as if under a very high pressure. Is this due to the deep packing-boxes? Each stuffing-box is 6 in. deep, and the 12 in. of packing, when tight enough to prevent leaking, causes a great deal of friction besides the pressure and vacuum duty.

My suggestion is to replace 2½ in. of the packing-box with a bronze ring made to fit the stuffing-box and



Proposed Bushing for Stuffing-Box

the plunger closely, but not tight enough to cause friction, and to fill the other 3½ in. with three rings of soft square flax packing, thus reducing the total amount of packing from 12 to 7 in. I believe this will permit us to tighten the packing and stop the leaking and still allow the plungers to work freely. I have reduced the number of rings on other pumps from four to two and found that they work better with less power. The packing lasts just as long, and the lining lasts longer than when four rings were used.

Charles E. Sherman.

Manasquan, N. J.

Priming a Centrifugal Pump

The article in the Mar. 2 issue, page 294, on "Priming a Centrifugal Pump," by J. F. Jones, is interesting. Many would like to know more of the details of this unique installation, accident, and repair. In the first place, will Mr. Jones tell how far above the lower water level the pump was and how high the water had to be elevated to reach the irrigating flume? I suppose the dimension of the pump (30 in.) refers to the diameter of the suction and discharge pipes; and this and the capacity (25,000 gal. per min.) stamp the machine as belonging to the class of large pumps. Will Mr. Jones also tell whether he had any trouble with the side thrust from the unbalanced condition implied by the use of one feed pipe? The principle of priming this pump, though a rather large one, should apply to smaller pumps, with which we have all had our troubles.

I have seen centrifugal pumps which were said to work without priming over a suction rise of 6 to 8 ft. These were only 5- or 6-in. pumps, delivering 1000 or 2000 gal. per min. to a discharge rise of 5 or 10 ft. In my experience I have almost invariably had to prime centrifugal pumps, and my experience covers several, from small ones to 10- and 12-in. pumps throwing 4000 gal. per min. to a height of 50 ft.

The tricks of priming were many. One of the easiest was to let enough water from a storage tank flow back to cover the blades of the pump, and then start, when almost invariably, it would pick up the load at once. There was a check valve below the pump, which, of course, made matters much easier than the conditions described by Mr. Jones. He certainly used his wits in sealing the discharge end with the revolving impeller beating the water that remained in the discharge pipe, and then catching the pump with enough vacuum from the steam ejector to raise the water from the intake below the pump. It would be interesting to know the maximum lift for which this method of starting a pump with steam ejector would apply, and still more so to know just how high this particular pump did work, for it is true, in my experience, that such tricks as this of Mr. Jones' are comparatively easy with small pumps, but become increasingly difficult with increasing size of the pump.

The matter of the collapse of the discharge pipe, built to stand 150 lb. internal pressure and failing under less than 15 lb. external pressure, is also interesting, and I hope that experienced pipe men will favor us with some good common-sense explanation.

Newtonville, Mass.

Analyzing the Plant's Condition

The report on the condition of the plant under the care of J. C. Hawkins, in the Feb. 16 issue, is interesting and instructive. It also tends to develop enthusiasm, and this alone helps more than anything else to maintain high efficiency in the plant.

The questions in the "New Years Letter" (Jan. 19 issue) cover nearly everything, but a few more might be asked:

1. Is the coal-storage pit moisture-proof? If it is not, much time and labor are lost from too much moisture in the coal.

2. Is the distance between the storage pit and the furnace as short as possible? If not, there is a further loss in time and labor, also wear and tear on extra machinery.

3. Is the percentage of the redeemed waste heat, that is, the heat in the chimney gases and in the exhaust steam, high or low?

4. Have we all the tools necessary for emergencies? If we have, the length of shutdowns will be minimized.

5. Are we using the right grades of cylinder and machine oils?

6. Is all the lubricating oil handled without waste—the proper quantity in the right place at the proper time?

7. Are the suction heads on the boiler-feed pumps right to allow the pumps to operate economically? And are all the pumps operated at the speed conducive to a low percentage of slip?

8. Is the friction horsepower of the plant as small as possible?

SAMUEL L. ROBINSON.

Providence, R. I.

Blocking Up the Governor

It is to be hoped that none of the readers of POWER who operate engines will blindly follow the reasoning in the letter under the above title on page 317 of the Mar. 9 issue, without proving for himself what the effect might be under the various conditions that could arise in the operation of the plant. It will probably not add to the store of knowledge of the average engineer to tell him that the governing of a single engine in a plant where two or more are operating, could be dispensed with provided the load on the plant were always to be more than the maximum capacity of the ungoverned engine and the transmission means between the engine and the load could be depended on to be always in order.

The writer is not an operating engineer and does not want to pose as having superior knowledge in regard to power-plant operation, but unless street-railway power-plant practice has changed remarkably in the past fifteen years, it would seem foolish to say that anyone could guarantee a fixed load for any specified interval during the period of peak loads, when the circuit-breakers are apt to be most active. About fifteen years ago I had some experience in street-railway operation as an engineer, and at peak-load periods had to block the governors on some of the engines to prevent them from dropping. I was an uneasy individual until the load decreased sufficiently to allow the governor-blocking devices to be removed.

If any engineer is forced to operate under similar conditions, even for a limited time, I would advise him to be just as uneasy. If a governor on an engine should become deranged through the breaking of a belt or from any other cause, he should quickly stop it until repairs are made.

There is no class of power plants, as far as the experience of the writer goes, where the load is so likely to be changed from maximum conditions to no load at all, as in street-railway power plants, and if any reader intends to operate such a plant with the governors blocked, as a steady practice, it might be well to block the circuit-breakers, so that they also would be inoperative.

While it is a criticism based purely on snap judgment, the method of applying steam below the dashpot piston of the average governor equipment would not seem to be practical. In the first place, one would expect that when this device operated, the engine room would be showered with oil from the dashpot, and also, that if the piston were as loose fitting or had the area of holes through it usually required to make the operation of the dashpot satisfactory, a 3/8-in. pipe could hardly be expected to furnish a sufficient volume of steam to insure the raising of the governor weights.

However, as stated above, this criticism is not based on actual experience with the device, but since the force of gravity can be had in unlimited quantity and is sometimes used as a pilot to cause the operation of the device as described, it would simplify the apparatus to omit the steam connection and allow gravity to do all the work through a suitable arrangement of levers.

J. E. TERMAN.

New York City.

Uniflow or Una-Flow

Referring to the editorial on page 201 of POWER, Feb. 9, 1915, I should like to add to the discussion the results of a little research on my part.

If you will turn to your Latin dictionary, "Andrews' Latin-English Lexicon," for instance, you will find: "*Una*" (adverb) = in one and the *same* place, or at the *same* time. This seems to be the only form of *unus* which has a distinct sense of *same*. It seems to me that this would make the spelling "una" more nearly equivalent to the German "*gleich*."

The hyphen in una-flow seems to me essential in view of the fact that the use of an adverb would imply that the word "flow" had the strength of a verb.

If the above does not entirely supply the "more subtle" or logical reason for calling the engine by the name "una-flow," which Mr. Alexander finds lacking, we at least are willing to take the additional trouble which the unusual way of spelling entails in view of its advertising value as a unique (unaque) form.

CHARLES C. TRUMP,
Stumpf Una-Flow Engine Co.

Syracuse, N. Y.

Grouting under Heavy Machinery

Some erecting engineers use iron chips or filings and ammonia water, instead of cement or sulphur, for grouting under machinery.

This grout does not set like cement and its action is different. After the ammonia water evaporates, the filings rust quickly and combine into a mass that is about as difficult to chip as cast iron. The engine or other machine is held up on wedges until the filings are hard, and the wedges may then be removed and the holes filled in with the same material.

S. F. WILSON.

New York City.

Referring to the article on this subject by D. N. McClinton, on page 310, in the issue of Mar. 2, he states that it is a matter of considerable discussion whether the leveling wedges should be left under the machinery permanently. From a number of years' experience in erecting engines, I would strongly advise never to leave them in; furthermore, they should be taken out before the grouting has set hard.

A method that I practiced with good results during the last few years of construction work, was to set the bedplate on four wooden blocks a trifle higher than the position desired and close to the anchor bolts nearest to the balancing point of the two ends of the bedplate. Then these bolts were pulled down until the proper height and level were obtained; the wooden blocks would squeeze enough for this. Then the tension on the bolts was removed and the grout was poured in. I found that one part cement and two of sand made the hardest and most lasting grout. When the cement is hard the wooden blocks will give enough so as not to interfere with the proper tightening of the machine to the foundation, but iron wedges will not. Balancing the bedplate at the two heaviest points eliminates much of the danger of springing.

One of my early experiences in the erecting field was replacing a broken shaft of a vertical-engine generating set that had been installed less than two years. The old shaft was removed and no apparent cause for its breaking was discovered at that time. The new shaft was put in place and the engine reassembled. When about to replace the outboard-bearing pedestal it was noticed that the engine and shaft were low. As new bearings were put in with the shaft, it was at first thought that the upper shells were not of the same thickness. These, however, lined up all right. The engine was then raised from the bedplate and it was found that the outboard-bearing end was $^{29}/_{64}$ in. higher than the engine bed. When the bedplate was raised and the old grouting removed, an iron wedge was found driven tight under the part on which the outboard-bearing pedestal was set. No other wedges were found, showing that an inexperienced erector in leveling the outfit had used the generator end of the shaft for a leveling point and had driven the wedge under the small end, springing it up until the shaft showed level. It was surprising that the shaft ran so long without breaking. This incident occurred about eleven years ago, and the shaft then put in is still doing duty.

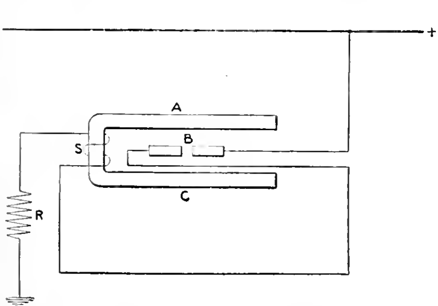
Modern Lightning Arresters

I have read with interest, "Modern Lightning Arresters," by Charles C. Raitt, in the Dec. 22 issue. The article gives an excellent review of the subject, together with cuts of modern types of arresters, but I would like to call attention to an error in Fig. 11, which is a diagrammatic sketch of a magnetic blowout type of arrester for direct-current circuits.



Magnetic Blowout Type of Arrester (Fig. 11)

The sketch as published shows the lightning-arrester discharge path passing through gap *B*, through coil *S*, and to ground through the resistance *R*. One of the fundamental principles of lightning-arrester design is to eliminate inductance from the discharge path, consequently the magnetic blowout-type arresters as actually designed do not have the coil *S* in series with the discharge path, but are arranged so that this coil is in shunt with the whole or part of the resistance *R*. In other words, the discharge path from the line is through the gap *B* and resistance *R* to ground. After the abnormal potential has broken down the gap *B*, the direct dynamic current follows and the field is built up by the coil *S* which blows the arc *B* from its normal path and extinguishes it by virtue of its elongation.

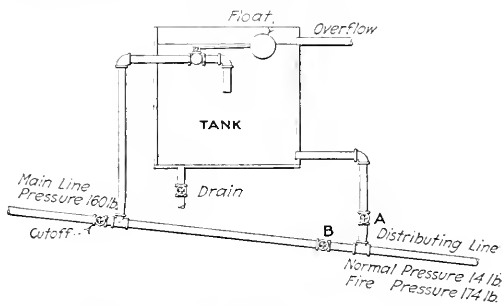
Leaky Valves in a Water System

In a certain mining camp receiving its gravity water-supply under a 400-ft. head, the valves of the hydrants, about 200 in all, were cut by grit in the water after a few weeks' service. A tank was placed at a point about 30 ft. above the highest hydrant. The water was allowed to flow into the tank under the control of a float-operated valve and thence into the distributing system, as shown in the illustration.



Tank and Float to Control Pressure

High pressure for fire protection was provided for by closing valve *A* and opening *B*.

H. M. Howell.

Los Angeles, Calif.

Good Treatment, Good Service

The human, man-to-man treatment of firemen is being successfully applied at the Mechanical Rubber Co., Cleveland. In short, the firemen at this plant, in the words of the operating engineer, George Lowe, "cannot be driven from their jobs."

The plant contains three hand-fired and three stoker-fired boilers, ranging from 220 to 420 hp. The men are paid a bonus on the CO_2—20c. bonus per 10-hour shift for 9 per cent., 30c. for 10 per cent., 40c. for 11 per cent., 60c. for 12 per cent., and 75c. for 13 per cent. The last figure is frequently reached.

The men have been provided with arm chairs in the firing room and a shower bath near-by. "I believe we are successful with our firemen," says the chief engineer, "because we treat them as men and place them on their own responsibility. There is no question of driving them. They work as if they had an actual financial interest in the success of the plant, as indeed they have."

This attitude toward the firing force is only a reflection of a general spirit of progressive efficiency throughout this plant. In the past year or so, by the application of the system mentioned and its resultant increase in efficiency, by installation of other stokers under the three stokered boilers, which enables them to burn coal at $1.85 instead of at $2.10 per ton, and by the installation of a suction ash conveyor eliminating five ash wheelers at $2.50 per day, this power plant has saved over $18,000 per year net.

E. W. Waldron.

New York City.

Tank Vents

The vapor pipes from return tanks, blowoff tanks and open heaters should each extend separately through the roof; otherwise, blowing down the boilers may cause a back pressure on the other tanks. Where separate lines are impractical, check valves on each line joining the vent from the blowoff tank will prevent back pressure, but they will cause a slight resistance, due to the weight of the check. Such check valves should be so located that no condensate can accumulate above them, because it will tend to hold the valve closed and may at some time freeze.

All outlets such as those from feed-water heaters should empty into a funnel in order to make noticeable any excessive waste of water to the sewer.

T. W. Reynolds.

Mt. Vernon, N. Y.

Trip for High-Voltage Switches

Referring to the description of a "New Series Trip for High-Voltage Oil Switches" in the Mar. 2 issue, I would say that we have such a switch installed on a 60,000-volt circuit.

We found that the wooden rod running from the relay to the trip coil on the operating lever was of such small material that it buckled under action and made the switch late in opening, so that the switches on the low-tension side of the transformers opened first.

This was remedied by putting an ordinary tube insulator half way up the rod, thus preventing it from buckling in the center.

Duluth, Minn.

Paints for Engineering Purposes

In your issue of Feb. 16 appears an article by E. W. Percy, entitled "Paint for Engineering Purposes." To some of the assertions made in this article I believe anyone with a technical knowledge of paint and painting would feel impelled to make objection.

I find myself at variance with Mr. Percy's statement that pure white lead and boiled linseed oil are unequaled for purposes of protection. As a matter of fact, I am sure that there are many combinations that are better. Even for white work many believe that white lead is improved for protective purposes by the addition of other pigments. Be that as it may for white paint, there are at least half a dozen colored pigments that protect better, last longer, and cost less than any white paint.

The usual substitute for white lead is not zinc, but barytes. The zinc is used to give a good color and, when lead is also used, to improve the wear of the latter. Whether it does this or not is a subject of controversy, but I am convinced that it does.

Red lead is not "cheaper than" white lead, but much dearer, because it covers less surface, pound for pound. It does protect steel excellently—but "there are others."

Mr. Percy is sadly "off" in his varnish technology. Varnishes are usually made with fossil gums (resins and not rosins) that were once tree gums, as Mr. Percy states, but which probably have not been in contact with a tree since man appeared on the earth.

Amyl acetate is the orthodox solvent for pyroxylin. I quote from Worden a typical lacquer formula:

	Lacquer, Ounces	Thinner, Ounces
Pyroxylin	5.5	
Amyl acetate	45	40
Refined fusel oil	7	6
Wood alcohol, 97 per cent	24	35
Benzine, 62 deg	32	20
Benzine, 71 deg	20	27

"Metallic Paints," by long established usage, are certain iron-oxide paints made either by grinding native hematite ores or, indirectly, by roasting certain native ores until the iron content is completely dehydrated and converted into ferric oxide. They are red or brown in color. The type of paints to which Mr. Percy refers are known in the trade as bronzes.

The copper paint used on ships' bottoms is usually the oxide or finely divided metallic copper (copper scale).

G. B. Heckel.

Philadelphia, Penn.

More about Graphite

In a plant in Pittsburgh we have five vertical water-tube boilers, each rated at 310 hp., working 24 hr. a day at 25 per cent. over rating. After the use of graphite for some two months we found it necessary to open these boilers about once a week and inspect them by running a light through each tube, as the scale was coming off in such quantities and in such large pieces that it was liable to block some of the tubes and interfere with the circulation. After using graphite four months, our boilers were clean and free from scale. Before using it we were compelled to clean them completely every six months and the front bank of tubes every 30 days. This was expensive, as shown by the following figures. When we were cleaning the boilers with an air-driven turbine it cost about $1300 a year, besides having them out of service from 30 to 60 days each year. Since we have used graphite it has cost us about $475 a year, and we have the use of the boilers continuously.

When we started to use graphite we fed 3 lb. per 100 hp. per day of 24 hr., and after the boilers were clean we cut down the amount to 1½ lb. per 100 hp. per day of 24 hr. Every time we wash out a boiler, which is every 30 days, we put 3 lb. of graphite in the rear steam drum.

John L. Armstrong.

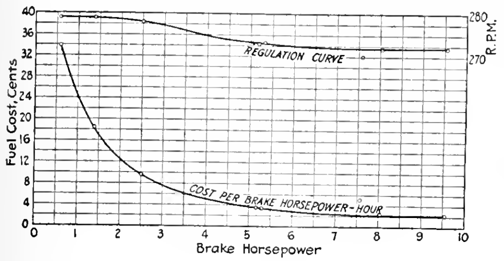
Pittsburgh, Penn.

Correction

Mr. Wentworth's discussion of "Oil Engine Tendencies" in the Mar. 16 issue, page 383, contains the statement: "I have demonstrated that for a running engine 150 lb. is sufficient to ignite the fuel, the hot plate being needed only for starting in the engine which I have developed." The latter part of this sentence should have read: "The writer has developed a type of engine not limited in size and which needs *no* hot plate."—Editor.

A Gasoline-Engine Test

The accompanying curves show the results of a brake test on a 10-hp. gasoline engine, made to determine the cost per brake horsepower per hour under different loads and, incidentally, the regulation under these loads. The gasoline pump was disconnected and the gasoline was fed to the vaporizer by gravity from a 5-gal. can provided with a nipple and cock; the flow being regulated so that only a small amount appeared at the overflow. This was



Regulation and Cost Curves

collected and poured back into the supply can, which was weighed at the beginning and at the end of each run. The revolutions per minute were taken almost continuously by speed indicators and the average readings were used in the calculations. Each run was of 30 min. duration, which, although not long enough to obtain extremely accurate results, was sufficiently accurate for the purpose. The cost is based on gasoline at 15c. per gallon.

R. S. Hawley.

Golden, Colo.

Lignite in Deep Furnace

A plant owner purchased two 72-in. by 20-ft. high-pressure tubular boilers to be erected in the West. One of them was to be equipped with shaking grates, the other with a special grate and furnace using forced draft through a sealed ashpit and also through a hollow bridge-wall. This type of furnace had been successfully installed in other plants using Wyoming lignite, the coal to be used in the new plant. The advantage claimed for the special furnace was the admission of enough air through the fuel bed to burn it to CO, which, rising above the bed, mixed with the warm air entering through the hollow bridge-wall and burned to CO_2.

In arranging the details of the plate-steel boiler fronts, the contractor's representative noted that the special furnace required a height of 54 in. from grate to boiler. This required the boiler to be set much higher than usual; so to make the fire-doors of all boilers the same distance from the floor, he raised the second boiler so that the furnace height was also 54 in.

Test runs on both boilers were conducted and the boiler with the special furnace showed an evaporation of 5.2 lb. of water per pound of coal, and the efficiency was, roughly, 67 per cent. The other boiler, equipped with shaking grates, under like conditions, gave but 2.5 lb. of water per pound of coal, the efficiency being approximately 33⅓ per cent. The result was so much lower than that attained in the old plant, where plain grates were used and the boiler walls badly cracked, that the owners entered an emphatic protest.

Since the type of shaking grate was a good one, the stack capacity ample and the setting air-tight, it was conceded that the trouble lay in the extreme depth of the furnace. Luckily, the steel front was so sectionalized that the fire-door could be raised along with the grates so that the furnace depth would be made 26 in. instead of 54.

This was done and on a second test an evaporation of 4.15 lb. of water per pound of coal was obtained. This value is good for shaking grates using lignite that slacks badly and that causes an appreciable loss of fuel into the ashpit. Perhaps the cause was that the lignite gave a short flame and the great depth of the furnace allowed too much air to come in contact with the burning gases.

L. H. Morrison.

Dallas, Tex.

[If the setting was air-tight above the grate the additional height of the furnace should have given good instead of poor furnace efficiency.—Editor.]

Diagonal Joints

The efficiency of a diagonal seam is a matter of angles and should be calculated for each different angle. J. E. Terman, March 2 issue, p. 296, compares the strength of a diagonal joint in a testing machine to a longitudinal joint of a cylinder. To take another view of it, let us compare the diagonal with a girth seam. That there is an additional strain in a diagonal joint in a boiler not exerted in a testing machine is pointed out by Mr. Terman. There is a generally accepted statement that the force tending to rupture a cylinder girthwise is one-half as great as that tending to rupture it longitudinally. This is equivalent to stating that the effective efficiency of a girth seam is twice as great as that of a longitudinal seam of like design. This can easily be shown mathematically, and the relation is so apparent that tests are not necessary to prove it. The relative strength of a diagonal seam compared to either a girth or longitudinal joint can be calculated, but under test conditions do not apparently come up to expectations.

As an illustration, consider a single-riveted diagonal seam to hold a patch. Suppose the single-riveted seam has an efficiency by test of 50 per cent. of the solid plate. It will then have an efficiency of 50 per cent. as a longitudinal seam and a comparative efficiency of 100 per cent. as a girth seam. A diagonal seam of the same proportion will have an effective efficiency somewhere between these two values, decreasing as it swings from the girth seam. If a section of the diagonal joint were tested it would probably fail at less than 50 per cent. The inclination is to jump at the conclusion that the diagonal seam is weaker than the longitudinal and that the calculations on the strength of diagonal joints are in error. A little further consideration of the matter shows that the test of the straight joint showed 50 per cent. and no more, yet with this joint in another position it will be, relatively, twice as strong.

If, then, we compare the strength of the diagonal seam to a girth seam instead of to a longitudinal seam, as has been the practice, we will approach nearer to the calculated efficiency for a diagonal joint. The test efficiency will show higher than calculated, and the error will increase as the diagonal joint deviates from the girth joint. This comes about because in the machine there is a pull in one direction, while in a diagonal boiler joint there is an endwise and longitudinal pull combined, and until a testing machine is made that will pull in the two directions at right angles to each other, the result of tests along a diagonal line will not give very accurate results.

THOMAS GRIMES.

Houghs Neck, Mass.

In calculating the strength of a diagonal seam it is necessary to take into consideration the well known fact that internal pressure exerts twice the strain on the longitudinal seam or section of the sheet as on the girth seam or sheet section. In Fig. 1, AB represents a longitudinal seam, CD a circumferential seam, and EF a diagonal seam. Since the strain on a longitudinal seam AB is twice that on a girth seam CD, it is evident that

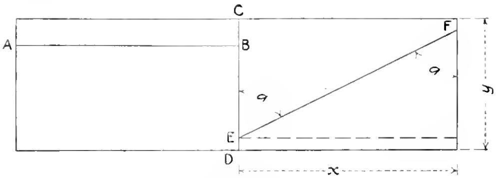


FIG. 1.

FIG. 1. RELATIVE POSITION OF SEAMS

the smaller the angle a, the greater the internal pressure a given diagonal seam will withstand.

Now, the force acting on a unit of length on a diagonal seam EF is the component of the girthwise and longitudinal stresses. In the three types of seams suggested, with the plate, size and pitch of rivets the same, the efficiency of the seams will be identical, but the internal pressure they will withstand will depend on the direction of the seam with reference to the axis of the cylinder.

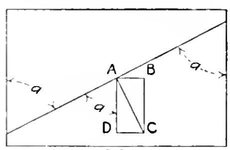

FIG. 2.

FIG. 2. CALCULATION OF EFFICIENCY OF DIAGONAL SEAM

P = the bursting pressure of the cylinder through the solid sheet and if E = the efficiency of the joint, the bursting pressure through the joint AB, Fig. 2, will be PE.

From this is derived the formula

$$AC = \frac{PE}{\frac{1}{2} P \sqrt{1 - 3 \sin^2 a}} = \frac{E}{\frac{1}{2} \sqrt{1 - 3 \sin^2 a}}$$

effective efficiency of diagonal seam, and from it a table of constants may be calculated.

The effective efficiency of the diagonal seam may be determined from the formula

$$EE = \frac{E}{\frac{1}{2} \sqrt{1 + 3 \sin^2 a}}$$

where

EE = Effective efficiency of diagonal seam;

E = Efficiency of joint calculated as a longitudinal seam;

a = Angle made by girth seam and diagonal seam.

With a table calculated from the formula, and by its use E and a being known, it is only necessary to divide E by the required factor to determine the effective efficiency of the diagonal seam; or, the efficiency of the longitudinal seam being known, to lay out a diagonal seam of equivalent efficiency at a given angle, multiply the efficiency of longitudinal seam by the factor corresponding to the given angle. The product will be the efficiency of the joint at that angle. In repair work we can calculate the efficiency of the longitudinal seam, assuming the highest efficiency E practical for the seam in the patch. Dividing the first into the second will give the greatest angle at which the effective efficiency will equal the longitudinal efficiency.

R. D. IRVINGTON.

Boston, Mass.

Piping Bubblers to Avoid Waste

Of all inefficient things, a bubbler drinking fountain seems the most wasteful. When, as boys, we used to lie down at the edge of a brook to drink, we did not think of the brook as flowing for that express purpose, but when we open a bubbler valve the flow is solely for the sake of getting a drink, and we consume about one per cent. of what flows and waste the rest.

We think of the installation of a drinking fountain as a plumber's job. A plumber will tell you at once that any waste pipe must go into the sewer. The water that has gone by one of these bubblers is just as good to feed the boilers, flush the closets, or for any mechanical purpose as it ever was.

The waste pipe can be made to discharge into an open tank or into the return tank of a vacuum heating system and thus improve the vacuum because the water is cold. There should be an effective check valve in the line so that hot water cannot back up into the bubbler. This is especially necessary if the drain pipe surrounds the feed pipe for a short distance. I know of a case where the water in the bowl which had backed up heated the supply pipe enough to scald a man by the first rush of water. It is better to discharge into a separate tank from which the water can be pumped wherever desired, and in that way prevent waste.

E. F. HENRY.

Worcester, Mass.

Vacuum Helps in Making Repairs

With high steam pressure and superheat there is likely to be more or less trouble when making repairs, on account of leaking stop valves on the sections of headers which have been cut out.

In some plants it is the practice to cross-connect the suctions of the dry-vacuum pumps. A convenient use can be made of this connection when making pipe repairs. If the section of the header cut out has a connection to an engine or turbine, the throttle can be opened wide, the inlet valves blocked open, the connection to the condenser opened, and the dry-vacuum pump will then draw the leaking steam past the point of repair.

Of course, the proper way would be to replace the valves, but this cannot always be done. However, with the bolts out of a flanged joint and the steam burning the hands, the foregoing stunt will be found worth while.

JOHN F. HURST.

Inquiries of General Interest

Crushing Strength of Boiler Plate—In computing the strength of a boiler joint what is understood by the crushing strength of the plate?

J. R.

The crushing strength of the plate is its ability to resist distortion from the compressive stress which is incident to drawing the sheet against one side of a rivet in exerting shearing stress in the rivet.

Safety of Cracked Mud Drum—Would it be safe to continue the use of a cracked mud drum of a water-tube boiler after drilling and plugging the ends of the cracks?

F. S.

The drilling and plugging might reduce the tendency of the cracks to extend in length, but could not otherwise increase the safety of the drum, which may not have sufficient strength for safety even if the cracks do not extend

Relative Heat Value of CO_2 and of CO—What are the relative heat values derivable from carbon in fuel burned to CO_2 and to CO?

G. B.

When carbon is burned completely to CO_2 there will be given off 14,500 B.t.u. for every pound of carbon burned, but when CO is formed there are 4400 B.t.u. given off per pound of carbon burned, or less than one-third as much heat.

Relative Lengths of Pump Cylinders—Why is the water cylinder of a steam pump made longer than the steam cylinder?

J. W. D.

So that there may be latitude in length of the piston rod without the water piston overrunning or leaving too little clearance in the ends of the water cylinder for the greatest possible stroke of the steam piston in either direction.

Boiler Foaming from Temporary Use of Good Feed Water—How is it explained that the temporary use of a good quality of feed water causes a boiler to foam?

G. N.

Where a boiler is coated with scale a pure feed water will sometimes dissolve the scale, leaving the metal bare in spots which transfer heat much faster than parts that are covered with scale, and the violent boiling over places where there is little or no scale is likely to result in foaming or priming.

Circulating Pipe for Blowoff—How can a circulating pipe be connected to the blowoff pipe of a return-tubular boiler?

R. C.

A circulating pipe of a size smaller than that of the blowoff pipe can be connected from a point in the blowoff, outside of the rear wall and on the boiler side of the blowoff valve, to a point in the rear head of the boiler a short distance below the water line. The circulating pipe should be provided with a stop valve, which should be closed whenever the boiler is blown off, but at all other times should be left wide open.

Per Cent. of Fuel Saved by Heating Feed Water—What is the formula for calculating the per cent. of fuel saving from the use of a feed-water heater?

A. S.

For practical purposes the heat saved in raising the temperature of feed water may be regarded as directly in proportion to the rise in temperature. The steam pressure and feed-water temperatures before and after heating being known, the fuel saving can be computed by the formula,

$$\text{Fuel saving in per cent.} = \frac{100\,(t - t_1)}{H + 32 - t_1}$$

in which

t = Temperature F. of feed water after heating;
t_1 = Temperature F. of feed water before heating;
H = Total B.t.u. above 32 deg. F. per pound of steam at the boiler pressure (to be obtained from tables of properties of steam)

Maintaining Air Supply in Air Chamber—How can a supply of air be maintained in the pump air chamber of a high-pressure service pump?

J. G.

An automatic air pump for supplying the air chamber may be provided by connecting a vertical 2-in. or 2½-in pipe about 30 in. long, with a stop valve at its lower end, to one head of the water cylinder and providing the upper end of the pipe with a tee and 1¼-in. check valve opening inward and a ¾-in. check valve opening outward and connected to the pump air chamber. For operation of the air pump it is necessary that the pump to which it is attached shall be in operation. To start the air pump, first open the valve connected with the water cylinder to charge the air pump with water; then partly close the valve until the check valves begin to work.

Compression of Steam in Duplex Pump—How is compression of exhaust accomplished in the steam end of a duplex pump?

W. L.

Separate steam and exhaust passages are provided in each end of each steam cylinder, the cylinder ports of the steam passages being located in the extreme ends of the cylinders or nearer the ends than the cylinder ports of the exhaust passages. The exhaust ports are placed so near together that before completing the stroke from one end of the cylinder the piston covers the exhaust port at the other end of the cylinder. When the exhaust passage is thus closed, any exhaust steam then remaining in the cylinder and steam passage on the exhaust side of the piston is compressed by it during the remainder of the stroke.

Computation of Indicator Diagrams—An 8x10-in. engine having a 2-in. diameter piston rod runs at 200 r.p.m. The indicator diagram from each end of the cylinder has an area of 2.5 sq.in. and a length of 4 in., and the scale of spring is 50 lb. per sq.in. What is the i.hp.?

S. H. E.

In each diagram the mean effective pressure would be

$$\frac{\text{area}}{\text{length}} \times \text{scale of spring, or } \frac{2.5}{4} \times 50 = 31.25 \text{ lb. m.e.p.}$$

The area of the 8-in. diameter piston being 50.265 sq.in. and the cross-section area of the 2-in. diameter piston rod being 3.1416 sq.in., then for 10-in. stroke and 200 r.p.m., there would be

$$\frac{31.25 \times [50.265 + (50.265 - 3.1416)] \times \frac{10}{12} \times 200}{33{,}000} = 15.37 \text{ i.hp.}$$

Application of the Prismoidal Formula—What would be the cubical content of a piece of timber 16 ft. long, 6x6 in. at one end and 4x8 in. at the other?

T. E. H.

Assuming that the ends are parallel planes, as, for instance, both square with one of the edges of the timber, then the content can be found by the prismoidal formula

$$\text{Volume} = L \times \frac{A + a + 4M}{6}$$

in which

L = Length;
A = Area of one of the parallel ends;
a = Area of the other parallel end;
M = Area of cross-section midway and parallel to the parallel ends.

The ends being, respectively, 6x6 and 4x8, the parallel mid-section would be 5x7, and the length being 16 ft., then the volume would be

$$(16 \times 12) \times \frac{(6 \times 6) + (4 \times 8) + 4\,(5 \times 7)}{6} = 6656 \text{ cu.in.}$$

or

$$\frac{6656}{1728} = 3.85 \text{ cu.ft.}$$

Future Methods of Utilizing Coal*

SYNOPSIS—Economic pressure due to increased demand and cost of coal will force improved methods of combustion and the recovery of the various byproducts contained. The relative costs of fuel and capital are the determining factors. There is no need for conservation as ordinarily understood. Future generations, with their fuller knowledge and wider vision, will be better able to take care of themselves.

There is at the present day a certain amount of coal buried in the earth's crust. Coal is being slowly formed at some points on the surface of the earth, but the rate of formation is so low in comparison with the rate of consumption that for all practical purposes the supply available for human consumption may be assumed to be that already formed. If this view is taken, it is evident that the amount of coal which can be used by man in the future is definitely limited; when he has used up the coal now in the earth's crust, or that part of it which he can extract, there will be no more available for use.

The estimates of the length of time which will elapse before this condition is attained vary greatly, but most of them allow humanity at least a few hundred years before the exhaustion of all available coal. Opinions as to what may happen when the time of ultimate exhaustion arrives are equally variable. Some believe that humanity must perish because of the enforced cessation of industries and because of the impossibility of keeping warm during the cold seasons of the year. Others believe that by that time hydro-electric development will have been carried to such a point that electrical energy will entirely take the place of heat derived from coal. Still others are satisfied to let the future take care of itself and to assume that the human brain is going to be able to continue to devise methods of changing the environment to suit the needs of the human animal.

I am inclined to take the last view myself, as I believe that the centuries of human history which are available show that each successive generation has become better able to force its dictates upon nature rather than to be subservient to the unrestricted action of natural forces. In other words, subsequent generations will be better able to care for themselves than the present generation and there is no need to waste good time and effort in trying to solve their problems for them with a smaller stock of knowledge and a narrower vision.

In taking this viewpoint it is not necessary to hold ourselves responsible to future generations for the use we make of the coal stores which we are depleting at such a rapid rate. We may consider ourselves free to use this material as our industrial development requires, though we are, in a certain sense, morally bound to make that usage as economical as possible on the basis of the general principle that it is not good economics to waste wealth of any sort.

If, then, we attempt to look into the future for the purpose of predicting the methods which will be in use for the utilization of coal, we must not warp our vision by an erroneous assumption of the necessity of conserving the supply. We must rather study industrial developments of the past and after discovering their general trend, attempt to apply this knowledge to the particular field under discussion.

It has been characteristic of nearly all industries that they started in a small way under conditions which did not require the most economical production. Thus the shoe industry was started by numerous individuals scattered over the country, who purchased leather, nails, thread and other raw materials in small quantities and then worked them up into shoes on individual orders received from people living in the immediate neighborhood. The modern packing industry sprang from the small butcher who slaughtered for local consumption and disposed of the hides and other byproducts in the easiest way possible. The clothing industry was originally confined to the home, the land or the live stock producing the raw material, which was worked up by the family of the owner into the clothing required by that family.

All of these industries have grown until they are scarcely recognizable as the offspring of their forebears. This has been brought about by organization, which is merely the combination of capital and the division of labor for the purpose of producing the biggest possible yield from given raw materials or natural supplies.

In the shoe industry scientific development produced the marvelous machines which are now used in producing leather and shoes and the railroads which later transport the factory-made product to the scattered consumers.

In the packing industry the refrigerator car made possible the concentration of the slaughtering industries and, coupled with mechanical and chemical invention, assisted in building up large modern plants.

Spinning and weaving machines, cutting, sewing and pressing machines, coupled with the railroads, have made possible the huge centralized clothing industries of the present day.

The study of the packing business tends to throw considerable light upon the probable future development of the coal industry. It is not so many years ago that, in this country at least, meat on the hoof was so plentiful that it could be slaughtered in most expensive ways and still be sold at a profit at such a low figure as to bring it within the reach of practically all families. Conditions are now different and meat on the hoof is comparatively scarce. It therefore brings comparatively high prices and if all or practically all of the purchase price, transportation and slaughtering expenses had to be borne by the meat and hide, the prices of these commodities would be so high as to put them beyond the reach of many families even in this comparatively opulent country.

But the modern packing house manages to sell every part of the animal for some purpose. Some parts, such as those sold in the form of dressed meat, are disposed of after little modification, while others, such as horns, hoofs and fat, pass through elaborate manufacturing processes before they are ready for the market. When it is remembered that every one of the numerous products is sold on the average at such a price as to bear its share of the cost of the animal, of its transportation, and its slaughter and dressing, it is evident that the principal product, meat, can be sold at a lower price than would otherwise be possible. Moreover, waste has been reduced to a minimum; all parts of the animal which cannot be used for food are used for other purposes.

The coal industry, particularly in this country, is in much the same position today as would be a packing house which produced meat only. Coal is removed from the mine, put in marketable condition with the minimum possible expenditure and shipped to the consumer. The greater part of it is burned under boilers just as it is received or after breaking to smaller sizes.

As the supply in sight in the ground decreases, as mines become deeper and as freight rates increase, coal becomes more and more expensive. This process must continue so long as the methods at present in vogue in the industry continue and the cost of coal must ultimately become a serious burden on industries in which the coal charge forms a large fraction of the total charge. In view of what has happened in other industries it is but natural to assume that when economic pressure makes it necessary, the coal industry or the methods of utilizing coal will be so modified as to obtain the maximum possible number of products with the maximum possible economic value from each ton mined, provided such products are obtainable.

We are accustomed to think of coal as merely so many stored or latent units of heat energy purchasable at so much per thousand or million. It is far better, however, to view it as a collection of chemical substances and combinations which are capable of almost an infinite number of transformations and recombinations to form innumerable new end products. If coal were merely a collection of units of heat energy the cost per unit would of necessity continue to increase until it reached a prohibitively high value. Taking the view just suggested, however, it is possible that chemical jugglery of the constituents may be made to develop substances marketable at such prices as to materially reduce the necessary selling price of units of heat energy.

The principal constituents of coal are carbon, hydrogen, oxygen, nitrogen and sulphur, and these are the blocks out of which innumerable organic and inorganic chemical compounds are built. Just how these various constituents will be liberated or recombined for the purpose of increasing the economic value of a ton of coal in order that the selling price of units of heat energy may be kept down to a reasonable figure, must be more or less a matter of speculation. It is, however, pertinent to note that processes of this kind are already in use in some of the European countries and particularly in Germany, and it is reasonable to suppose that

*Abstract of paper read by Prof. C. F. Hirshfeld before the Detroit Engineering Society, Mar. 23, 1915.

future development will follow along some such lines as those already partially developed. An investigation of these methods may therefore assist in arriving at a more correct prediction of future methods.

In general, development is carried on along three lines: First, the thermal efficiency of heat engines and plants is brought to the highest possible figure in order to reduce to a minimum the number of heat units which must be purchased by anyone concerned in the generation of power; second, byproduct fuels of various varieties are made from the raw coal, or from the coal in the process of utilization and some of these may have such desirable properties as to be worth more per unit of heat energy than is the raw product. Their use or sale therefore tends to reduce the price paid for heat units in the raw coal. Third, many byproducts useful in numerous arts are made and their economic value helps to reduce the cost at which units of heat energy or their products must be sold to yield a profit.

It will be observed that when the coal-mining and consuming industries develop in this way, they begin to approach the condition of the modern packing industry. The capital involved is enormously increased; many more kinds of labor are required and the subdivision of labor is carried to a far greater extent; and the economic value of the product per ton of raw coal is enormously increased.

The parallel may be drawn still more closely. Meat for human consumption may be considered the primary product of the packing industry. The selling price is continually increasing, but the rate of advance is kept lower than it otherwise would be by increasing the number of products per unit of raw material, giving a greater economic value to the products per unit and reducing the charges against the primary product. Heat energy may be said to be the primary product of the coal industry and the selling price of this is continually increasing. The rate of advance is kept lower than it otherwise would be by increasing the number of products per unit of raw material, giving a greater economic value to the products per unit and reducing the charges against the primary product.

Development along these lines has thus far progressed along two principal paths. The raw coal is subjected either to a destructive distillation process with the exclusion of air, or to a process of incomplete combustion in the presence of air The former method yields a solid fuel called coke; combustible gases of a more or less permanent nature; condensible vapors of great chemical and fuel value; and other substances, such as ammonia, cyanides, sulphur compounds and others. The latter method yields solid, incombustible refuse or ash of comparatively small value; large quantities of combustible gas of great value; condensible vapors which are becoming of greater chemical importance daily and are also becoming available as fuel; and small quantities of chemical compounds of more or less value.

By such means as these fuel material becomes available in solid, liquid and gaseous forms, and the particular variety best suited to any use may be chosen therefor if price permits. It is, of course, impossible to obtain more heat units than were originally contained in the fuel. There is in reality always a loss in these processes, but the thermal efficiency with which the smaller number of resulting heat units can be used may more than balance the thermal losses occurring during the modification of the fuel. Great developments have been made in the use of gaseous and liquid fuels during the past few years. It is now possible to use such fuels for the generation of steam, for industrial heating, and for the operation of prime movers at efficiencies much higher than seemed possible of attainment a short time ago. Surface combustion and the internal-combustion engine in its various forms are pointing out lines of development leading toward constantly increasing thermal efficiencies.

These statements must not be interpreted as an argument for the immediate adoption of gas firing and of the universal use of the internal-combustion engine. Other matters must be given consideration as well as the cost of fuel. The cost of capital is of equal importance.

At present the costs of capital and of fuel are both increasing, but the cost of the latter is increasing more rapidly than that of money. Even now the cost is such as to warrant greater capital investment for procuring greater thermal efficiency than could have been justified a few decades ago. Ultimately the cost of fuel must rise to such values as to warrant the investment of the necessary capital and the training of the necessary labor to make possible the use of fuel in such ways as to produce the greatest economic production per ton of raw material.

When that time comes it is probable that coke, or something resembling it, will be the principal solid fuel; gases formed during the production of the solid will be used in internal-combustion engines, or by surface combustion, or in ways not yet discovered; and liquid fuels formed during the production of solid fuel will be used in high-efficiency, liquid-fuel engines. Before they are used the liquid and gaseous fuels will be robbed of many valuable constituents, which will be used in producing fertilizers, medicines, paints, dyes, preservatives, waxes, flavoring extracts, commercial chemicals and many other products yet undreamed of.

Summarizing these ideas, it seems probable that:

1. Improved or more economical methods of utilizing coal will not and need not be brought about by any consideration of conservation as ordinarily understood.

2. Such methods will be brought about by cumulative economic pressure due to the natural operation of increased demand for fuel combined with decreased quantities and increased cost of mining and transportation.

3. When such methods are thus forced upon humanity they will follow, in a general way, the course developed in other industries under the force of similar circumstances.

4. These methods will consist of a preliminary treatment of the raw material to produce fuels with different physical and chemical characteristics which will adapt each form to use in particular kinds of apparatus or in particular industries.

5. Coincident with this treatment will be produced numerous non-fuel byproducts of great value in the then existing markets.

6. The spreading of the cost of the raw material over so many products will prevent the excessively rapid rise in the selling price of fuel per heat unit and this, combined with high efficiency methods of utilization made possible by the relative prices of fuel and capital, will yield the same sort of an economic balance as now exists. Humanity will probably then, as now, bemoan the fact that it could not have lived several generations before, when fuel was "cheap," and will probably express great sympathy for the coming generations that will have to face the problems of life with a still more depleted coal supply.

Many will probably object that the cost of modifying coal, as, for instance, by the destructive distillation process, has always been so expensive that little is to be hoped for along such lines in the future. In answer to such criticisms it is only necessary to point out the fact that despite the rising prices of coal, labor and capital, the selling price of gas made by such processes has steadily decreased. It is admitted that further decrease cannot be brought about by exactly the same methods as have been used in the past, but it shows very little faith in the progress of the human race to assume that the present status in any industry represents the ultimate development of which humanity is to prove capable.

Refrigeration Night, Chicago Section, A. S. M. E.

The chief paper presented before the meeting in the Grand Ball Room of the LaSalle Hotel, Mar. 19, was by Heywood Cochrane, Western manager for the Carbondale Machine Co. The subject was "Ice Making as a Byproduct for Central Stations," a digest of which follows:

One point of difference between the electric-light and the ice plant is that of distribution. There is hardly any limit to the extent of the former, but the latter soon reaches a size where the cost of distribution more than offsets the saving. Individual plants of from 80 to 150 tons, located in the best centers of distribution, are preferable to large-capacity plants adjacent to the station.

With condensing water under 70 deg. F. it is possible to use exhaust steam at 3 lb. pressure in the generator of an absorption system. This steam is condensed, furnishing a portion of the distilled water required for making ice. About 55 to 60 lb. of steam per hour per ton of ice is required for this purpose. With condensing water at 90 to 95 deg. it is not possible to run on less than from 20 to 25 lb. exhaust-steam pressure, because of the high condensing pressures necessary. Such pressure would seem prohibitive, yet plants operating under these conditions are proving economical. It is not generally known that, properly designed, the absorption machine is an ideal installation for warm water conditions. Just as it takes little more coal to carry 125 lb. boiler pressure than it does 100 lb. (less than 1 per cent.), it takes comparatively little more steam in the generator to produce an ammonia pressure of 200 lb. than it does 150 lb.

An electrically driven compression plant will require from 43 to 70 kw.-hr. per ton of ice, depending upon its size and local conditions. At 1c. per kw.-hr. the power costs per ton will usually average between 50 and 60c. From the central-station manager's standpoint, in the larger cities, such as Chicago, the privately owned electrically driven plant is the proper combination, while in smaller cities it is much more profitable to own the ice plant direct.

It is possible in a properly designed compression and absorption plant, say of 80 tons' capacity, with a 20-ton machine of the former type and a 60-ton of the latter, to make ice at a lower fuel cost than 35c. In this case there should be two 40-ton tanks, the compression machine being used on one-half the coils of one tank and the absorption machine on the rest. The steam from the compressor and auxiliaries would furnish the 3600 lb. of exhaust required for the generator of the absorption machine. Making all raw-water ice with coal at $2 per ton, having an evaporative efficiency of only 6 to 1, 6½ tons would be required and the fuel cost would be 16c. per ton of ice. Such an 80-ton plant could be run on a 125-hp. boiler, and with a second such boiler in reserve, the first cost, interest, depreciation, etc., would be low, so that including labor it should hardly be more than 30c. per ton.

If a neighbor could be found requiring a certain amount of power and heat, a straight 80-ton absorption machine could be installed. By using the expansive force of the 4800 lb. of steam per hour required by the generator, in an economical uniflow engine, current could be sold, not bought, which would further reduce the operating cost.

One drawback about the electrically driven plant is the possibility that public-service commissions at any time may decide that the rates quoted ice plants are too low and order them raised. Rates higher than 1c. per kw.-hr. seem prohibitive, although they are paid in some places. Sometimes the ice-plant manager looks only at the comparatively low operating cost when running full capacity and forgets that service charges add to the cost at other times. The importances of such charges should never be underestimated.

A properly designed combination plant owned by a central station in a Southern city of about 50,000 inhabitants was described.

REFRIGERATION VS. HEATING

Otto Luhr was asked to explain in an elementary way the principles of operation of a refrigerating system. He did this by comparing it to an ordinary steam-heating system, as in reality it is nothing more than a heating system reversed, with the only difference that in a steam-heating system heat is carried into the rooms that are to be heated, whereas in a refrigerating system heat is carried out of the rooms that are to be cooled. In both cases the latent heat capacity of the heat-carrying mediums is of vital importance. In ordinary steam-heating systems there is a boiler and heating coils. The boiler is partly filled with water, and the heat that is created by the combustion of fuel is absorbed by the water, which is changed into steam by the constant addition of heat. This steam is conveyed to the heating coils at comparatively low pressure and temperature, the latter usually being about 212 deg. F. As the room temperature is generally about 70 deg. there is a difference of 142 deg., and heat will constantly flow from the radiators into the surrounding air.

With the refrigerating system the reverse process takes place. The system consists of a heat-carrying medium confined in piping similar to that of the heating system. If the medium could be purchased cheaply no further apparatus would be necessary, but as it is expensive the heat absorbed by it must be abstracted and used over and over just as is the water in a heating system. To do this a heat elevator in the form of an ice machine and a heat extractor in the form of a condenser become necessary. The temperature of the medium is raised either directly by steam or by the application of power in the form of compression. It is necessary to raise the temperature of the medium in either of these two ways so that water or air of ordinary temperature will remove some of the heat contained. Water is generally used, as it is cheaper. It has the same effect on the heat-carrying medium as the room temperature has on the heating system. When it arrives at the condenser the medium is in a gasified state, and by the action of the cooling water, which constantly takes heat away from the gas, it is liquefied. It is then ready to start on the same cycle, which is constantly repeated.

Mr. Luhr explained how the liquid ammonia in the coils was vaporized by absorbing heat from the room to be cooled, and enumerated some of the qualifications which go to make up a good refrigerating medium.

As to the different systems, each was well adapted for specific cases. For instance, it is not good policy to use a CO_2 machine when the cooling water is scarce or high in temperature. On the other hand an ammonia-compression machine would not be desirable when there was plenty of exhaust steam and an abundance of low-temperature cooling water, especially when low temperatures were to be carried in the cooling system.

The principles of operation of refrigeration systems can best be understood by keeping a steam engine or a heating system in mind and considering the refrigerating end a reverse process. In a steam engine the efficiency is the greatest the farther apart the inlet and outlet temperatures of the steam. In the compressor it is just the reverse; that is, the closer the two temperatures can be brought together the higher will be the efficiency. For this reason it is necessary to work with a suction pressure as high as possible and with a condenser or discharge pressure as low as possible, as long as the proper refrigerating results can be obtained. This means that the pipe surface in the refrigerating room must be large, so that the difference in temperature of the medium in the pipe and the air surrounding the pipe can be small.

CO_2 MACHINES

Fred Wittenmeier, vice-president and chief engineer of Kroeschell Brothers Ice Machine Co., explained the action of the CO_2 machine, which is now made in capacities up to 150 tons. Its greatest application is in hotel basements, on board ship and in other places where space is limited and where the escaping fumes from a possible rupture of the pipe lines might cause serious inconvenience.

In the last ten years air cooling by means of the CO_2 system has also made rapid progress. The usual practice is to place direct-expansion coils in the air washer. The properties of CO_2 were briefly given, and the results of tests made on an air-cooling system in a church and on an ordinary refrigerating system on board ship were shown on the screen. The principal object was to show that with condenser water in the eighties good results could be obtained from the CO_2 system, notwithstanding the general belief that it is not adapted for use with high-temperature cooling water. In the test on the air-cooling system, the water went into the condenser at 84 deg. and came out at 106 deg. From the ship log the inlet temperature of the water was 82 deg. and the outlet temperature 88 deg. As far as economy was concerned, under normal conditions the CO_2 system gave results comparable to those obtained from ammonia or SO_2 systems.

FROM THE VIEWPOINT OF THE CENTRAL STATION

E. W. Loyd, of the Commonwealth Edison Co., discussed the topic of the evening from the viewpoint of the central station. In efforts to obtain a load which would improve their load factor, particularly in the summer months, an investigation was made of the ice-making field. Many data were collected and the amount of power required for refrigerating installations determined. This was turned into kilowatt-hours and a price fixed at which the company could sell current. Rapid progress has been made and one third of a million tons of ice is now produced in the City of Chicago by central-station power. This is 10 per cent. of the total made in Chicago, and has been made possible by the recent developments in raw-water ice making. The trend seems to be toward raw-water ice where fairly pure water can be obtained. It was originally estimated that the load factor on an ice plant was about 65 per cent., but according to data collected by the company the annual load factor does not exceed 45 per cent. Exceptions were found, but in any case it was not above 65 per cent. on an annual basis. As to the kilowatt-hours required per ton, there was a wide variation, largely due to the varying efficiencies of the plant and the equipment installed. The company found that the number of cans employed per ton of ice has a bearing on the subject. At the present time they were supplying 7000 hp. for ice making, and the total amount of power required for this purpose in the city was estimated at 70,000 hp. The rate charged was 1c. per kw.-hr. An analysis shows that the distributing cost is low, as the current is delivered in large quantities to one service. The increment of cost to take on this business was a minimum. It increased the summer load and reduced the overhead charges, and it could be shown that the rates were comparable to those for other classes of service.

MULTIPLE-EFFECT COMPRESSION

By means of some simple experiments and lantern slides Gardner T. Voorhees explained the action of his device designed to obtain multiple-effect compression. Low-compression vapor first enters the cylinder, and near the end of the stroke vapor under a higher pressure is admitted. The cylinder thus contains a denser charge and at the same speed does more work, or the same amount of work with less power. The device by which these results were obtained was illustrated and the results of a number of tests given to show the economies obtained. In one particular case, with 90 deg. F. cooling water, 70 per cent. more ice was made for 25 per cent. less power, after the compressor was fitted for multiple-effect compression. Slides of the Quincy Market Cold-Storage

& Warehouse Co.'s (Boston) machine, the largest in the country, were shown. This machine, designed by F. L. Fairbanks, is fitted with a multiple-effect compression device and has given excellent results. For a complete description of this machine see "Power," Dec. 8, 15, 22, 29, 1914, and Jan. 6, 1915.

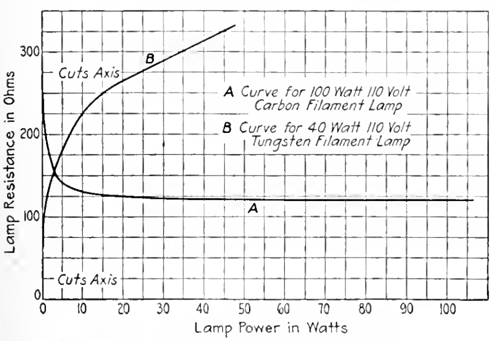
Dimmers for Tungsten Lamps*

By A. E. Waller

The introduction of tungsten lamps has brought about a complete redesign of the apparatus used for lamp dimming in theatrical work. The control rheostats, or dimmers, which were built to regulate the illumination of carbon lamps were found unsatisfactory when the carbons were replaced by the metallic-filament tungsten lamps.

The resistance characteristics of the two types of lamps in actual operating conditions indicate the reason for the difficulty. Tungsten has a positive temperature coefficient of resistance, while carbon has a negative temperature coefficient. For instance, if we have a carbon and a tungsten filament of the same cold resistance, when both are at full incandescence, the tungsten will have 35 times the resistance of the carbon filament.

The curves shown were plotted from tests made on a 40-watt tungsten lamp and on a 100-watt carbon lamp, both giving practically the same candlepower at 110 volts. Curve A, which is for the carbon lamp, has little slope between the 10- and the 100-watt abscissas, an interval which represents the working range of the lamp. Since the lamps must be totally extinguished without opening the circuit,



Lamp Resistance vs. Lamp Power

the dimmer is built with enough resistance to reduce the input below 10 watts, in this case to 6 watts, which is attained at 28 volts.

The calculation of the resistance per step of a dimmer for a carbon lamp is similar to that of a generator field rheostat, or of any other controller operating in series with a substantially constant resistance across a constant-supply voltage. The current of the lamp at the rated 110 volts is 0.9 amp., the minimum to which this will be reduced by the rheostat is 0.18 amp., and the working resistance of the lamp is approximately 122 ohms. At the minimum current the resistance is actually 138 ohms, but it is satisfactory in designing to take the resistance as constant at 122 ohms.

The negative coefficient of the carbon filament produces a slight change of resistance which assists the action of the dimmer. When a resistance step is cut into circuit, the current flowing is reduced, the filament cools and increases in resistance, which causes a further slight decrease in the current. Any part of the rheostat cut out of circuit increases the current, thus raising the filament temperature and allowing a slightly greater current to pass. This action is most pronounced at low voltages, the lamp resistance remaining practically constant over the greater part of the working voltage.

In striking contrast is the tungsten lamp, which opposes every attempt at control, and must be regulated by much finer divisions of resistance to get gradual dimming. The shape of curve B indicates that the tungsten filament changes in resistance throughout the entire working range of the lamp; furthermore, that the rate of change is not constant. The correct resistance for each step is readily obtained by calculating the resistance required in series with the lamp at various voltages. At 110 volts the tungsten lamp takes 0.35 amp., and the minimum is 0.08 amp. at 10 volts. The corresponding resistance change is from 312 to 125 ohms.

A comparison of curves A and B shows the marked contrast between the tungsten and the carbon lamps. The resistance of the tungsten lamp at full incandescence is about 16.5 times its cold resistance, while that of the carbon filament at full incandescence is approximately half the cold resistance. The tungsten filament becomes visible red at 10 volts, the carbon at 28 volts.

*From a paper presented at the midwinter convention of the American Institute of Electrical Engineers, New York, Feb. 17 to 19.

Two Flywheels Explode at Illinois Steel Co.'s Plant

During the morning of Mar. 17, shortly after 3 o'clock, two immense flywheels exploded in the No. 1 rail mill of the Illinois Steel Co. at South Chicago. Out of 150 employees imperiled, one man was killed, two have since died, two more were scalded about the face and arms by escaping steam and a fifth received two scalp wounds. The property damage is estimated at $75,000, and about 300 employees will be thrown out of work until the mill can be rebuilt, which will probably take about six weeks. That more were not killed or injured is a marvel that might be explained by the immediate rush for safety by employees accustomed to danger and consequently alert to the slightest warning.

After a shutdown for the winter, the mill had been reopened about 10 days previous to the accident. It consists of a long building about 80 ft. wide, housing three compound engines and their respective rolls. The dummy engine, which caused the accident, was located at the north end of the mill, the finishing engine 112 ft. south, and 104 ft. farther on the blooming engine. They are all of the tandem-compound type and practically in line. The dummy engine was installed in 1890 and compounded in 1905. It had cylinders 34&60x66 in. and a speed of 80 r.p.m. The flywheel, which was of the solid-rim split type, weighed 65 tons, and its dimensions were about as follows: Diameter, 25 ft.; face, 20 in.; thickness of rim, 20 in. The finishing engine had cylinders 40&70x66 in. and a 70-ton flywheel. The blooming engine was about the same size.

From the blooming rolls the bars of metal are passed along to the roughing rolls driven by the finishing engine, then to the dummy rolls and back to the finishing rolls. At the time of the accident a bar had just been rolled by the dummy engine and passed back to the finishing set of rolls at the center of the mill. While waiting for another bar to be delivered from the roughing rolls, the dummy engine speeded up and the flywheel exploded. The flying pieces from this wheel caused the flywheel on the finishing engine to give way, and between the two 125 ft. of the roof was brought to the floor. A traveling crane having a 77-ft. span, and at the time being located above the dummy engine, was demolished, but in stopping some of the heavy parts helped to save a considerable portion of the roof. Of the few pieces landing outside the building, one passed down into a shed and damaged a number of motor armatures which had been stored there.

The low-pressure cylinder of the dummy engine was demolished, the connecting-rod broken and the bedplate cracked at the bearing. The finishing engine was stripped of its valve gear. A piece of one of the flywheels smashed a valve bonnet on the high-pressure cylinder of the blooming engine and ruptured the steam connection between the two cylinders. A wiper on this engine was instantly killed and a machinist and a helper burned about the face and arms by the escaping steam. More damage at this point was prevented by a roll rack containing nine 30-in. rolls, three high and three wide. Seven were broken. The engineer on the finishing engine was so badly hurt that he died a little later, but the engineer of the dummy engine escaped with a couple of scalp wounds.

Fortunately, the steam piping had been designed for just such a contingency. The main supply pipe had been carried outside the building. The pipe leading to each engine passed through the wall, then down and directly across to the throttle, so that there was no overhead piping to flood the mill with steam in case of a rupture.

The governors were of the standard automatic-cutoff flyball type, driven from a sheave on the main shaft by three independent ropes. In addition, each engine was equipped with a quick stop which might be operated from a number of push buttons placed in convenient locations. There was no automatic stop to set a definite limit on the speed. Such a device in working order, whether electrical or mechanical, would have prevented the accident.

Several years ago an automatic electric stop had been tried out on the blooming and finishing engines, but the graphite, scale and dirt common to steel mills interfered with its operation. The contacts would build up, close the circuit prematurely and frequently stop the engine with a bar in the rolls. It was not stated how often the contacts were inspected, but the result was a discontinuance of the automatic feature. Dependence was placed on the engineer at the throttle and the hand-operated stops previously mentioned.

In his report the engineer of the dummy engine claimed to have pushed one of the buttons, but apparently too late to save his engine. This action, however, would shut off the steam and eliminate one of the sources of danger.

Admission to the scene of the explosion was not granted, so that it is impossible to form accurate conclusions as to the cause of the accident. It was claimed that all the equipment was in good order, as far as known. No flaws were detected in the metal of the flywheels, and the governors had operated satisfactorily during the 10 days since the shutdown.

The following theories are advanced as possibilities. Not infrequently, water finds its way into the pits of the flywheels. Some of it may have been splashed on the ropes driving the governor, causing them to slip and allowing the engine to run away. Breakage of the ropes would produce the same result. Either might happen in the grease- and scale-laden atmosphere of a steel mill, depending upon the frequency and thoroughness of inspection.

Water-Power Motor Drive in a Flour Mill

An extremely flexible arrangement has been worked out by the Northwestern Consolidated Milling Company for one of its large flour mills at Minneapolis. This plant is driven by both a waterwheel set and a large synchronous motor connected to the same shaft. When water is plentiful the turbine wheel is operated at full load, pulling the mill and converting its surplus power into electrical energy in the motor unit, which is for the time operated as an alternating-current generator. The electrical energy thus generated, amounting to several hundred horsepower, is used to supply other mills and elevators operated by the same company.

When, however, the output of the waterwheel is insufficient to pull the mill itself, the synchronous motor is called into service, taking its supply from the mill steam-turbine plant. In case of low water this motor is used to drive the whole mill. On still other occasions, when the mill is shut down and it is desired to utilize the water power, the waterwheel can again be used to drive the motor unit as a generator, feeding its entire output into the mill system. In preparing the switchboard connections for this flexible arrangement it was, of course, necessary to provide for reversing the wattmeter connections by means of a reversing switch when the motor is operating as a generator.—"Electrical World."

Turbines in Warships

Once more the U. S. Dreadnaught "North Dakota" is in drydock for repairs to her turbines. These engines have been in trouble a good part of the time since the big ship was launched in 1910, and the navy's experience in this case has been such an unhappy one that it is unlikely that engines of this kind will be installed in new battleships.

Something like $200,000 has been spent on the "North Dakota" for repairs in five years, nearly half of which has been for repairs to the turbines. Naval experts deny that the frequent troubles with the engines are due to defects in material or construction, but charge the cost wholly to inaptitude.

Curtis turbines were installed in the "North Dakota" as a test for this type of engine and the "Delaware," a sister ship finished and launched in the same year, was equipped with reciprocating engines. On their trial trips the "North Dakota" made her required speed of 21 knots an hour, while the "Delaware" did half a mile better. Navy Department officials say that in coal consumption and efficiency the turbines have not made good, in comparison with other types of engines. At cruising speed, the coal consumption of the "North Dakota" has been from 30 to 40 per cent. greater than that of the "Delaware," even when the turbines were working well and in good repair.

Most of the trouble with the "North Dakota's" engines has been with her blading, and most of the repairs have been in renewing defective blading, nozzles, and the like. When she was sent to the Norfolk yard last month, to again underge repairs, an examination disclosed that most of the blading in the first and second rows of the first stage were broken, having been bent over and twisted out of shape by the steam pressure, almost like so much cardboard. It is now being repaired, and when finished, the ship will again be placed in commission, although it is the opinion of the department steam engineers that eventually the turbines will have to be removed and replaced with either electrically driven machinery or turbine reduction gear.

OBITUARY

W. C. GREEN

W. C. Green, well known to the Western mining trade for the past 25 years, and for the past six years representative of the Mechanical Goods Department of the Diamond Rubber Co., died Feb. 13, from an attack of pneumonia. Mr. Green's work for the Diamond Rubber Co. will be carried on by C. A. Tracy

FREDERICK W. TAYLOR

Frederick Winslow Taylor, distinguished for his labors in the field of increasing industrial efficiency, and the originator of the Taylor system of scientific management, died in Philadelphia, Mar. 21, of a sudden attack of pneumonia.

He was born in Germantown, Penn., in 1856, and received his early schooling in this country and in France and Germany. Impaired eyesight prevented his entering college at the age of 18, and he began an apprenticeship in a Philadelphia pump works. Completing this course, he entered the Midvale Steel Works and shortly afterward was in charge of the toolroom. In six years he was chief engineer of the company. By night study he was enabled to obtain an engineering degree from Stevens Institute in 1883.

While at Midvale he studied systematically the production and its expense, and increased the output 200 to 300 per cent. by increasing the men's pay 25 to 100 per cent. Later, this became his specialty: "The development and application of the science of shop organization and management." From 1890 on he practiced as a consulting engineer along these lines. In 1898, while retained by the Bethlehem Steel Co. to increase its machine-shop output, he with Maunsel White discovered the Taylor-White process of heat treatment, increasing the cutting efficiency of tool steel.

He presented two notable papers to the American Society of Mechanical Engineers: "A Piece-Rate System and Shop Management" and "The Art of Cutting Metals." In 1906 he was president of the society.

PERSONALS

W. D. Ranney has been appointed chief smoke inspector for the City of Columbus, Ohio.

William Siebenmorgan, formerly chief engineer of the C & C Electric & Manufacturing Co., of Garwood, N. J., is no longer connected with that company, his resignation having taken effect early in February.

ENGINEERING AFFAIRS

The American Society of Mechanical Engineers is to hold a meeting in San Francisco on Sept. 16 and 17, in connection with the Panama-Pacific Exposition. For the benefit of those who will attend, a special train schedule will be arranged over the Southern Pacific. It is planned to pick up at New Orleans those members who will start from the Middle West or South and other points farther west than New York. According to the schedule as at present arranged, the party will leave New York either Thursday evening, Sept. 9, or Friday evening, Sept. 10, and will stop at Niagara Falls, the Grand Cañon and possibly Colorado Springs. The Hotel Clift has been selected as the headquarters of the society during the meeting. An International Engineering Congress will be held in San Francisco from Sept. 20 to 25.

Two Ways of Going to Work

Both are getting the same salary now, but not for long

(Suggested by the letter from Milton W. Elmendorf, Wilkinsburg, Penn., page 515)

Hydro-Electric Power Plant at Chittenden, Vt.

By Thomas Fraher

SYNOPSIS—This hydro-electric development operates under a head of 430 ft. and was built to utilize the storage of a reservoir already provided, the water of which performed no work in flowing to the lower reservoir through East Creek. The plant consists of two 1850-hp. turbines, which drive two 1000-kw. generators. Provision has been made for a third unit.

The hydro-electric plant of the Pittsford Power Co., which is located in the town of Chittenden, about seven miles north of Rutland, Vt., presents an interesting feature in the fact that it operates under a higher head than any similar plant in the East.

The purpose of this development was to utilize the storage of a reservoir already in existence, the waters from which, in flowing along what is known as East Creek to a lower reservoir, performed no useful work. As the lower body of water served a hydro-electric plant of 1200-kw. capacity, erected in 1905 and in active operation, no water could be diverted from this basin, and the logical location of the new station was one as near to the elevation of the lower reservoir as nature would permit, to secure the maximum head, and so placed that all water discharged through the new plant would be available for subsequent use at the existing station already in operation.

The upper reservoir, although several times larger than the lower, is of comparatively small capacity, the quantity of water impounded being about one billion cubic feet. The area of the reservoir is 2414 acres, and that of its watershed about twenty-seven square miles. Notwithstanding the static head of 487 ft., the small amount of water available makes the horsepower development rather limited. The capacity of the two units at present installed is about 3300 hp., but provision has been made for the future addition of another similar unit.

After surveys and examinations of the territory, the location of the Pittsford Power Co. plant was decided upon as shown in Fig. 1, where it is possible to utilize the maximum head with a minimum length of penstock.

A study of the contours of the East Creek valley showed that by keeping the pipe line on the east side a suitable gradient of 0.3 per cent. could be obtained, which would permit a wood-stave penstock being built from the outlet of the reservoir to a point about 2700 ft. east of the proposed power house. At this latter location the drop is abrupt, thus requiring a steel penstock from there to the power house.

From the outlet of the dam of the Chittenden reservoir, a wood-stave penstock, 5-ft. inside diameter, extends 13,400 ft., except a section *A*, where the contours compelled the introduction of a $\frac{5}{16}$-in. steel pipe on an 80-ft. radius curve. At *B* there is a curve of 80-ft. radius, 75 ft. long, formed of three lengths of $\frac{5}{16}$-in. steel pipe, the first of which is a taper section, changing from 60 to 54 in. From *B* to *C* the diameter of the steel pipe is 54 in., and from the latter point to the venturi meter, just outside the power house, it is 52 in. The thickness varies between $\frac{5}{16}$ and $\frac{9}{16}$ in.

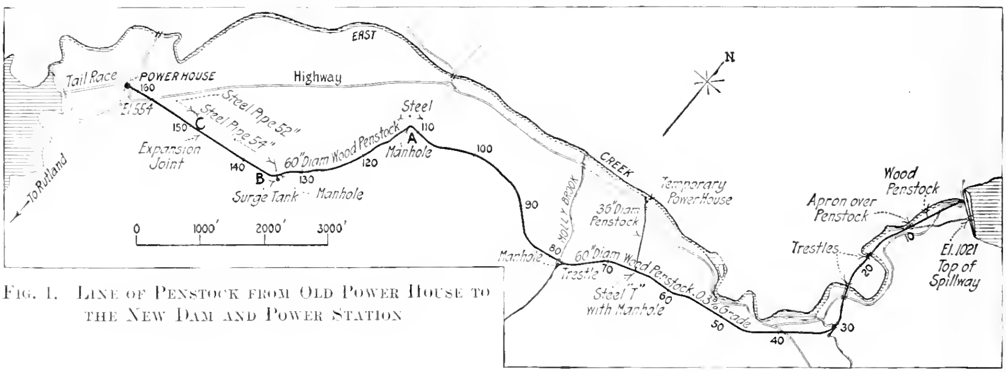

Fig. 1. Line of Penstock from Old Power House to the New Dam and Power Station

The elevation of the water in the Chittenden or upper reservoir, when the flashboards are on the dam, is 1021 ft., and the center of the outlet pipe in the dam is 975 ft., so that, dependent upon the stage of the water in the reservoir, the initial head on the penstock may vary between 46 and 5 ft., which is about as low as it is desirable to operate.

Connection between the outlet valve of the reservoir and the penstock is made through a steel nipple, which has a manhole and a 24-in. nozzle. Upon this nozzle was placed a 24-in. steel pipe, 55 ft. high, to act as a vent to prevent collapse when drawing off the water. This pipe was protected by a double frost casing of wood staves and is heated electrically by an old car heater.

For a distance of about 1400 ft. from the outlet of the dam the penstock was made of spruce cut from the company's tracts near the site of the work. The spruce staves were $2\frac{5}{8}$ in. thick, made from 3x8-in. and 3x6-in. stock and milled so that it took 21 staves from the wide stock and 7 from the narrow to make a section of pipe.

The wood-stave penstock, except the first 1100 ft., is made of live Douglas fir, 2½x6-in. stock, kiln dried, the finished staves being 2⅛ in. thick and 36 pieces being required to make a section of 60 in. diameter.

All bands were ⅝-in. diameter openhearth steel, a complete band consisting of two pieces, one having standard heads at each end and the other having 7-in. rolled threads at each end.

The spacing of the bands varied between 6½ in. at the dam, where the maximum head would be 46 ft., to 3 in. at the end of the wood-stave section, where the maximum head would be 85 ft. Manholes of pressed steel are provided at intervals, as indicated.

1000-kw. generator, together with the necessary auxiliary apparatus, and to keep this plant in operation until the permanent plant could be built and a similar unit installed, whereupon the apparatus in the temporary station would be removed to the permanent power house.

Early in February work on the temporary power house was abandoned, as it had been decided to build the entire project, and work was begun on the excavation necessary to provide a uniform gradient of 0.3 per cent. for the pipe line.

Tile drains of 12-in. diameter were put in at the places where fills were to be made. The tile was laid in a bed of clean sand or gravel, and the joints cemented. Small

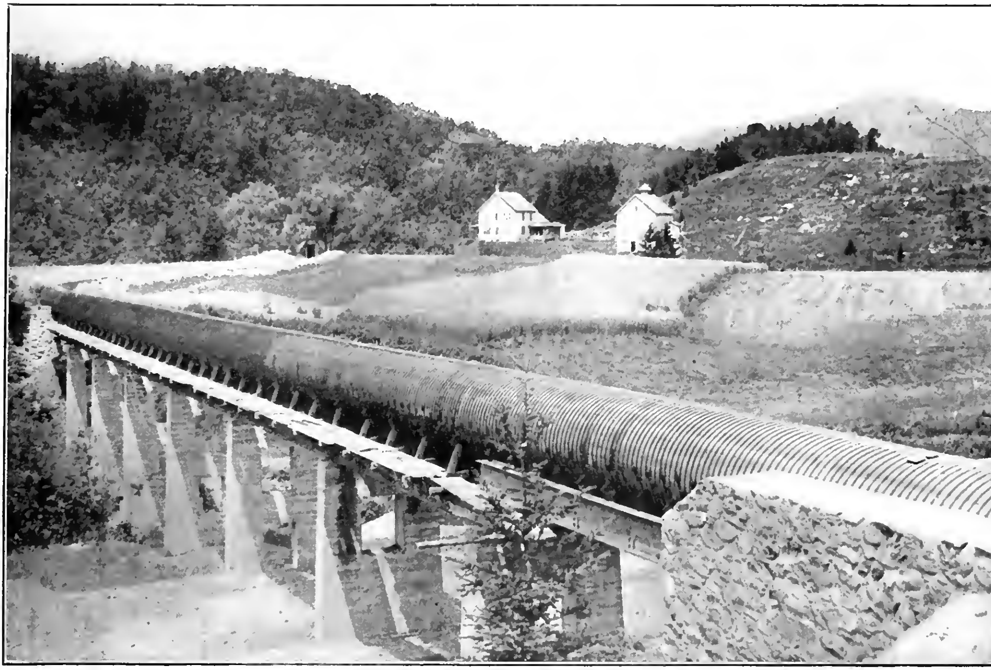

Fig. 2. Concrete Trestle Supporting the Penstock

At a point near where the wooden and the steel pipes join, an equalizing tower 14 ft. in diameter and 90 ft. high is located. The elevation of the bottom of this tower is 950, or 16 ft. above the center line of the end of the wood pipe, and the top of the tower is 19 ft. higher than the flashboards at the dam. This tank consists of one 10-ft. ring at the bottom and sixteen 5-ft. rings above. Each ring is made up of three segments, bent and dipped before shipping.

About Jan. 1, 1914, it was decided to undertake the construction of part of this development by the company forces, as it had a contract which stipulated that from July 1, 1914, it was to deliver a maximum of 600 kw. To live up to this agreement, provision was made to build the main penstock from the dam to a point about 6500 ft. distant, where at *D* a right-angle turn was made, and by running a distance of 1080 ft. a static head of about 200 ft. would be available. It was intended to set up at this point one of the two 1875-hp. turbines and a

rubble walls were built at the intakes and outlets of these culverts.

The wood-pipe line crosses East Creek twice, requiring two trestles, and also crosses a small brook. The trestles have rubble abutments, and the intermediate piers are of a uniform type, being 2x8 ft. at the top, with the front and back vertical and the sides battered ½ in. per foot from the top. They are of 1:2:4 gravel concrete, reinforced with vertical and horizontal bars. Fig. 2 is a photograph of the largest trestle.

The Chittenden dam is 1000 ft. higher than Rutland and 10 miles distant; the power house is 500 ft. higher and 7 miles distant. With the exception of about two miles near the city, the roads are poor. The freighters hauled at the rate of $3 per ton, and in all about 2000 tons had to be moved. The 30-ft. lengths of steel pipe varied between 3¼ and 5 tons.

About 40 per cent. of the wood stave line was composed of curves. With the exception of the stretch between *A*

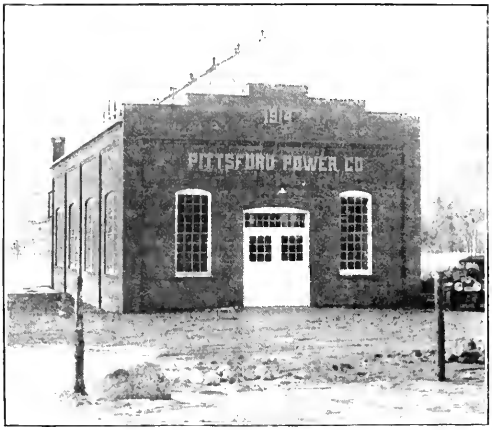

Fig. 3. Chittenden Power House

and B, all curves were either 360 or 300 ft. radius. In the locality mentioned there were some curves of these radii, but also a few sharper ones, notably one at about 175 ft. radius. The average construction progress on curves was about 200 ft. per day of 10 hours, and on tangents about 300 ft. The best day's work was 420 ft., made on a tangent where the staves averaged about 25 ft. in length.

At points where the stave pipe joined the steel pipe, the latter had the rivets countersunk for a distance of 4 ft. from the end, and presented a smooth outside surface for the staves to be fitted over.

It became evident in the latter part of May that the permanent power house could not be in operation by July 1, and so it was decided to build the temporary installation. Therefore, work was resumed with a view to getting in the foundations for the turbine and generator.

At the point D, Fig. 1, a steel tee had been inserted in the main line, and from this a 3-ft. penstock line 1080 ft. long, of which the upper 580 ft. was of spruce and the lower 500 ft. of $\frac{1}{4}$-in. steel plate, single lap, with $\frac{5}{8}$-in. rivets, was built. The spruce staves were milled by the company, and one-piece bands were used. The steel pipe was sublet to a local firm, which made it right at the site of the work.

The ends of the steel tee were punched for $\frac{5}{8}$-in. bolts on 3-in. centers and the staves of the penstock were bolted to the steel tee. At the back of the tee a connection was made to a 2-ft. diameter steel pipe, 80 ft. high, erected to fulfill the function of a surge tank and vent.

About three feet from the downward end of this steel tee a 5-ft. diameter $\frac{1}{4}$-in. steel boiler head was set up as a bulkhead to divert the water through the temporary power-house penstock and to permit turning on the water before the rest of the line was finished. Oakum was packed in wherever possible between the bulkhead and inside of the pipe.

The temporary plant was in operation until Oct. 1, at which time the machinery was dismantled and placed in the permanent plant. The penstock was taken apart and utilized at Molly Brook, where a small collecting basin was built at an elevation of 80 ft. above the penstock at that point and the water conveyed through the 3-ft. penstock into the main pipe line.

The steel pipe was placed alongside the trench by the

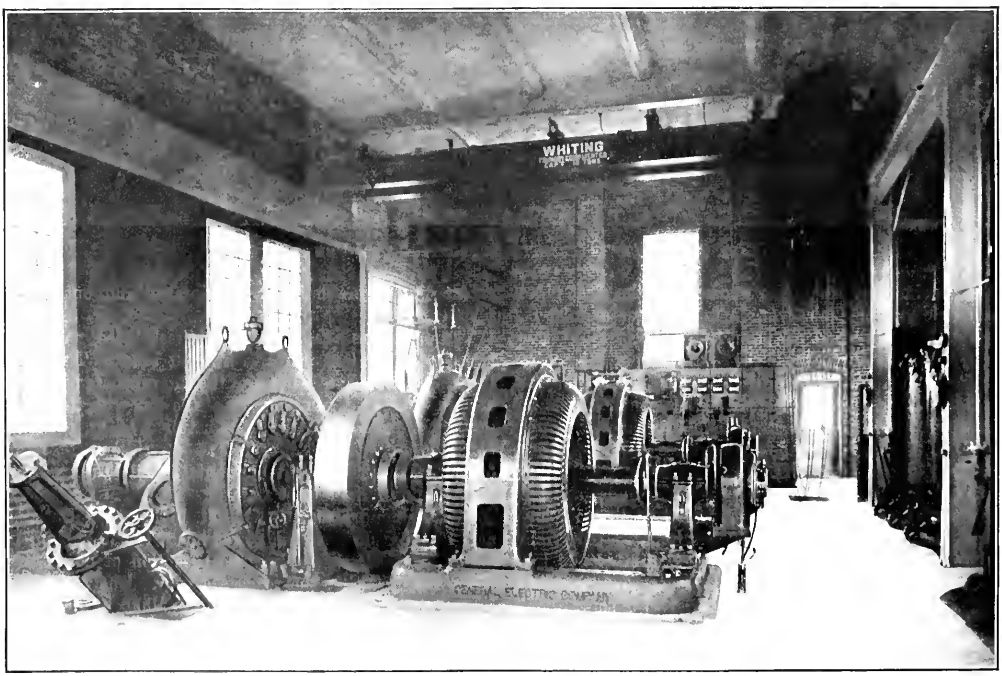

Fig. 4. Interior of the Chittenden Power Plant

company and the pipe contractor's gang rolled the lengths in the trench and used two small derricks to aid in bolting up.

The reaming, riveting and calking followed in the order named; an expansion joint was placed 1418 ft. from the dam to allow for movement of the pipe previous to filling it with water and covering it.

The surge tank is on a rocky knoll at the point *B*. The concrete foundation is, on an average, 3 ft. thick, and six 2½-in. stay-bolts, fitted into holes drilled in the rock and also embedded in the foundation, provide against movement. The connection between the penstock and the tank consists of a 18-in. steel pipe. Between this pipe and the end of the wood pipe, a distance of about 10 ft., is a 60-in. butterfly valve. At the bottom of the penstock, just in front of this valve, is a 12-in. blowoff valve designed to pass such water as might leak past the butterfly, so that no water could leak down the pipe when not so desired. There are manholes in the steel pipe near the butterfly valve and at two intermediate points and the pipe may also be entered through the turbines.

The surge tank has a manhole near the bottom, and a ladder outside affords access to the top. After testing, a frost casing 18 ft. in diameter, or 4 ft. larger than the diameter of the tank, was built. Old 2-in. planks of various widths were used, butted off square without the edges being beveled radially. The first set was placed so that adjacent pieces broke joints, nailed plumb in place, and then ⅝-in. bands on 2-ft. centers were clinched tight. The remaining sets were easily added. At the top is a silo roof, in which a door is arranged to admit air if the drawing off of the water should tend to form a vacuum. The frost casing was covered with a coating of cement-lime plaster applied to a wire lath as a protection against fire and decay; provision was made for heating during the winter months.

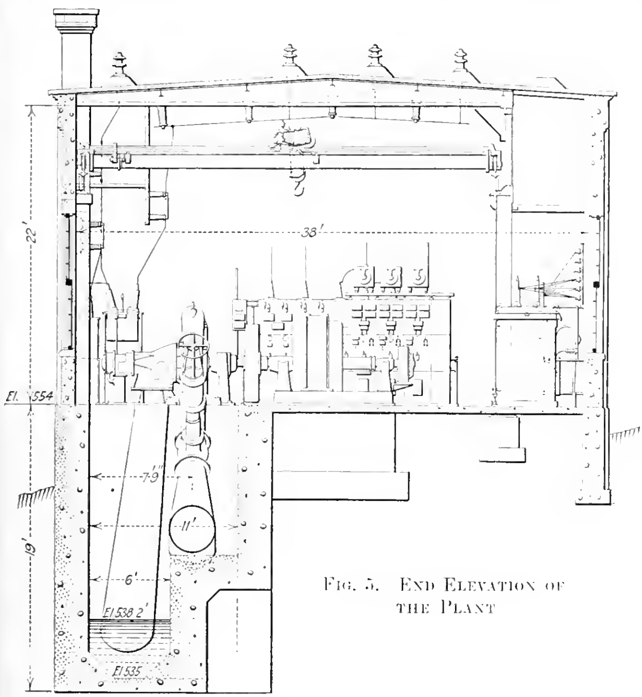

Fig. 5. End Elevation of the Plant

Power House

The permanent power house is a single-story structure 38x71 ft. inside and 22 ft. high (Fig. 3). The foundation walls are of 1:2:4 gravel concrete of an average depth, excepting the south wall, of about 6 ft.; they are 18 in. thick and rest on a 12-in. footing course 3 ft. wide. The south wall, which forms one side of the tail race within the building, has a depth of from 12 to 19 ft. and is 30 in. thick.

The walls of the building consist of a 12-in. double-faced brick wall, pilasters 28 in. square being introduced so as to divide the north and south walls into four bays and the east and west into three bays.

The roof is framed of three transverse girders, between which are standard I-beams, and is covered with a 4-in. concrete slab reinforced with triangle-mesh reinforcing. The roof is waterproofed with six layers of tarred felt and stone screenings.

The steel penstock enters the building normal to and through an opening in its front wall, and about eight feet from the south wall. Three nozzles lead from the penstock to feed the turbines; they are 24 in. inside diameter and flanged to take a 24-in. valve, fitted both for hydraulic and hand operation. When the pipe had been filled and tested the penstock was heavily anchored with concrete.

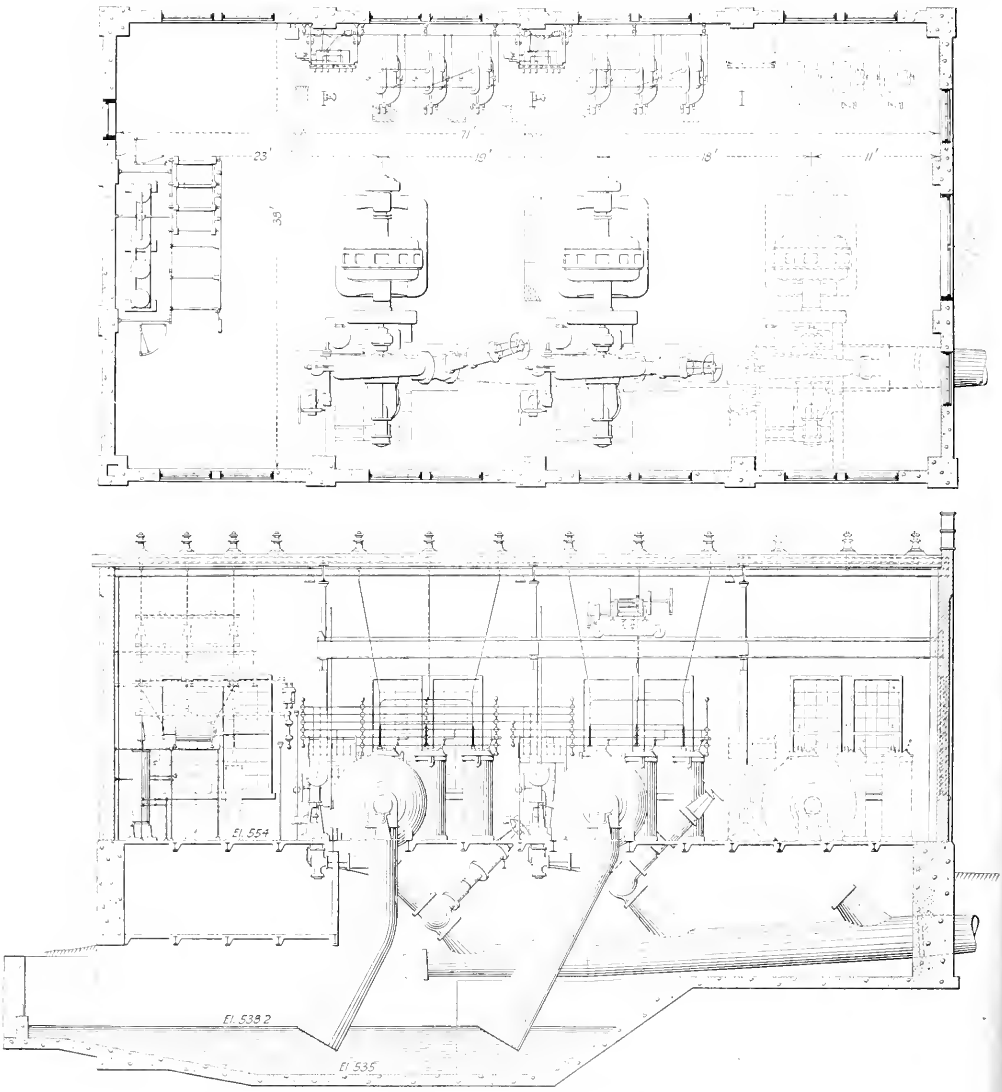
The tail race lies at the south side of the building and is 11 ft. wide, and 18 ft. deep. Over the west or back end of this building was built a small room, in which is installed a low-pressure boiler for heating the building.

The turbines are placed over the tail-race, each being carried by a pair of 12-in. H-beams, secured by anchor bolts and concreted in. Space has been provided for three units, although at present only two have been installed. The turbines, of the Francis type with wicket gates, are of 1850 hp. at 720 r.p.m. under a 430-ft. head at full gate opening. All the gate-operating mechanism is on the outside of the flume, and is controlled by a governor of the direct-connected type, arranged for electric control. The runner consists of a bronze runner band with a cast-iron hub, the latter being securely keyed to the turbine shaft. The spiral flume is made of a single iron casting and has the form of a true evolutionary spiral. The gates and the guide ring are made of cast steel, and the gate ring of cast iron. The turbine shaft is made of hammered steel, 6 in. in diameter on the driving end and 4½ in. on the remote end. The driving end of the shaft is fitted to the hub of the 5-ft. 9-in. cast-iron flywheel, which weighs about five tons. The remote end rests in an end-thrust bearing arranged to operate in a bath of oil.

The draft tube is about 15 ft. long and has a diameter of 48 in. at its lower end. To protect the line against undue rise in pressure caused by the action of the governor under the varying conditions of load, a relief valve capable of discharging 30 cu.ft. per second is installed.

The side of the flywheel remote from the turbine is fitted with a flange, to which a forged flange on the generator shaft is fitted to couple the two together.

An interior view of the power house is shown in Fig. 4. Figs. 5, 6 and 7 are plan and elevation of the power plant. Just outside the power house there is inserted in the pipe line a venturi meter with a 52-in. inlet and 27x42-in. outlet. Both the inlet and outlet ends of the castings are flanged, and faced and drilled to take the $\frac{9}{16}$-in. flanges of the adjacent steel pipe. The meter is connected to an automatic register indicator recorder.



FIGS. 6 AND 7. PLAN AND SIDE ELEVATION OF THE HYDRO-ELECTRIC PLANT

ELECTRICAL EQUIPMENT

The station is designed for a maximum continued capacity of 3000 kw. at 44,000 volts and 80 per cent. power factor, this energy to be generated by three units and delivered through two 44,000-volt feeders. Two units and one feeder are now in regular operation, and the third unit and second feeder will be added when necessary to take care of the future increase in load.

Each generator is rated at 1250 kv.-a., 2300-volt, three-phase, 60 cycles; and with a 25-per cent. overload for two hours the rise in temperature is guaranteed not to exceed 55 deg. C. above the room temperature of 25 deg. C. Each generator has its own direct-connected exciter, operating in parallel at 125 volts.

There are at present two banks of transformers, each consisting of three single-phase, 100-kv.-a., 2300-44,000-volt, water-cooled transformers, and with a 25-per cent. overload for two hours, the rise in temperature is guaranteed not to exceed 55 deg. C. above a room temperature of 25 deg. C. Cooling water is supplied from the penstock at a reduced pressure.

The switchboard is of marble and consists of exciter feeder panel with voltage regulator, generator, lighting and a blank generator panel. All control and instrument wiring is installed in iron conduit laid in the concrete floor. As the oil switches are remote-controlled, 125 volts is the maximum on the switchboard.

A 2300-volt bus of copper tubing is supported vertically on the north wall back of and above the transformers. The generators connect to this bus by means of lead-covered, varnished-cambric insulated cables laid in fiber ducts below the main floor, and the usual oil switch and disconnecting switches.

Each transformer bank is connected to the 2300-volt bus through disconnecting switches and to the 44,000-volt outside bus on the roof by means of copper tubing through the roof bushings and a three-pole air-brake switch, this switch being hand-operated from the station floor.

The 44,000-volt bus, three-pole, air-brake switches and lightning-arrester horn gaps are mounted on pipe framework supported on the roof, the entire roof being used for this purpose.

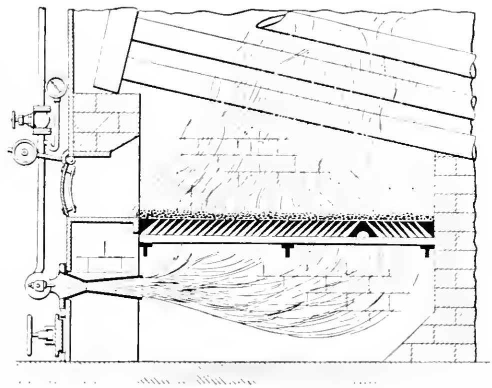
An iron stairway at the west end of the building provides easy access to the roof through a door and landing at the main-floor level.

Electrolytic lightning arresters of indoor type are connected to the horn gaps through roof bushings. The present feeder connects to the 44,000-volt transmission line through a three-pole, 44,000-volt, indoor-type, remote-controlled auto-oil switch and the usual disconnecting switches and choke coils.

The Pittsford Power Co. development was designed and constructed under supervision of W. S. Barstow & Co., engineers and managers, of New York City.

Poillon Furnace Grate

The Poillon grate illustrated herewith is designed to burn fine dust, lignite, coke and other grades of coal. The particular feature is that the direction of burning gases is from the ends of the grate toward the center of the furnace.



Poillon Furnace Grate

In the ordinary furnace the liberated gas flows toward the bridge-wall and upward. With this grate the currents are from the front of the furnace toward the rear and from the rear toward the front, caused by the angle of the air spaces in the grate. The result is that the liberated gases from freshly fired fuel at the front mingle with the hot gases from the rear end of the furnace, and their combustion takes place before striking the cooling surface of the boiler tubes.

The mingling of the two currents distributes the flames over a large tube area and prevents the hottest flames from striking the tube in the form of a jet, as would be the tendency were they to go to the tubes with no interruption.

As illustrated, the grate (which is placed on the market by Julian Champeaux, 36 Downshire Hill, London, N. W.) is used in connection with a blower.

PRINCIPAL EQUIPMENT OF CHITTENDEN HYDRO-ELECTRIC POWER PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
2	Turbines	Francis, wicket gate	1850-hp.	Driving main generators	430 ft. head, 720 r.p.m	S. Morgan Smith Co.
2	Generators	Alternating-current	1250-kv.-a	Main units	720 r.p.m., 2300 volts, 3-phase, 60-cycle	General Electric Co.
2	Governors	Direct-connected		With main turbines	Electrically controlled	Lombard Governor Co.
2	Exciters	Direct-current		With main generators	Coupled to generator shafts, 125 volts	General Electric Co.
1	Switchboard	Marble		Electrical control of units		General Electric Co.
6	Transformers	Water-cooled	400-kv.-a.	Stepping-up current	2300-44,000 volts, single-phase, 60-cycle	General Electric Co.
	All electrical apparatus in power house, such as switches, lightning arresters, etc					General Electric Co.

Illumination is obtained from six 250-watt tungsten lamps in deep-bowl reflectors hung close to the ceiling, the outlet boxes and connecting conduit for wiring being cast in the concrete roof. Extra illumination and plug receptacles for portable lamps are conveniently distributed on the walls of the building. Outdoor lighting is provided for the roof by means of street lighting fixtures, thus assisting greatly in inspection and repair at night.

Illumination is controlled from the eight-circuit lighting panel, which is a part of the main switchboard. A double-throw switch mounted on this panel enables the lighting supply to be taken from the 2300-volt bus through a 3-kw. transformer or from the exciter bus.

The permanent power house was placed in operation about Oct. 1, 1914, and the unit from the temporary plant was set up during that month.

Boiler Accidents—A report submitted at the convention of the American Society of Mechanical Engineers in New York City last December contained the following statement:

Every year there averages in the United States between 1300 and 1400 serious boiler accidents, of which 300 to 400 are violent explosions. These accidents kill between 400 and 500 persons, injure 700 to 800 more, and destroy more than half a million dollars' worth of property. In a single explosion, that of the R. B. Grover Shoe Co., at Brockton, Mass., 58 persons were killed, 117 more were injured, $250,000 worth of property was destroyed, and an aggregate of $280,000 was claimed in the personal injury and death suits that were brought. In a period of 46 years, since 1867, over 10,000 people have been killed and over 15,000 injured in boiler explosions

Pre-Efficiency

By Geo. F. Willis

SYNOPSIS—The importance of the preliminary work while laying out a power installation. Only by studying the conditions and selecting the equipment to suit can one expect to have a truly efficient plant.

This is the day of efficiency in all classes of manufacturing, and the successful manufacturer looks for it all along the line. After a plant is built, the operation is closely watched in order that efficiency in all departments may be secured. Many schemes, from piecework to bonus payment, are used, all to add to the one proposition—efficiency.

But how few manufacturers or owners go at this matter from the first inception of the plant! It is decided to build a factory for a certain purpose, costing say $250,-000. It is easy to find architects competent to build the housing, and the plans are made, submitted and accepted. But the power plant, the real heart of the proposition—the boiler and engine equipment, the electrical power to be used for lights and motors, the pumps, economizers, heaters, condensers—all this is usually left to the architects, who are the last people who should have any say as to this part of the outfit, as their experience and efficiency are practically limited to the building itself. They work out the balance of the scheme as best they may, as an accessory to the original in which they are most interested, and men are too often influenced by personal acquaintanceship and prejudice.

The use of oil and gasoline engines, producer-gas equipment, electrical driving and its advantages and disadvantages—these problems are neither thoroughly considered nor gone into expertly, but are usually left to the good or bad judgment of the original designers of the building itself. When it is known that in building a factory costing the amount mentioned, there might be made a saving of 10 per cent., or $25,000, by calling in engineers in the special lines mentioned, their cost being but a small part of the saving named, it is curious that such technical ability is seldom called for, and the factory is built without the owners knowing what might have been saved for the same capacity or what might have been added to the capacity reached, by the advice of technical experts in the particular line for which the factory is built.

The writer is often confronted by the advertisement of some manufacturer of belts, for instance, who will take a whole page in some technical journal to tell about a big belt he has just supplied to some concern. This will be a triple leather belt, 84 in. wide and 160 ft. long, we will say, and he goes on to tell how many steer hides it took to make it, how much it weighs, what it will drive, etc. In the writer's opinion, anyone shows poor judgment who uses a belt any wider than, or even as wide as, 24 in. He also believes that manila-rope transmission for anything in the way of main drives from 50 hp. up is cheaper and better than any belt drive. In the case of such a belt as mentioned, the saving in the original cost by using ropes would be some $2000, and the ropes would have as long life as the belt, with less slippage and a smoother and more positive drive all around. In such a case it is probable that the designers of the plant have seen so many wide belts in other plants that they have no idea anything else could be used. It is a case of mental suggestion.

Take the case of a company building a $75,000 sawmill. It is willing to and usually does build the plant from the plans of the maker of the machinery to be used, who is naturally a much interested party. As a judge of the design the purchaser calls in his old foreman, who has been with him many years, and as he ran the old plant successfully he is considered an authority. He well knows every weak place in the old plant, and he is firmly resolved that in case he has anything to say about the new one, these weak spots will be eliminated. So when the new plans are offered him for his criticism, he rigidly turns down anything that looks like the trouble spots he had to contend with for so many years, and finally approves the plans submitted. He does not know what new troubles the new plant will bring, and he is not capable of selecting from the mass of technical details of machinery offered the best to be used. So the concern buys, and the mill is built. It may run to the satisfaction of the owners, but like a doctor's mistakes, all that have been made are buried; and while it might have been possible to build the same mill for less money, to build a better mill for the same money, to build a mill at the same cost which would produce the same amount of lumber with a few less hands, all this is unknown, and the expert engineer was never called in, everything being left to the judgment of one man who knew all about one mill and nothing of any other.

The writer's experience of something like twenty-five years in designing and building plants has shown him that efficiency rarely begins at the commencement of the operation—where it more properly belongs than at a later period—and that nine out of ten plants are built from crude ideas of owners and employees. One manufacturer who intends building is positive that he will use electrical transmission throughout. He does not know exactly why, but he has read of the great strides that have been made in introducing this system, and as a factory a few blocks away has just been completed and this transmission is used throughout, why should not he use it? It may be that this is the least desirable system for his special requirements, but he does not call in a transmission expert to secure his views and advice. The electrical people are willing to meet him more than half way and confirm his views and wishes. So he spends much money for a power-transmission scheme that does not suit his conditions and is satisfied forever afterward because his factory runs and produces.

No one maker of machinery builds a full line of the best. He may have one or two machines that cannot be equaled, one or two that are about as good as others, and the rest of his line not so good as those built by his competitors. But the tendency is to buy the full equipment from one maker, on a blanket proposition covering the full list of machines required. This, in a way, largely depends upon the salesman that secures the order. Many times the writer has sold the complete equipment for a plant on the strength of one machine which his company originated, and built better than anyone else. The fact that this machine cost several hundred dollars more to build than was got for it mattered not, as this was made up on the remainder of the order. Six out of ten times we sold the power plant, which we did not build at all, and which we bought as cheaply as we could so long as it approached the requirements—said requirements being suggested by ourselves, of course. Had a competent engineer been called in on these jobs, it is likely we would have secured the order for the one machine we built better than our competitors and that the rest of the equipment would have been ordered from other makers—as it should have been.

Were a man to contemplate building a home to cost $75,000 or an office building to cost $250,000, he would first go to the best architects he knew of to procure the plans. They would supposedly have at their command technical engineers who were thoroughly conversant with all building requirements and whose efficiency would be added to that of the members of the designing staff. The plans would be prepared with great care and thoroughness, and after a careful analysis by the owner, would be accepted and built from. Were the same man to contemplate the building of a sawmill costing as much or more, he probably would leave the important part of the whole proposition to "Jim," who had run the old plant for thirty years and who should know just what was needed in a new one.

As to power efficiency, the proper kind and character of the boiler plant, whether steam or gas or electricity should be used, all swings on the opinion of the old employee, whose influence is not to be laughed at either. Good or bad, his advice is followed, greatly to the embarrassment of the expert, should one be called in.

In the city in which the writer lives, is one of the largest and, supposedly, one of the most advanced companies in the world, which has become famous by dividing its profits with its employees, with which strikes are unknown, and whose power plant is one of the sights of the city. It has been shown by technical engineers of high standing, after an investigation lasting for weeks, that by scrapping its beautiful engines—nickel-plated and in a room as beautiful as any parlor—the company could make a saving in fuel and upkeep amounting to many thousands of dollars yearly. Would it do it? No, because a man who had been for years close to the president and had sold the company its valves and small equipment advised against it—said the plant was all right as it was and that the experts did not know what they were talking about. His advice "went," and no change has been made. This simply goes to show the small amount of credence given the technical engineer in matters within his own province, and on which he has absolute information.

In the really great and advanced plants engineers may be found who are employed at salaries running up to $25,000 a year and more, and they are cheap men at the price. But in the half-way plants, the ones costing up to the half-million mark, where the technical engineer is nearly always badly needed, he is seldom called in. It is easy to be too technical, so to speak, but the combination of fifty-fifty—half experience and half technical knowledge—will, when secured for even a small plant, well repay the owners, not only in the original cost, but in the following years of operation.

Just for Fun

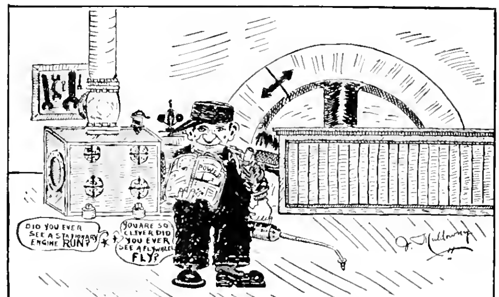
[*More stories of stupidity and ignorance competing with "Some Original Ideas," as printed Jan. 19, 1915.*]

"What's the matter?" asked the superintendent of the second-class licensed engineer on hearing the receiver relief valve blowing fiercely on the 1200-hp. compound engine.

"I guess the exhaust pipe has burst between the engine and the condenser."

"Well, the vacuum is up to 27 in., isn't it?"

But the engineer was making haste to start the larger engine and did not wait for argument. The superintendent, who had formerly been the chief in that station, walked over to the low-pressure side of the engine and pushed the reach rod up forward on the governor, and the relief valve stopped blowing. The engineer returned hastily to see what had caused the engine to become quiet so suddenly. He was cautioned not to tell anyone that he thought the exhaust pipe on a condensing engine had burst with 27 in. of vacuum, but thereafter to watch the governor on the low-pressure side to see it did not unhook again, leaving both steam valves closed.—*R. A. Cultra, Cambridge, Mass.*



A WELL KNOWN EXPRESSION
"MORE POWER TO YOU"

A young man recently out of college secured employment as helper around a power plant in an industrial establishment. One day the engineer was called to another part of the plant and left the young man alone in the power house.

After a time the engineer noticed a cloud of steam coming from the blowoff pipe. He did not pay much attention to it at first, thinking that the young man had too much water in the boilers and wanted to blow down a little, but when the blowing had continued for some time he started for the power house to investigate.

Upon arriving, he found that a gage-glass had broken and that the helper had the blowoff valve wide open. When questioned concerning his reason for having the valve open, he said that he wanted to let out the pressure so that he could put in a new glass.

It might be well added that the young man had not studied engineering while at college, but is now a good engineer and has had some six or eight years of experience in the "school of hard knocks" since the incident related.—*Earl Pagett, Coffeyville, Kan.*

Diesel-Engine Installation at Palo Alto

By Herbert Haas

SYNOPSIS—By installing a 300-hp. Diesel engine to carry the day load and using one of the steam units to help out on the peak, a saving of about $6000 has been effected. Heavy California residue is used.

In 1913 the City of Palo Alto, Calif., contemplated replacing its old and rather wasteful steam engines with a steam turbine of excess capacity above the equipment then in operation, which consisted of a cross-compound, slide-valve engine coupled to a 200-kw. alternator, a similar engine driving a 100-kw. alternator, both operating noncondensing, and a single-cylinder, simple engine, with Corliss valve gear, belted to a 50-kw. generator. The two larger engines furnished practically all the load, which for a short period, between 7 and 10 p.m., rose to 330 kw. The steam turbine was to be a 500-kv.-a. unit, operating condensing, its excess capacity being intended to take care of expanding power and light business.

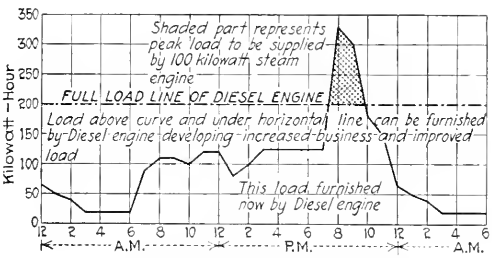


Fig. 1. Load Characteristics for 24 Hr.

Fig. 1 shows the load characteristics during 24 hr., based on a yearly average of the load in 1912. It will be noticed that it is a typical lighting load, only a portion of the power being used in the daytime to operate pump motors. With a load factor, then, of about 30 per cent., this would have become still more unfavorable after the installation of a 500-kv.-a. turbine, for the load would have been around 20 per cent. of the rated capacity of the turbine during the greater part of the time.

Therefore, the writer advocated the installation of a Diesel engine, which, to save in initial investment, was to be of moderate size only, sufficient to carry the entire load except between 6 p.m. and 10 p.m., when one of the existing steam engines was to operate in parallel with the Diesel engine to supply the peak load. The average fuel consumption of the steam plant was 11,000 lb. per day for an average output of 2620 kw.-hr. per day, or 4.2 lb. of fuel oil per kilowatt-hour. It was figured that the Diesel engine would furnish 2400 kw.-hr. (operating at fractional loads, as shown in Fig. 1) with a fuel consumption of 1800 lb., and that the 100-kw. engine unit, operating at full load, would furnish the other 200 or 250 kw.-hr. with a fuel consumption of about 4 lb. per kw.-hr., or 800 to 1000 lb. of fuel oil, in addition to a moderate amount of oil to keep one of the boilers always under steam as a stand-by. Thus, about 22 to 24 bbl. of fuel oil, costing 90c. per bbl., could be saved per day. Against this saving had to be charged interest and amortization on the capital invested in the Diesel engine plant, the slightly higher cost of cylinder lubrication and maintenance. It was thus figured that a saving of $6000 to $7000 per year could be made by the installation of a Diesel-engine set. The operating force was not increased, so the labor item remained the same. It will be seen from the load curve that the Diesel engine would be operating only at about 50 per cent. of its capacity during the day, so that considerable reserve capacity was available for a future increase in load during this period, and any increase in the peak load could still be furnished by the existing steam equipment.

One of the requirements of the engine was the burning of California crude oils or residues, of the same or similar quality as that which is burned under the boilers. The power plant is some distance from the railroad, the fuel oil being pumped to it through a pipe line, which would make it difficult to supply two different oils, one for the boilers and the other for the Diesel engine.

In view of the extensive development of this type in Germany, and after thorough investigation, the Körting Diesel engine was selected, as this engine was found to be giving excellent service in Mexico, running on the heavy asphaltic oils and residues similar to the California oils. The engine is of horizontal construction and has four cylinders. The shaft is extended, and carries the flywheel and the alternating-current generator between the left outer main bearing and an outboard bearing. Beyond the outboard bearing there is a further shaft extension, to which are keyed the armature and commutator of a 10-kw. exciter. The shaft is forged in halves, coupled together between the halves of the engine. To the right-hand shaft end is bolted a crank disk, from which is driven the air compressor. Each shaft section has two cranks, set at 180 deg. The generator is a two-phase, 60-cycle, 40-pole Fort Wayne machine, wound for 2300/2400 volts, and rated at 250 kv.-a., which at 80 per cent. power factor is equivalent to an output of 200 kw.

The pistons are of trunk pattern made especially long to reduce pressure exerted through the crank and piston pins and prevent wear of the cylinder liners. The valves are seated in the cylinder heads, and are all easily accessible, being mounted in individual cages, and can be quickly exchanged. This is of importance, as the exhaust and fuel-injection valves have to be cleaned monthly; spare valves are put in their places and the removed valves are then cleaned at leisure, and kept in readiness.

The governor and valve-gear shafts are operated directly from the main shaft through helical gears running in oil. The governor shaft operates the engine governor, lubricating pumps, and fuel pumps. Of special note is the construction of the fuel pump and the fuel injector. The pump does not have to force the oil against the injection air stored around the fuel-valve needle at a pressure of 800 to 900 lb., a practice common to many

Diesel engines. Instead, the pump works at just enough pressure (only a few pounds) to lift the oil into a chamber in the fuel injector during the suction stroke of the piston. The governor can, therefore, act directly on the pump plunger and vary its stroke according to the exact fuel requirements of the engine, proportionate to its load. The fuel injector has no needle valve, but consists of an open Körting atomizing nozzle. A few degrees before the completion of the compression stroke, a valve in the fuel injector connecting with the injection-air supply pipe is opened, admitting the highly compressed air, at 800 to 900 lb. which carries the fuel-oil charge (stored in the injector during the suction stroke) into the cylinder, at the same time completely atomizing it.

Each cylinder has its individual fuel pump, two pumps being mounted on each valve-gear shaft. The Hartung governor acts on all four pump plungers simultaneously, through wedges which increase or decrease the throw of the plungers with an increase or decrease in the load of the engine. This method of governing is very sensitive, the engine adjusting itself instantly to changes in load.

Another feature worthy of note is the method of starting. Instead of using high-pressure air, which takes considerable power to compress, the engine is started with air at 220 lb. and can be started with a pressure as low as 110 lb., if necessary. The air is stored in a sheet-steel receiver. This method of starting is made possible by having the exhaust valves open during the compression stroke, so that the cylinders work against atmospheric pressure only; when the engine is up to speed, the sequence of the valve play is changed, the air is compressed, and the fuel charge is admitted, the exhaust valves then discharging the products of combustion.

The air for starting the engine and the injection air for atomizing the fuel and forcing it into the engine cylinder is furnished by a three-stage compressor, the low-pressure stage being vertical, the intermediate and high-pressure stages being tandem horizontal cylinders. Between each stage there in an intercooler and oil separator, and the compressor cylinders are all water-jacketed for cooling. The interposition of coolers and oil separators is an important safeguard to prevent explosions. The injection air is stored in two wrought-steel bottles, 8-in. diameter by 6 ft., of which one only is in use, the other acting as a reserve.

The oil flows to the fuel pumps by gravity from a supply tank holding one day's supply and supported on a shelf attached to the wall of the engine room. It is pumped to this tank from the concrete main storage tank, which is built into the ground outside the power house. This fuel oil, being a residue of California crudes (topped oil), has to be heated on account of its high viscosity. This is usually done by using the heated jacket water of the engine. For starting, a gas oil is used (Standard Oil Co.'s Star fuel oil) and, after a few minutes' operation, the engine and circulating water are warm enough to substitute the residue. At Palo Alto, however, the latter is now heated by steam and the engine runs continuously on the residue.

The air intake for the engine and for the compressor is on the outside of the power house, the air main and individual air conduits leading from it being built into the engine foundation and connecting with the air-intake pipes of the cylinders. The exhaust gases are passed through two double silencers and then through pipes leading under the boilers, from which they are carried off by the boiler stack. The pipe connections between the exhaust ports and the silencers are water-cooled to prevent excessive radiation and heating of the space immediately around the engine heads.

All internal lubrication is supplied by two Bosch lubricating presses operated from the governor shafts. The

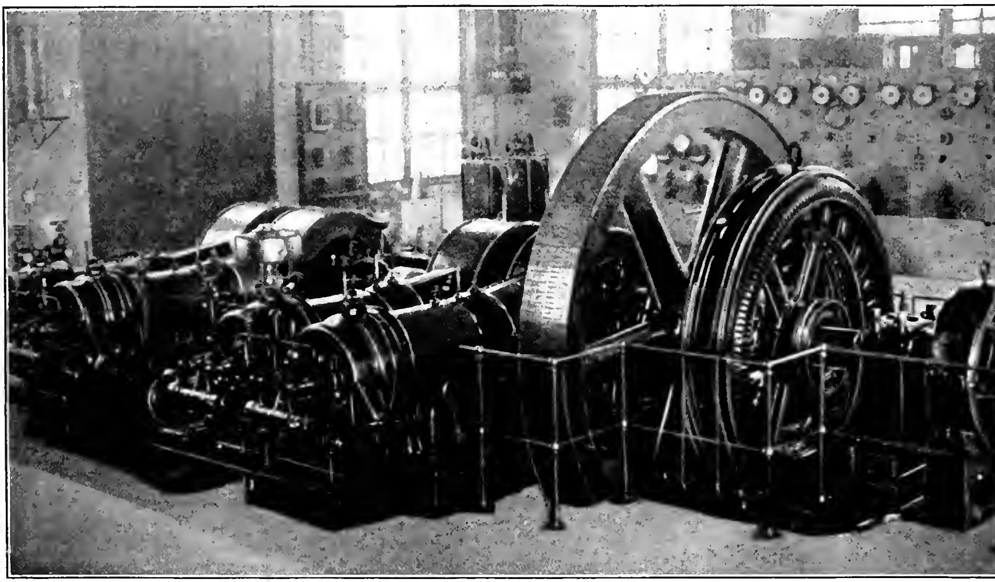

Fig. 2. Installation of Körting-Diesel Engine at Palo Alto, Calif.

piston pins are also lubricated by these. The lubrication of the main bearings and of the crankpin bearings is supplied by a geared lubricating pump, which forces a stream of oil to each bearing, collecting rings preventing any being spilled. The oil is fed to the crankpin bearings by lifting rings. All oil is collected in the crank case, flows through a filter and cooler, and is returned to the main container, located below the floor. The bearings are also provided with individual glass reservoirs and rings for use in case the lubricating-oil pump should fail.

For testing the engine before shipment, 4 tons of Standard Oil Co.'s Richmond fuel oil (a residue) was

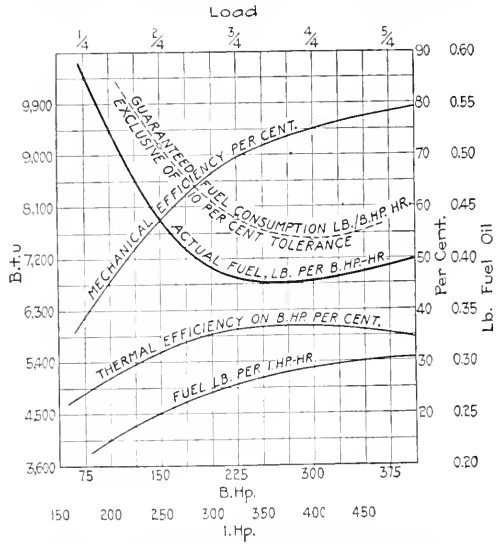

Fig. 3. Performance Curves of 300-Hp., Four-Cylinder Körting-Diesel Engine

shipped to Germany. R. E. Mathot, of Brussels, acted as consulting engineer for the City of Palo Alto, and conducted the tests at the works of the builder. The principal test data are here given, and the engine performance is shown in Fig. 3.

The California fuel oil (Richmond Fuel Oil) had the following properties:

Lower heat value	17,741 B.t.u.
Gravity at 59 deg. F. (15 deg. C.)	0.948
Flash point in open air	185 deg. F.
Boiling analysis—	
Oil begins to boil at	223 deg. C
Amounts distilled in per cent. of the volume at 250 deg. C.	1.5
at 300 deg. C.	12.5
Contents in ash, per cent	0.01
Contents in coke, per cent	5.29
Contents in asphaltum, per cent	1.65
Contents in water, per cent	0.1
Contents in insoluble matter, per cent	0.002
Viscosity (Engler) at 20 deg. C	129.3
at 50 deg. C	12.9
at 80 deg. C	3.48
Chemical analysis—	
Carbon, per cent	86.59
Hydrogen, per cent	11.47
Oxygen and nitrogen, per cent	1.33
Sulphur, per cent	0.61

Note—The oil is very high in constituents, boiling above 300 deg. C., also high in coke.

The guarantees for fuel consumption made by the builders, with a 10 per cent. tolerance in their favor, with oil having a mean lower heat value of 18,000 B.t.u. per lb. per b.hp.-hr., were: At full load, 0.420 lb.; at 3/4 load, 0.0440 lb.; and at 1/2 load, 0.510 lb.

The fuel consumptions determined by test, using the oil with a heat value of 17,741 B.t.u. per lb., were as follows: At full load, 0.388 lb.; at 3/4 load, 0.385 lb.; and at 1/2 load, 0.439 lb.

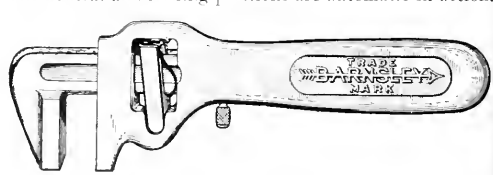
These figures are lower than those guaranteed, especially if the difference in heat value of the oil used is taken into consideration. Indicator diagrams were taken simultaneously on all four cylinders, also on the low and intermediate pressure stages of the air compressor. The small clearance space in the high-pressure cylinder of the compressor did not permit of attaching an indicator to it. The fuel consumption given includes all work done by the engine and the compressor and represents the net work delivered at the shaft.

Since the engine has been installed and its output has been checked by the output of the generator, the average fuel consumption falls within the guarantee. Some difficulty was at first experienced in finding a cylinder oil which would stand the high temperature in the engine cylinders and compressor. This was met by lowering the cooling-water temperature issuing from the jackets, and principally by experimenting with different oils until one was found that had the desired properties and gave satisfaction. The most gratifying result of the installation is the fact that the predicted saving has been fully realized, the City of Palo Alto saving about $20 daily above its previous practice; and the work of Messrs. J. F. Byxbee and A. V. Youens, representing the City of Palo Alto, is an example of what a progressive municipality under proper guidance can do in furnishing cheap lighting and power service.

Quick-Acting Wrench

The wrench shown has instantaneous adjustment. It is operated by placing the object to be turned between the jaws and pressing the movable jaw in, or drawing it in with the thumb-trigger under the handle, until it strikes the object.

The grip is then maintained and increased by an automatic locking clutch which acts as a cam and has a neutral position that allows the jaw to move freely in and out. The neutral and locking positions are automatic in action.



Automatic Quick-Acting Wrench

The clutch is made of one piece, and with the mechanical principle involved, the harder the pull on the wrench the tighter is the locking action. A slight pressure on the clutch opens the jaw.

This type of wrench is made in several styles by the Automatic Wrench Manufacturing Co., Boston, Mass.

Mouse Caused Plant Shutdown—Recently a dead mouse was discovered between the terminals of a 2200-volt oil switch connected to a 2000-kw. generator in a small central station in the Middle West. The engineer, while attempting to remove the mouse with a pair of sticks, accidentally got it across two exposed parts of opposite polarity, thereby causing a short-circuit, which severely burned him, destroyed the switch and shut down the plant.

Direct-Current Three-Wire Systems

By Gordon Fox

SYNOPSIS—The different methods of equalizing the voltage on a three-wire system, with special reference to the motor-generator set.

In the majority of plants in which direct current is used there are two competing conditions affecting the selection of the voltage. Economy in wiring for motor service demands the highest voltage consistent with reliability and safety, which is commonly considered to be 230 volts at the generator; whereas the lighting layout usually employs tungsten lamps on a 115-volt circuit. These conditions have led to the extensive adoption of the three-wire system. The 115-volt load will ordinarily be much smaller than the 230-volt load, and the unbalancing of the two sides of the low-voltage system is not likely to be great if care be taken in making the wiring layout.

A number of different means are utilized for obtaining the three-wire service and double voltage. The earliest method is but little used. This employed two separate generators, each wound for 115 volts, placed in series. The two machines combine in carrying the load on the outer wires, while each handles its own 115-volt load. The voltage regulation may be manual or automatic. Perhaps the most common present-day application of this system is that in which a generator having a double commutator is used. The armature is wound with two separate 115-volt windings, each connected to one of the commutators on the opposite ends of the machine. The commutators are connected in series for 230-volt service and their common point supplies the neutral. A machine of this kind is represented in Fig. 1.

The most popular means for providing three-wire service is the so called three-wire generator. This is, ordinarily, a standard 230-volt machine in which the arma-

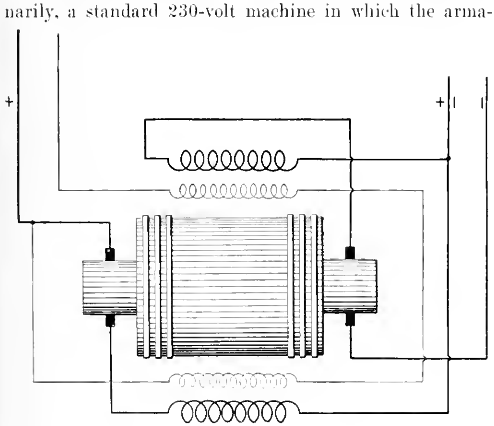


Fig. 1. Three-Wire Generator with Double Commutator

ture is tapped at two or more points 180 electrical degrees apart, the taps being brought out to collector rings. Where the unbalanced load is small two rings will suffice, but if the unbalancing is likely to be considerable it is better to provide four rings and to tap the armature at four points 90 electrical degrees apart, so as to secure a two-phase arrangement. Leads from the collector rings are brought out to a compensator that is merely a reactance coil. An alternating current is collected from the

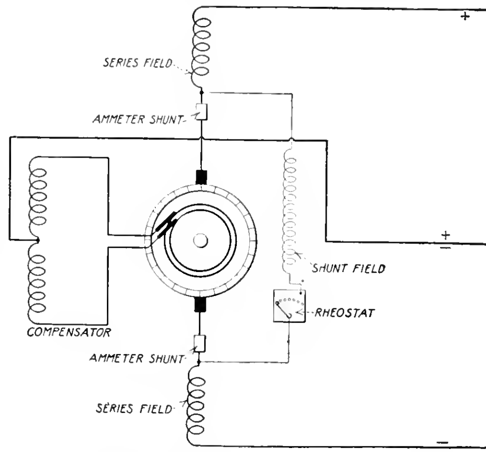

Fig. 2. Connections for Three-Wire Generator

rings and this current magnetizes the reactance coil, inducing a counter voltage such that only a small magnetizing current flows across. The central point of the coil is always the neutral of the system, since it is always half way between symmetrical conductors of opposite polarity. In this manner the half-voltage point is provided. In the case of unbalanced load a direct current passes through the reactance coil and collector rings and part of the armature winding. In a two-phase arrangement the unbalanced load current is distributed over more armature coils, so that heating is more uniform and voltage regulation is better; hence, the preference for this type where unbalancing is likely to be severe. Recently, there have been placed upon the market three-wire generators in which the reactance coil is built into the spider of the armature and the neutral is brought out from the center of this coil by a single collector ring. This makes it possible to tap the armature at more points for a multiphase reactance coil, without the disadvantages of a multiplicity of collector rings.

Three-wire generators are commonly designed and rated for 10 per cent. unbalancing, although sometimes a greater amount is specified. These generators may be flat, drooping or overcompounded in their two-wire voltage characteristic, and they will ordinarily maintain the neutral within a 5 per cent. range. Three-wire generators are connected as shown in Fig. 2, the shunt field being connected across the armature and the series field being divided into two sections, one-half in each side of the line. In this manner the compounding effect is averaged for unbalanced conditions. These machines may be operated in parallel the same as two-wire machines. However, there must be two equalizers because of the division of the series field. In adjusting the compounding of three-wire generators it is necessary to use similar german-silver shunts around each of the series fields, and in proportioning the load division between two machines to operate in parallel it is necessary to adjust the series circuit resistances between both equalizers and busbars instead of just upon one side, as for two-wire machines. When two-wire machines are paralleled the ammeter shunts are placed between the brushes and the series fields to prevent cross-currents from one machine affecting the instruments of the other.

It is possible to provide two-voltage service from a two-wire system by the use of a series of storage batteries connected across the outer lines with the neutral wire connected to the middle point. On balanced load the battery floats across the line. If the load is unbalanced the battery on the heavily loaded side discharges, while that on the lightly loaded side charges. The combined charge and discharge currents flow through the neutral supplying the unbalanced current. The neutral voltage must shift enough to cause this charge and discharge action, so that the regulation is imperfect. The voltage can be adjusted by means of end cells or by the use of a booster.

Double generators or three-wire machines are feasible for plants generating their own power. If only 230-volt power is available and three-wire service is desired, it is necessary to provide a means for locally maintaining the fixed neutral and providing unbalanced current. This is commonly done by the use of some form of balancer. There are several types of such sets, the more common of which will be here discussed.

Motor-generator balancer sets are ordinarily composed of duplicate units direct-coupled and mounted upon a common bedplate. They may be either shunt or compound wound and are sometimes equipped with interpoles. The armatures are wound for half line voltage and are connected in series across the outer leads, their common point being the neutral. The difference in the sets lies mainly in the arrangement of the field connections.

Shunt-wound balancer units may have the fields wound for either half voltage or full voltage. If wound for full voltage the fields are paralleled, and if wound for half voltage the fields may be in series with their central point either connected to the neutral or isolated from it. Fig. 3 shows one connection for a shunt-wound balancer set. With a balanced load both machines run light as motors. With a greater load between the neutral and the positive side, machine *A* acts as a generator and *B* as a motor, the two combining to feed the extra current to the heavily loaded side. The motor armature carries a current greater than that of the generator armature by an amount sufficient to supply the losses of the set. When the machines are running light their counter electromotive forces are equal and are almost equivalent to the impressed voltage. When an unbalanced load occurs on one side the voltage of that side decreases so that it is less than the electromotive force of the balancer unit, and that side of the set becomes a generator. The voltage across the other unit increases so that its motor action is strengthened and it is enabled to carry the generator load of its mate. It is necessary that an appreciable shift of the neutral occur in order to bring about this change, so that compound balancers are often used in order to secure better voltage regulation.

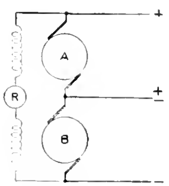

FIG. 3

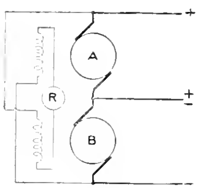

FIG. 4

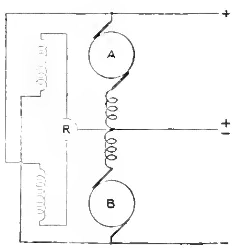

FIG. 5

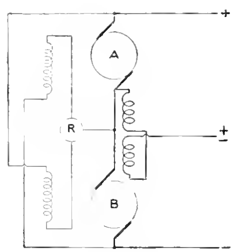

FIG. 6

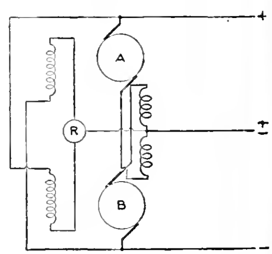

FIG. 7

FIGS. 3 TO 7. DIFFERENT BOOSTER FIELD CONNECTIONS

Shunt-wound balancers having the fields in series or parallel across the outer wires have practically constant excitation for both units. If the central point of the series-connected shunt fields be connected to the service neutral the excitation on the loaded, or generator, side is weakened and that on the motor side is strengthened. This tends to increase the motor electromotive force and reduce the generator electromotive force. The regulation with this arrangement is therefore poor. If the fields be interchanged as in Fig. 4 the generator electromotive force will be strengthened on the loaded side, tending to maintain the voltage, while the counter electromotive force of the motor is decreased, tending to speed it up, run the generator faster, increase its electromotive force and likewise maintain its voltage. Hence, this connection gives the better voltage regulation.

The action of the compound-wound balancer set (Fig. 5) differs somewhat from the shunt-wound type. Here the series field of the motor side opposes its shunt field, while the series field on the generator side assists its shunt field. Hence, the motor speed is maintained better or is caused to increase, while the generator voltage is likewise built up, tending toward good regulation. With the connection shown in Fig. 5 the series field of the motor carries more current than the series field of the generator, since the motor armature circuit carries the current to supply the losses of the set. The differential action upon the motor is, therefore, strong and the motor is likely to be unstable and to race under heavy loads.

The arrangement shown in Fig. 6 causes both series fields to carry the same unbalanced current, thereby improving stability. That of Fig. 7, in which the series fields are interchanged, places the generator series field in the motor circuit and *vice versa*. Since the motor armature current is greater than the generator armature current, the cumulative action of the generator field carrying motor current is stronger than the differential action of the motor series field carrying generator current. The excess of compounding is shifted from the motor to the generator, the rise in speed under load is decreased, there is less tendency to instability, and the voltage regulation is improved.

The units composing a balancer set act alternately as motor and generator. Therefore, the brushes must be set in a central position corresponding to no-load neutral. The neutral of a generator shifts in a direction with the rotation, while that of a motor shifts against the rotation. The brushes, therefore, cannot be located properly for both conditions. Since the motor end carries the greater load, it is well to give the brushes a slight motor lead to favor this mode of operation. It is a characteristic of the interpole motor or generator that the neutral remains fixed for all loads. Therefore, the condition of interchangeability can well be met with interpole machines and one position of the brushes will be correct for all operating conditions. Without interpoles commutation is a limiting feature and the units must be rated low to prevent sparking under load with the brushes set at a compromise position. The tendency to instability is somewhat greater for interpole sets than for those without these poles. The fact that the brushes of noninterpole machines are behind the full-load neutral as a motor, tends to hold down the load speed. In the interpole machine this effect is removed and the general tendency to maintain speed under load and to race is sometimes evidenced. The interpoles of balancer sets may require shunting with german silver, the same as is done with ordinary interpole motors.

The stability of compound-wound sets depends to some extent upon the degree of compounding. Balancers are ordinarily flat compounded or are adjusted for this degree of compounding by means of german-silver resistance shunted across their series fields. If a balancer set is connected to long feeders it may be desirable to overcompound to compensate for drop in the feeders. About 5 per cent. overcompounding is as much as can be safely provided in most sets.

Balancer sets are started with the shunt fields connected directly across the outer lines, with the center point disconnected from the neutral. The two armatures are connected in series through a starting box and are brought up to speed without load. The central point of the fields is then connected to the neutral of the set, and the voltage is adjusted for equal division. Then the neutral of the set is connected to the service neutral, and the unit is in operation.

Balancer sets may be successfully operated in parallel, but careful adjustment is necessary to secure even voltage regulation and proper load division. The units must be connected in the same manner, so that their relative speed and voltage-regulation characteristics will correspond. If the units are compound-wound one or more equalizers are necessary. If the fields are connected in series in the neutral line, as in Fig. 6, one equalizer will suffice. If they are connected as in Figs. 5 or 7 two equalizers will be required. Care must be taken to see that the equalizers connect corresponding points. The series fields should be connected on the inside next to the neutrals, as shown; if connected outside and the units were paralleled, there would be cross-currents through the equalizers into the leads to the line wires. Since the machine ammeters, fuses or circuit-breakers are connected in these leads, it is desirable that only the current for the unit protected should be able to traverse this circuit. In paralleling balancer sets the same rules hold as in paralleling any direct-current generators. If the series field circuits between the equalizers and the neutral do not have resistances inversely proportional to the machine ratings, then it is necessary to insert german-silver resistances in the series field circuit of that unit in which the resistance is proportionately low.

Adjustments

There are a number of adjustments possible upon balancer sets. Consider the case of two compound-wound interpole sets that are to be adjusted to regulate properly and to run in parallel. First, the brushes of one end of one set should be located upon neutral by running that end as a motor upon half voltage and shifting the brushes until the speed of rotation is the same in both directions running light. This procedure is then repeated for the other end of the set. Next, connect one end as a motor and the other end as a generator, separately. Connect the shunt fields as they will be connected in service. Load the generator end and note the voltage and speed regulation. If the voltage regulation is not flat (assuming that flat compounding is desired) then shunt both series fields with similar german-silver shunts and adjust the shunts until the desired result is approximately obtained. If violent sparking or racing occurs it may be necessary to shunt the interpoles also. The correct interpole shunt is best found by using a low-reading voltmeter and "exploring leads" which bridge from segment to segment of the commutator and indicate the position of no voltage between bars. When the interpole is of the correct strength the neutral will be at the same point both at no load and full load.

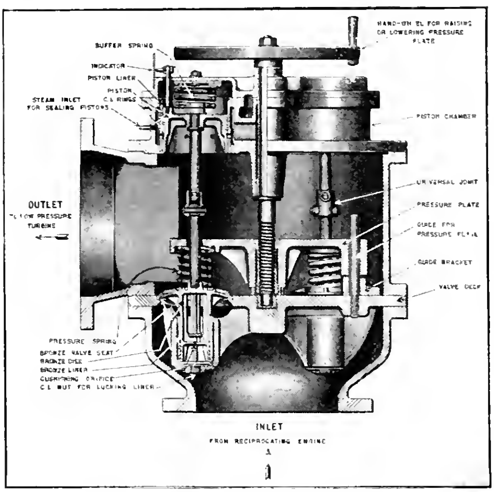
With these preliminary adjustments made, the set may be tried out as a balancer. The rheostats should be set for equal voltage division at no load. Then full unbalanced load may be thrown first on one side and then on the other and the voltage regulation noted. If it is not exactly as desired a slight adjustment of the german-silver shunts may be necessary. Possibly, one method of connection will be found to give more satisfactory results than another. Both sets having been thus adjusted and tried out singly, they may then be tried for parallel operation. If they fail to divide their load properly it may be necessary to insert german-silver resistance in the series field circuits of one of the units.

The method of protecting balancer sets depends upon the importance of uninterrupted service and the delicacy of the connected load with voltage change. Lamps are more susceptible to injury through excessive voltage than are motors. Fuses are quite frequently used in the line leads of balancer sets. A circuit-breaker in the neutral operating the circuit-breaker in the main lines by means of a trip coil will cause severance of power when excessive unbalanced load occurs, or a differential voltage relay may be used to trip the line circuit-breaker when excessive voltage inequality occurs.

The required rating of balancing equipment compared to the connected load depends largely upon local conditions. One side of a building may be dark while another side is light, or lights may be required in the central portion of a room when not necessary near the windows. Many causes contribute to unbalancing, and the amount as compared to the load is rather difficult to determine. It is desirable to maintain the unbalanced load in any system as low as possible. For this purpose throw-over switches are sometimes provided, which make it possible to transfer one or two two-wire circuits from one side of the system to the other to maintain an approximately balanced condition. Where this is not done it may be possible to connect over some of the circuits from one side of the system to the other to secure a better average balance. Sometimes, three-wire switchboards for distribution circuits are arranged to make interchange and rearrangement of circuits easy, so that balanced conditions may be maintained even though circuits are added or modified. Balancers are most frequently installed capable of handling 10 per cent. unbalanced load, that is, a load of one-tenth of the connected load all on one side of the line. Balancer units must each have a capacity equal to one-half of the rated unbalanced power, plus the losses of the set.

Cochrane Multiport Flow Valve

Among the various types of multiport valves built by the Harrison Safety Boiler Works, at 17th St. and Allegheny Ave., Philadelphia, Penn., is the multiport flow valve for use with mixed-flow turbines. Its pur-



MULTIPORT FLOW VALVE IN SECTION

pose is to close communication between the exhaust line from the engine and that stage of the turbine to which the exhaust steam is admitted, whenever the pressure in the latter falls below atmospheric.

In performing this function a vacuum is prevented in the engine exhaust pipe, the presence of which would result in the infiltration of air through leaks and past piston-rod and valve-stem packing, which would result in an overburdened condenser air pump.

In preventing the formation of a vacuum the draining of the receiver oil separator is not interfered with; this also applies to the oil separators on heaters and receivers in the engine exhaust line.

When a mixed-pressure turbine, one which receives steam at two different pressures, usually live steam and exhaust at about one or two pounds above atmosphere, is equipped with this flow valve, the exhaust steam is automatically cut off as soon as the pressure in the exhaust line approaches a predetermined maximum, say one pound above atmospheric. This action causes the flow of exhaust steam to back up and maintain a pressure in the exhaust-steam main, live steam being used by the turbine during the period the valve is closed. As soon as the exhaust-steam pressure builds up above the predetermined point the flow valves open and the live steam is cut out by the action of the governor.

The construction of the valve is shown herewith. Each valve disk is connected to and balanced by a piston of the same area. As the pressure in the turbine intermediate inlet acts on the top of the valve disk and on the under side of the balanced piston, it has no effect so long as the disk is closed. The pressure of the engine exhaust acting on the lower side of the valve disk is opposed by the pressure of the atmosphere acting on the upper side of the balanced piston. Whenever the pressure in the engine exhaust line exceeds the atmospheric a certain amount, determined by the tension of the spring pressing on the upper side of the disk, the valve opens wide, because as soon as it leaves its seat the pressure on the two sides of the balanced piston forces it out against the spring. Striking of the piston is prevented by buffer springs. When the pressure in the turbine inlet opening drops near to atmospheric pressure it, reinforced by the spring, forces the disk to its seat.

The valve thus prevents steam from flowing from the engine exhaust line to the turbine unless the absolute pressure in the former exceeds a certain minimum. As the balanced pistons are steam-sealed, no air is admitted by them.

A Cheap Covering for Steam Pipes

A nonconducting coating for low-pressure steam pipes and the like, used for the past ten years with perfect satisfaction by a Boulogne engineering firm, is described in a recent issue of the "Revue Industrielle" as being conveniently applied and cheap, while it can be prepared by any steam user. It consists of a mixture of wood sawdust with common starch, used in a state of thick paste. If the surfaces to be covered are well cleaned from all trace of grease, the adherence of the paste is perfect for either cast or wrought iron. For copper pipes there should be used a priming coat or two of potter's clay, mixed thin with water and laid on with a brush.

The sawdust is sifted to remove too large pieces, and mixed with very thin starch. A mixture of two parts of wheat starch with one part of rye starch is the best for this purpose. It is the common practice to wind string spirally round the pipes to be treated, keeping the spirals ½ in. apart to secure adhesion to the first coat, which is about ¼ in. thick. When this is set, a second and third coat are successively applied, and so on until required thickness is attained. When it is all dry, two or three coats of coal tar applied with a brush will protect it from the weather.

California's Crude-Oil Production in 1914 was 103,623,695 bbl., against 97,867,148 bbl. in 1913.

Water Power in Switzerland is conserved and utilized to such an extent that in some towns not an ounce of coal is used. Power, light and heat are furnished by water power.

Safety Valves--A Discussion

By A. B. Carhart*

SYNOPSIS—Discusses a paper read by Donald MacNicoll before the Institution of Engineers and Shipbuilders, Scotland. This paper dealt chiefly with a special safety valve in which the passage through the seat is nearly equal to the full inlet area; the main or relief valve is not spring-loaded, but is controlled by the action of a pilot valve. The reviewer shows that this, as well as other ideas, is old, and that valves so constructed have never been successful. In America since 1860 only two principles of construction have proved mechanically satisfactory. Foreign practice compared with our own.

It was before the Institution of Engineers and Shipbuilders in Scotland that Hazleton R. Robson presented his paper in 1873 demonstrating the advantage of springs instead of dead weights and levers for loading safety valves. This was several years after spring-loaded pop safety valves had been introduced into this country.

Recently Donald MacNicoll, of Cockburns, Limited, Glasgow, read a paper on safety-valve design before that society, the paper dealing chiefly with tests of some special "full-bore" safety valves recently applied to boilers of destroyers in the British Navy. The interesting feature in these valves is that the passage through the seat is practically equal to the full area of the inlet. But the main relief valve is not spring-loaded and proportioned to give automatic opening and closing, to make the amount of blow-down in pressure adjustable, but is in effect simply an adaption of the "compound" whistle valve commonly used in this country, having a steam piston whose operation is controlled by the action of an auxiliary pilot valve. This idea is not new, for other valves operating upon the same principle have been patented in Great Britain and in this country; and as long ago as 1871 Thomas Adams read a paper before the same society, in Glasgow, describing a relay type of safety valve patented by him, in which the opening of the main relief valve was controlled in similar manner by the action of a much smaller valve. But none of these valves has ever been commercially successful, and Mr. MacNicoll's paper indicates that mechanical difficulties have been encountered in the latest type, and that much must still be accomplished before it is as satisfactory as the safety valves commonly used in this country. For example, he says: "All the valves lift at about 7 lb. above the working pressure, drop or close on their seats at the working pressure, and are absolutely tight at not more than 7 lb. below the latter."

Mr. MacNicoll's paper is interesting, but much of the work he refers to has already been done in this country, and much, if not all, that he describes as the latest endeavors in such experimental work in Great Britain, is shown in various American patents issued twenty-five to forty years ago.

The safety valves commonly used in Great Britain are not of the type so familiar here. Instead of having the "pop" feature, most of them are valves without any expansion chamber at the lip to give full initial lift, and which depend upon long and flexible springs to permit sufficient opening at the seat. But although many in this country know that the safety valves used abroad do not afford as much relief in steam discharge as pop safety valves, it is interesting to find the corroboration of this in Mr. MacNicoll's paper. Of safety valves commonly made there, he says:

> In connection with the Board of Trade type of valve, the accumulation allowance or the amount of excess pressure over the working pressure, when all stop valves and feed-check valves are shut and the specified amount of coal being burnt, must not exceed 1 per cent. of the working pressure. The Admiralty allowance is 7 per cent., but with the feed maintained; this latter, of course, is essential for water-tube boilers. In most cases, with Board of Trade valves it has been found that when the working pressure exceeds 210 lb. by gage, this allowance is exceeded.

Mr. MacNicoll says that a possible explanation of this undue rise in pressure, indicating insufficient valve-discharge capacity, lies in an insufficient escape-pipe area, resulting in a throttling of the escaping steam, causing back pressure on the valves and preventing them from lifting properly.

> This pressure has gone up as high as 40 lb., whereas it should never be more than about 15. . . . . It has been suggested that in certain cases an accumulation test has been stopped, owing to the accumulation having got considerably beyond the allowance, and was still rising, the surveyor knowing at the same time that he was not justified in condemning the valves, as the area was correct and compression of spring in order, according to the Board of Trade formula. It would appear in cases of this sort that the valve had not enough lifting effort.

Concerning the lifts of such valves, he says:

> It must be remembered, however, that American safety valves have very different fittings from those manufactured in this country. The rigid type of spring adopted in the former giving less than 1/8 the diameter of the valve for initial compression, necessitates a carefully designed seat and plate on the lid to lift the valve sufficiently. . . . . The short rigid spring is noticeable when compared with the present British Board of Trade type. . . . . Since the introduction of the spring-loaded Board of Trade type of valve, the design has altered but little. . . . . It should be set to lift at from 5 to 7 lb. above the working pressure, and when properly constructed should drop on its seat at about the working pressure. The compression of the spring at the blowoff pressure should be 1/4 the diameter of the valve.

He describes also the Admiralty type of spring-loaded safety valve, in which "the specified initial compression of the springs is equal to the diameter of the valve, or four times the elasticity of the Board of Trade springs." Even the great length of the springs, 11½ or 13 coils, or more, is not sufficient to insure proper lifting of the valves to afford free steam discharge, as is further evidenced by Mr. MacNicoll's quotation from a report of the trial, made some five or six years ago, of an experimental type of valve:

> The ordinary spring-loaded safety valve is usually big enough to take away all the steam that an ordinary boiler can generate under ordinary firing conditions. Certain peculiarities are inherent, but seem to have become accepted with resignation by engineers. For instance, the lift is usually inadequate, owing to pressure accumulating above the valves, and acting downward on the larger area provided by the lip. . . . . When the valves lift, the rush of steam past the lip prevents the valve closing until the pressure in the boiler has fallen considerably below the working pressure. This is known as "drop," and may amount to as much as 10 per cent. of the working pressure. It is usually looked upon as inevitable, but is a serious matter on a full-power trial where the loss

*Superintendent, Crosby Steam Gage & Valve Co.

of water is measured and where it is important to maintain full boiler pressure over a long period, hence the practice of having a man told off to watch if any valve lifts, and to at once tap it down again on to its seat.

Concerning the lift of safety valves, he comments upon the experiments made a few years ago, and says:

Although the balance-disk valve was not considered satisfactory, it was agreed that a valve giving a greater lift than the ordinary type was desirable. The ordinary type of valve lifts about $\frac{1}{24}$ of its diameter, while the Gibson valve lifted $\frac{1}{16}$.

Referring to the experiments made in 1874, he says:

It is suggested that with a specially designed Cockburn valve it reached the full amount—namely, ¼ of the diameter—but this is not likely, and certainly a rule proposed by the committee allowed for a lift of only $^1/_{36}$ of the diameter.

This would seem to indicate that foreign safety valves, in spite of the long springs, do not have the excessive lifts with which they are sometimes credited in discussions of the subject. The duty under our present tariff is not high enough to prevent the importation of safety valves from abroad if they were desired. Some manufacturers in this country are often called upon to duplicate such valves for marine boilers in special cases, but even this intimate knowledge of their construction has not led to their general introduction here. One statement made by Mr. MacNicoll concerning some of the valves tested, using large springs made according to the Admiralty rule, indicates that the long springs have disadvantages that might develop into exaggerated difficulties under American conditions of service:

In torpedo-boat-destroyer work also, the large springs had been found to be a source of trouble; excessive vibration keeping the springs continually on the dance, and serious leakage consequently ensuing.

Mr. MacNicoll describes the experiments of J. H. Gibson, of the firm of builders of the British torpedo boat destroyer "Cossack," which was one of the first vessels burning oil fuel in which serious difficulty was experienced with the ordinary Admiralty safety valves:

During the accumulation trial the steam pressure rose to a dangerous extent with the pointer of the gage going up rapidly. To prevent an accident the easing gear was applied. It was observed that it required only a very small additional lift to the valves, somewhere about $^1/_{64}$ in., to keep the accumulation within the specified amount. . . . . . While the new valves were being manufactured, he carried out an experiment on one of the original valves. A small steam cylinder fitted with a piston was attached to the boiler shell in the vicinity of the safety valve. The piston was attached to the easing gear in such a manner that on the piston moving outward the valves were eased. The bottom of the cylinder was connected with the waste-steam space of the safety valve. The effect was that the excessive pressure in the waste-steam space assisted the valves to lift instead of preventing them from doing so.

This experimental valve was described, at the time, in *Engineering* (London), Feb. 26, 1909, and mentioned by the writer in an article in POWER, Mar. 23, 1909. The comment is made that "the trials were most satisfactory," but subsequent events cast doubt upon this conclusion. It is apparent that only one such valve was ever made; and the idea of utilizing the excessive back-pressure in operating a lever to overcome its harmful effects seems too much like lifting one's self by the boot-straps. In the torpedo boat destroyer "Swift," constructed later by the same firm, each safety valve, "instead of having an external cylinder as previously mentioned, was fitted with a balancing piston, or disk, which neutralized the effect of back-pressure in the valve casing." This device was sufficient to overcome the difficulty with the safety valves, as far as the accumulation allowance under test was concerned.

But this idea also, of a larger disk fixed to the valve spindle, is not new, for it is shown in many of the older patents. A somewhat similar scheme for using the back-pressure to give extra lift to the valve was an important feature in the old "Crosby-Meady" muffled locomotive pop valve of 1885, that showed lift of ¼ in. This had a considerable sale thirty years ago. In justification of such a device, the report upon the tests of these experimental valves says:

To obviate the objectionable action of this pressure [the back pressure in the valve casing] and, if possible, to make it perform useful work is the object of this invention. By making the balancing disk equal in effective area to the valve, the effect of the fluctuating pressure in the valve box is eliminated, and the valve lifts gradually and quietly to the full amount permitted by the compression of the spring, and the allowable accumulation. . . . . The removal of the lips from the valve and seat steadies the action of the valve, and prevents "beating" or "chattering," thus increasing its life or period of steam-tightness.

"*Gradually and quietly*" in the original report emphasize the desirability, sometimes too little appreciated, of the practical advantages of smooth and quiet operation of a boiler safety valve, as compared with the sudden and violent explosiveness that sometimes results from an effort to obtain an excessive rate of discharge or an instantaneous relief. However, it is evident that the desired results were not fully realized, for Mr. MacNicoll says:

Subsequently, Messrs. Cockburns made valves of this type, but it is regretted that while amply meeting with accumulation conditions, the question of when the valves commenced to lift and when they shut off tight was a most vexed one. With the ordinary type of valve the lift is definite—a distinct "pop" is heard, although simmering may have taken place for some time previously. With the balance-disk type the first slight feather at the waste-steam pipe was taken as the commencement of lift, this gradually increasing till the valves were blowing full; the range of pressure every time the valves lifted was about 30 lb. per square inch. Similarly, on the valves closing again the range was 35 or 40 lb. per square inch. These valves were refitted repeatedly, with no betterment.

Mr. MacNicoll describes the difficulty they had with continued leakage at the valve seat (attributed to distortion of the seats of the valves, which were 3½-in. size) and mentions the improvement in the behavior of the valves after they were fitted with a different type of disk, but makes the significant statement:

After this they never gave satisfaction, and about 18 months thereafter were replaced. Subsequently, it was found that this type of valve had been used in the United States for a considerable time.

The next form of experimental valve tried was upon the same principle, but had a much larger piston fitted above the valve disk, so that back pressure in the body would force the disk further from its seat. It does not seem logical to have developed this idea so far; for the real purpose of any safety valve employed should have been to discharge the escaping steam, for the relief of the boiler, rather than to throttle the discharge pipe to gain more lifting power inside the valve body. For of what use is it to gain greater lift and larger opening at the valve seat if free discharge of the steam from the valve casing is not permitted? This valve appears to have been inoperative except under special conditions. To again quote Mr. MacNicoll:

The piston was made considerably larger than the valve, and a stop valve was fitted to the outlet as shown, so as to maintain any desired pressure in the waste-steam space. This valve could be made to give a lift of ¼ of its diameter under favorable conditions, but was found to be somewhat erratic in its action, and the slightest increase to the lift on the stop valve from that which allowed of full lift to occur in the safety valve prevented the latter from lifting more than a very small amount. The drop also was very inconstant —generally the valve was considered unsatisfactory.

As an alternative device, intended as an improvement upon the experiments described, a compound valve was devised, in which the opening of a small spring-loaded pilot valve allowed the steam behind a piston of larger area to force open a main relief valve against the boiler pressure.

Such valves are interesting in principle, but have been described in early U. S. patents; for example, in the patents to Shepard in 1873, to Anderson in 1877, and to Scovell in 1879, as well as in that to Collier in 1882. Many variations in the mechanical embodiment of the same idea have been tried, but have never been able to displace the familiar automatic safety valve of the "pop" type. In the discussion of Mr. MacNicoll's paper, R. A. McLaren stated that he had designed a valve on much the same principle between twenty and twenty-five years ago.

George W. Richardson, the inventor of one of the early successful American safety valves, was granted his first patent in 1866, and this was followed by another in 1869, the papers of which describe the adjustable ring for regulating the amount of blowdown in boiler pressure. Among the numerous safety valves shown in United States patents since 1860, only two fundamental principles of construction have proven mechanically satisfactory. These are Richardson's idea of an overhanging lip and stricture ring, forming an adjustable "huddling chamber" surrounding the valve seat, and Crosby's opposite plan of using a flat, double seat and controlling the blow-down by regulation of the small part of the discharge that is bypassed through a central chamber beneath the disk, instead of at the valve seat. All the later commercially successful improvements have been based upon the ideas of one or the other of these two pioneers.

One difficulty met with in the designing of any spring-loaded pop safety valve that is to be self-regulating and automatic in operation, is the limitation upon the amount of spring compression and lift of the valve that can be easily attained without sacrifice of some of the desirable characteristics of such valves. Therefore, the devising of other forms of boiler relief valves has been a favorite field for inventors' schemes. Even during the discussion of Mr. Robson's original paper before the Institution in Glasgow in 1873, David Rowan remarked: "When we have a safety valve which will lift one-fourth of its diameter, or to give an area equal to the diameter of the valve, then the question will be put on a scientific basis." This underlying idea has persisted ever since, and is rediscovered in turn by each one who gives original thought to the subject. This is doubtless the reason why so many have experimented with various forms of balanced-piston and relay valves, which apparently would give "full opening" for boiler relief.

A reliable automatic safety valve must do more than merely discharge steam. In fact, the opening of a relief valve to give "full discharge" is one of the simplest details in the problem, and easiest of solution. Even Mr. Rowan, back in 1873, said that it "could easily be done." The greatest difficulty arises in getting the valve closed again. The wide range of blow-down commonly accepted in foreign practice, or in the operation of valves on marine boilers, would not be countenanced by operating engineers in this country, after their experience with modern pop safety valves.

Comments appearing incidentally in Mr. MacNicoll's paper are especially interesting as indicating that some of the safety-valve specifications appearing in the new A. S. M. E. Code are wise and proper. For example, he emphasizes the lesson drawn from some of the safety-valve experiments, that discharge piping of ample size must be provided for carrying away the exhaust steam from the safety valve. In connection with the subject of springs for safety valves he says:

> There appears to be a broad rule, however, for determining a safe spring—that is, one which will remain for any length of time under a load with the coils almost touching, maintain this compression, and resume its free length when the load is removed.

The recently approved specifications of the A. S. M. E. on this subject are intended to accomplish this to insure that springs used in safety valves shall not under any circumstances take any permanent set.

After describing in detail the construction and method of operation of the piston type of valves in the latest experiments, Mr. MacNicoll comments:

> If they are placed near the top of the boiler and have easy leads in the waste-steam pipe, no vibration or movement will take place. If, however, they are fitted with internal pipes there is a tendency to vibration; apart from this, internal pipes are most dangerous when fitted to safety valves, and serve no useful purpose.

This seems to be further confirmation of the wisdom of the provision in the A. S. M. E. Code that safety valves shall be connected directly to the shell of the boiler.

There has been some discussion concerning the most practicable method of calculating the total boiler evaporation for which safety valves should be provided, and upon this point one comment of Mr. MacNicoll's is pertinent:

> With the advent of oil fuel in the Navy, the size of safety valves based on a formula taking coal as a factor proved altogether inadequate. It appears somewhat singular that the formulas for arriving at the size of safety valves, in the case of the Board of Trade rule, should be derived from area of fire grate and steam pressure, and in connection with the Admiralty, from heating surface and steam pressure. One would have thought the factors necessarily presenting themselves would have been evaporation and steam pressure. . . . .
>
> Turning to the rule formulated by the Board of Trade, it appears somewhat strange that they should have decided on a rule which gives a "disk area" and not a "clear area" for the escape of steam. . . . . As already stated, it now appears that it would have been better had the Board of Trade rule settled the actual area for discharge. During the experiments by the committee it was found that the lift was variable.

The Horsepower of a Cannon

A matter of speculation likely to interest engineers is the enormous energy or horsepower developed in the breech of a big modern cannon discharging a projectile weighing, say 1850 lb., at a velocity of 2000 ft. per sec., when

$W = 1850$ lb.;
$V = 2000$ ft.;
$g = 32.16$.

The formula $E = \frac{WV^2}{2g}$

gives 110,000,000 ft.-lb.

This amount of work must be accomplished during the projectile's travel in the gun, probably not over $^1/_{100}$ of a second. Therefore,

$$\frac{110,000,000 \times 100}{550} = 20,000,000\ hp.$$

or in another way, the vertical distance a body would have to fall to attain a velocity of 2000 ft. per sec. at a uniform rate of acceleration due to gravity would be about 60,000 ft. A projectile weighing 1850 lb., falling this distance would generate

$$1850 \times 60{,}000 = 111{,}000{,}000 \textit{ ft.-lb. of energy.}$$

The same amount of energy would be required to produce the same velocity at the muzzle of a cannon and represent in horsepower

$$111{,}000{,}000 \div 550 = 200{,}000+ \textit{ hp.}$$

if done in one second; but the actual time is probably about as the length of the gun is to the velocity, or 20 to 2000, or $^1/_{100}$ of a second. The energy exerted for the shorter period must be 100 times greater, or equal to 20,000,000 hp.

Foster Automatic Feed-Water Regulator

The Foster automatic feed-water regulator is designed to maintain water at the predetermined height. Normally, the water in the boiler or water column seals the end of the pipe leading to the top of the expansion tube, so that steam is excluded therefrom and the tube is cool or contracted. In this condition of the expansion tube the long arm of the bell-crank lever *A*, Fig. 1, is free to swing outward and allows the weight to depress the arm of the lower bell crank *B*, so as to slide the valve *C* downward into a closed position, cutting off and preventing water from entering the boiler through the feed line.

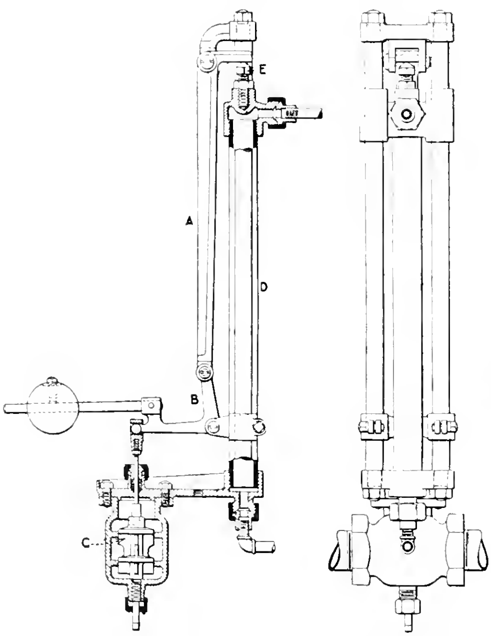


Fig. 1. Details of the Foster Feed-Water Regulator

When the water recedes below the predetermined level, it uncovers the opening in the pipe leading from the water column to the top of the expansion tube and permits steam to enter it. This heats and expands tube *D*, carrying the adjusting screw *E*, which can be set for any desired variation, upward against the short arm of the bell-crank lever *A*, thus swinging the long arm of the latter inward or toward the expansion tube. This carries the lower bell-crank lever *B* and raises the weight, drawing the valve *C* upward, opening the main feed valve, and permitting water to flow through the feed pipe into the boiler. The flow continues until steam is again cut off from the expansion tube *D*, allowing the latter to contract sufficiently to close the valve *C*. Fig. 2 shows the regulator and pump connections. This regulator is manufactured by the Foster Engineering Co., 119 Monroe St., Newark, N. J.

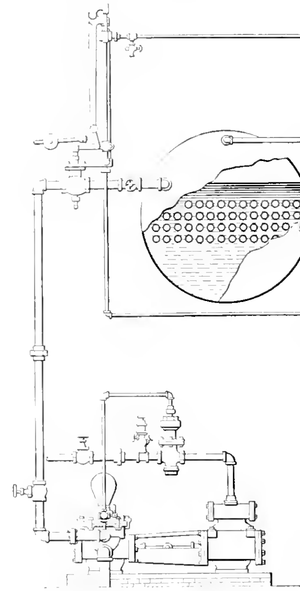

Fig. 2. Regulator and Connections

Rules for Properties of Copper and Brass Pipes

The British Board of Trade rule for the thickness of brazed copper steam pipes is

$$T = \frac{D \times P}{6000} - \frac{1}{16}$$

in which

T = Thickness of plate in fractions of an inch;
D = Diameter of pipe in inches;
P = Working pressure in pounds per square inch.

For working pressure of brazed copper steam pipes,

$$P = \frac{6000 \times (T + \frac{1}{16})}{D}$$

To find the weight of copper pipes,

$$W = 3.03\ (D^2 - d^2);\ \text{or}\ 3.03\ (D + d) \times (D - d)$$

in which

W = Weight per lineal foot of pipe in pounds;
D = External diameter of pipe in inches;
d = Internal diameter of pipe in inches;
3.03 = A constant.

To find the weight of brass pipes per lineal foot,

$$W = 2.82\ (D^2 - d^2);\ \text{or}\ 2.82\ (D + d) \times (D - d)$$

in which

W = Weight of pipe per lineal foot in pounds;
D = External diameter of pipe in inches;
d = Internal diameter of pipe in inches;
2.82 = A constant.

Editorials

License Laws in Massachusetts

There have been ructions in the good old Commonwealth of Massachusetts for the past few weeks. A powerfully organized attack has been made upon the existing law by the employers, who complain that it contains, in addition to its provisions for safety, features that impose unnecessary hardships upon the employees and useless burden upon the manufacturers; that it recognizes no difference in the risk of operation between steam engines and steam boilers; that it fails to limit the scope of examinations and permits the requirement of knowledge of the principles of design in the examination of applicants for license to operate, of a knowledge of the principles of boiler design in an examination for a permit to operate engines, and permits the examiner to require involved mathematical calculation, thereby denying employment to competent men.

There have been, for a long time, evidences of friction between the employing and the laboring interests, over the interpretation and administration of the law. Shall a single licensed man in responsible charge suffice for a plant, or shall everybody, down to the coalpasser, be required to have a license?

Shall the examiner simply satisfy himself that a man knows enough to keep water in the boiler and the safety valve clear, or shall he assure himself, broadly, of a man's ability as an engineer and of his general understanding of the principles of and of his familiarity with, the apparatus involved, in the processes of the oversight of which he seeks responsible charge?

Shall an inspector fearlessly and impartially enforce the provisions of the law and the Code, or must he handle friends of the appointing powers with particular consideration to hold his job?

Stories are told of an inspector who made seventy-three arrests and got seventy-two convictions, whose pernicious activity was checked by laying him off for three months "for using language unbecoming an official." On the other hand, it is maintained that the inspectors appointed by the District Police do not all know too much about boilers themselves.

The manufacturers, therefore, had a bill, known as House Bill No. 1111, introduced, which provided that with every licensed person employed there may be one unlicensed person employed, who, in the presence and under the personal direction of the licensed person, might operate steam boilers and their appurtenances; defined what was meant by "control," "operation," "have charge of," etc., as used in signifying where licensed men were required, etc. The bill also required a different examination and license for a man who was to have charge of engines than for one who was to have charge of boilers, and provided a practical examination for both, with the privilege of having present an observer who might take notes.

This bill met with strenuous opposition from the engineers, and on Mar. 22 the Governor addressed a message to the Legislature, in the course of which he said:

> As you are doubtless aware, there has been for some years a serious controversy between the representatives of organized labor and the representatives of the manufacturing interests, in regard to some of the provisions of the existing law relative to engineers' and firemen's licenses and in regard to the enforcement of law by the Boiler Inspection Department of the District Police. I am informed that after repeated conferences and long discussions these differences have now been amicably adjusted and an agreement reached whereby the opposition of organized labor to House Bill No. 1111, amending the law regarding engineers' and firemen's licenses, is withdrawn and the support of the manufacturers to the bill herewith transmitted is accorded.

The bill "herewith transmitted" takes the inspection of boilers and the examination of engineers entirely out of the hands of the District Police and establishes a Bureau of Steam Engineering and Inspection to take care of it. Bill No. 1111 was withdrawn by mutual consent of a committee composed of engineers and manufacturers, and in its place another bill has been drawn up, amending the present law so as to overcome the objections of the manufacturers without prejudice to the engineer.

New Methods of Producing Gasoline

Widespread interest has been created within the past few weeks by reports in the daily press of discoveries calculated to greatly increase the supply of gasoline, besides making available benzol and toluol, which heretofore have been produced from coal tar. The toluol is an important ingredient in modern high explosives. First came the announcement of Dr. Snelling's process, to be followed closely by that of Dr. Rittman, and finally the information that Edison had started a plant for the production of benzol and a number of residual products, ordinarily imported from Germany but now cut off as a result of the war.

In Dr. Snelling's process synthetic crude oil is produced from hydrocarbons such as kerosene, fuel oil, lubricating oil and paraffin (themselves originally obtained from crude oil), by heating in an air-tight vessel or "bomb" until about eight hundred pounds pressure is reached, the substance occupying only about three-elevenths the volume of the bomb. The action appears to consist of a rearrangement of the atoms, and upon cooling, crude oil is obtained. This synthetie crude oil, when subjected to fractional distillation, will give off approximately fifteen per cent. gasoline. Thus the process is cyclic and through repetition can be made to yield a large proportion of gasoline.

Dr. Rittman's process, it appears, depends upon "cracking," but the petroleum is first vaporized and then subjected to the necessary pressures and temperatures for the production of gasoline, or further, benzol and toluol. Fifty to seventy-five per cent. of gasoline is said to be attainable, besides the other products.

The Edison process has not been made public.

Both Dr. Snelling's and Dr. Rittman's processes are still in the laboratory stage and it would be useless to make any predictions as to their probable effect on the fuel and byproduct situation in this country. However, lest some be misled into the belief that the relatively large percentage of gasoline thus obtainable will greatly affect the price of that fuel, it may be pointed out that in the Burton process, controlled and employed by the Standard Oil Co., about seventy per cent. of the crude may be converted into gasoline. It is understood, however, that ordinarily not over forty to forty-five per cent. is extracted, not because of any mechanical or chemical difficulties, but solely for commercial reasons. That is, if the market demands are such as to make it more profitable to sell forty per cent. of the heat units of the crude in the form of gasoline, thirty per cent. as kerosene, twenty per cent. as fuel oil, etc., the process will be adapted to meet these conditions. If the market demands for these products are in some other ratio, the condition will be met. In other words, the Burton process is used as a "balance wheel" to suit the market and effect the most profitable production.

Now, if the new processes are developed commercially will they not to a large extent serve a similar purpose? As an economic problem it is not reasonable to suppose that the production of gasoline will be increased to such an extent as to greatly lower its price to the consumer if the demand for the heavier oils for use in the oil engine is such as to make an increased production profitable; similarly with the other distillates.

Perhaps the most important feature of Dr. Rittman's discovery, as concerns the public, lies in the fact that it is government property and as such will be free to all. Thus the independent refiners may take advantage of it and will be able to compete with the Standard. While they will also be governed largely by market demands, they may serve as a check against any artificial boosting of prices or demands; provided, of course, their supply is unhampered. Again, the production of the tolnol and the other residuals, while possibly unable to compete with the imported coal-tar products after normal conditions have been resumed, will nevertheless serve as an important asset in time of necessity.

Listing Motor Data

Inadequate records of local motor installations are a common source of delay in power plants in which the operating engineer has jurisdiction over electrical as well as steam equipment. Trusting to memory as to the size and speed of individual motors may be all right when only a few are in service, but in a large plant it pays to keep an uptodate card or loose-leaf record showing in detail exactly what each motor is doing. The necessary data include the horsepower rating of each motor, its pulley diameter and face, the speed at normal rating, and the pulley and speed particulars of the main shaft of machinery or grouped tools driven, pinion and gear sizes, and the number, make and capacity of the machines run by each motor. In a representative mill installation where this information is maintained by the plant engineer each motor is provided with an index card bearing the above particulars; and in addition, space is left for recording test data, so that at any time the plant manager can be informed accurately of the load on any motor, just how many machines it is driving, and how many it should drive if loaded to its full rating. With modern induction motors this plant runs its machine drives in many cases on the basis of loading individual motors from fifteen to twenty-five per cent. beyond their nameplate rating. In case of any desired change in tool arrangement, alteration of stock or other modification of the installation, the engineer's record shows at a glance just what the condition of each drive was at the last test and indicates the course to be followed with reference to the addition of machines to any group or the substitution of a motor of different size to meet the proposed load conditions. Every lineshaft in the mill is identified by a letter corresponding to the card record of the motors, and the amount of time saved in making estimates of local power requirements is surprising, compared with the ordinary method of making a new power survey every time any question of importance arises in connection with the capacity of the motors.

Specifications

Judging from the evidence, the average writer of specifications has little knowledge of piping work, but a great desire to catch the unwily bidder. Many specifications are voluminous, and many and devious are the methods used to avoid telling the bidder all that he should know in order that his bid may be intelligent and his chance of loss minimized. At the other extreme are the specifications that are manifestly lacking in detail.

Specifications of either kind are neither creditable to the architect or engineer who wrote them, nor valuable to the owner, nor are they in the interest of clean competition. Rather do they work against the honest bidder, who justly refuses to spend his time doing the architect's work, knowing from experience that others competing with him, with less respect for their trade, are only too willing to propose a system that will just pass. The honest bidder and the owner are the injured parties, and the less conscientious bidder has a field for his activities. It is true that piping work must conform to certain regulations, but the opportunity to skimp the job is ever present, and in heating work the chances are still greater and the use of inferior material more frequent.

After the contract is secured, there is invariably constant wrangling over the interpretation, both parties putting forth good reasons for their contradictory renderings, the owner trying to get the best service at the least expense and the contractor striving his utmost to make the contract call for the least material and labor. There is also room for argument regarding the acceptance of material supposedly "equal" to that called for, the final judgment being usually left to the representative of the architect, whose experience in such matters is by no means commensurate with the dignity of the position he is to fill.

Why should specifications not be written with precision, so as to be deserving of respect, inspiring the desire for clean competition, with scant opportunity for work that will barely pass?

The advocates of the Water Power Trust claim that it is better that the water powers should be developed, even at the expense of turning them over to private capital for this purpose, than that they should lie dormant and the fast diminishing coal supply be burned up to produce the power which they might generate. It is probably better that anthracite coal should be mined and supplied to the public even at eight dollars a ton than that it should lie in the ground, but it would be a whole lot better to have it mined by the people themselves and made available at half the cost. Don't let the white coal get where the black is.

Correspondence

Two Ways of Going to Work

It takes me from twenty to twenty-five minutes to get to my work. One morning, across from me in the car was a fellow who was very much engrossed in reading some article in POWER. Next to him was another man sound asleep, with his feet stuck out in the aisle. The former seemed to be enlightened on some subject which had puzzled him. The other, dead to the world, was keeping passengers busy stepping over his feet.

At the shop I again noticed the same two men. The "dead one" was at the drinking tank, complaining to a fellow workman about the small pay he was getting; the other was busily engaged with his work. I learned that they were getting the same pay, although the dead one had worked twice as long at the place. I went my way, satisfied that I had a mirror worth holding up to my fellow readers.

[The cartoon in this issue was drawn from a sketch accompanying the above letter.—EDITOR.]

Auxiliary Exhaust Valves on Uniflow Engines

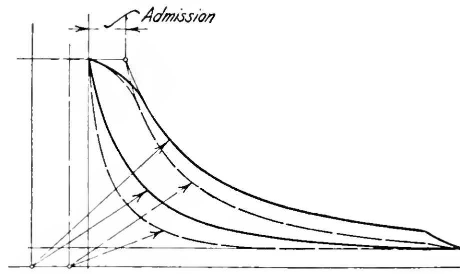
I have read with great interest the letter in the Mar. 30 issue of POWER, criticizing Professor Stumpf's article on the uniflow engine. In view of the distance of Professor Stumpf and the delay in the mails due to the war, I take the liberty of replying to this article. I was associated with Professor Stumpf during the introduction of the uniflow engine in Germany and am familiar with his work.

The question at issue seems to be whether or not uniflow engines should be fitted with auxiliary exhaust valves. There can be no question that condensing engines are better without these valves. They not only add to the mechanism and complication of the machine, but they decrease the thermal efficiency even if locked closed and absolutely tight, as they must have some clearance; and as the steam remaining in this clearance is not raised in pressure by compression, it causes a much greater loss than the same amount of clearance at the end of the stroke would.

It is true that when uniflow engines were first brought out several cylinders were wrecked, but these were cracked by initial strains due to improper design and not by high compression. There have been two accidents in this country that were probably due to excessive compression caused by loss of vacuum, but these engines had Corliss valves which could not lift sufficiently to relieve the pressure, and they broke at the cylinder heads and not through the exhaust ports.

The fact that there is in successful operation in Europe more than 600,000 hp. of condensing uniflow engines without auxiliary exhaust valves and that engine builders continue to leave them off, is proof that they are not required for safety. Since the first engines were built there has not been a single accident of the kind mentioned above with an engine built from Professor Stumpf's design.

The question of noncondensing engines presents a different problem. The uniflow engine requires large clearance and consequent loss (Fig. 8 of the article in question is incorrect and misleading, as may be seen from the accompanying cut, in which both cards have the same admission; the loss is by no means the shaded area *B*, as the description of Fig. 8 states), but this loss decreases with high steam pressures and low back pressures. Auxiliary exhaust valves also cause additional losses due to partially defeating the uniflow advantage and the additional clearance as mentioned above. These losses increase with high steam pressures and low back pressures. We therefore have two engines—one in which



AUXILIARY EXHAUST ON UNIFLOW ENGINES

the efficiency increases as the steam pressure increases and the back pressure decreases, and the other in which the efficiency decreases as the steam pressure increases and the back pressure decreases. The engine with auxiliary exhaust valves must be more efficient at low steam pressures and high back pressures, and the engine without auxiliary valves must be more efficient at high steam pressures and low back pressures.

Where these curves of efficiency cross cannot be accurately determined until there are more data of authentic trials of these types available than at present, but from the data at hand it is probably somewhere between steam pressures of 120 and 150 lb. at atmospheric exhaust.

It must not be understood that it is necessary only to build an engine on the uniflow principle to make it economical. There is just as much difference between uniflow engines as between those of any other type, and the engine must be properly designed to get good results.

I am not surprised that "One American builder, after having built and thoroughly tested a noncondensing uniflow engine having no auxiliary exhaust valves, now refuses to bid on the uniflow engine for noncondensing service," if he cannot build an engine which will do better than 24¼ lb. of steam per hp.-hr. If this engine had been properly designed for the work, it would have done at least 25 per cent. better.

One test does not prove anything, especially if the results are negative, and it is of no value whatever unless all conditions are noted.

There have been many trials by disinterested experts, and records as low as 14 lb. of steam per i.hp.-hr. (noncondensing) have been made with uniflow engines without auxiliary valves, and these records have never been approached with engines fitted with auxiliary exhaust valves.

Syracuse, N. Y.

Making a Spray Cooling Pond

High efficiency, low first cost, durability and attractiveness are the chief merits claimed for the cooling pond described herewith and illustrated in Figs. 1 and 2. The jets of spraying water have all the charm of a collection of fountains—a sight incomparable with the old-style towers or the newer masonry towers. The device described belongs to the Rea Patterson Milling Co., of Coffeyville, Kan.

Besides the pleasing appearance, the next important feature of this device is its durability. Being all iron and concrete, there is practically no wear and nothing to require attention or get out of order, and there is no danger from wind storms. Fifteen pounds' pressure is all that is required to operate the spray. The loss by evaporation is about the same as in other spray cooling devices.

This cooler handles 1500 gal. per min., reducing the water to normal temperature. This is regulated by the pressure, and thereby the height to which the spray rises; the humidity of the atmosphere is also a governing factor. The cost of the plant was as follows (estimated): Ground, $400; excavating (800 yd.), $250; concrete and labor, $1250; iron pipes and nozzles, $550; total, $2450.

The cost of a cooling tower with fan to perform the same amount of work was estimated at $5000. The brass

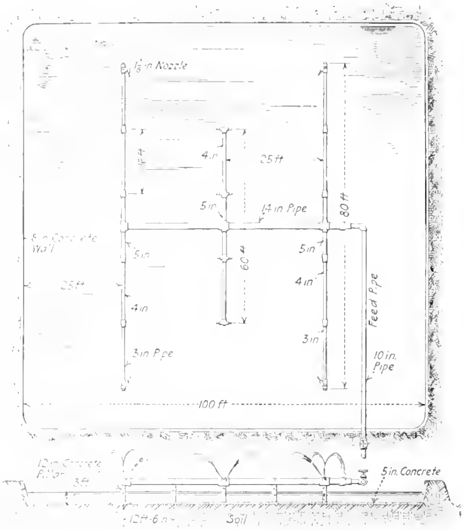

FIG. 2. PLAN AND ELEVATION OF COOLING POND

nozzles are of special make and cost $500 for the twenty used. The bottom of the pond is lined with five inches of concrete and the depth of water is about three feet. The concrete columns supporting the pipes are 12 in. square in cross-section, and they are spaced 12 ft. 6

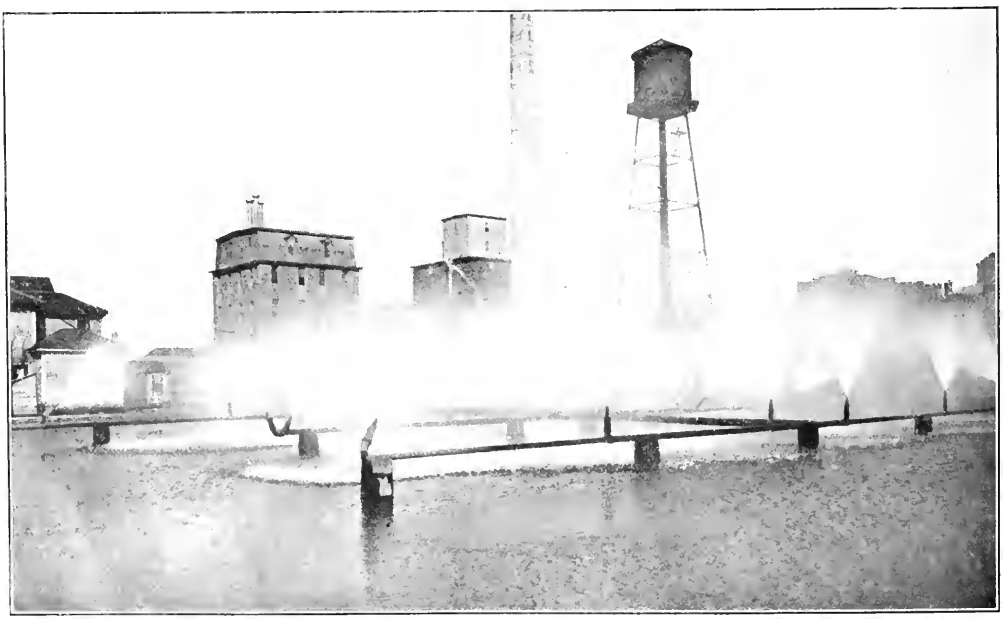

FIG. 1. COOLING POND DESIGNED AND INSTALLED BY THE PLANT'S OPERATING ENGINEER

in. apart on straight runs. The cooling pond has been in service about a year.

Plate Valve for High-Speed Air Compressors

I have read, with much interest, Mr. MacFadden's article on "Plate Valves for High-Speed Air Compressors," appearing in the Mar. 16 issue, and I wish especially to refer to the statement that it requires less power to operate these valves than it does other types of valves.

I have heard several discussions on the actual pressure required to open inlet and discharge plate valves and there seems to be a wide difference of opinion as to the actual pressure required. Many of us are interested in this subject and would be interested to know if there are any actual data by which we can determine the pressure required to open these valves. I presume that this, to a certain extent, depends upon the design of the valve, but authentic published data will be highly interesting.

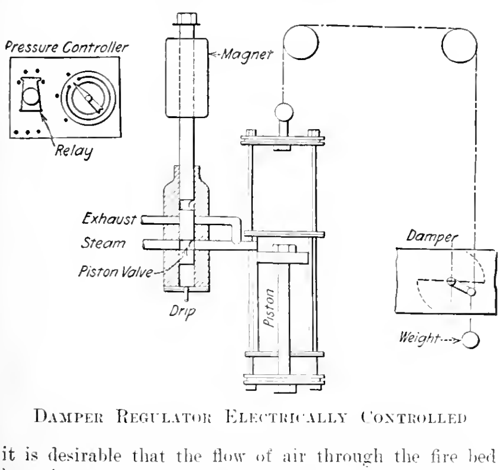
Electrically Controlled Damper Regulator

The function of a damper regulator is to check the draft when the boiler pressure reaches a predetermined limit. Having determined the amount of air required to burn a certain kind of coal and the quantity that it is desired to burn per square foot of grate area per hour,



Damper Regulator Electrically Controlled

it is desirable that the flow of air through the fire bed be maintained as nearly constant as possible. The damper should remain shut only long enough to check the rise in pressure and reopen when the pressure has decreased one pound below the predetermined limit. If it requires 0.68 in. of draft to burn No. 1 buckwheat coal at 20 lb. per sq.ft. of grate area per hour, and the damper is adjusted to control the air supply to that amount, then the regulator should open and close between the limits of 1-lb. rise and fall in steam pressure, and the fire will be allowed to cool but little before it is burning again at the full intensity. It will be found that under that close regulation with natural draft a much more uniform and higher average CO_2 can be maintained and the efficiency of the boilers increased, with the resulting saving in coal. The illustration shows an electrically controlled damper regulator that I designed to meet conditions where the closest possible regulation is expected. The results with natural draft are nearly equal to those obtained by a balanced draft system without the use of blowers, which increased the cost of power required to operate such systems.

Formulas for Bumped Heads

In the editorial in Power of Feb. 9 on "Formulas for Bumped Heads" you failed to mention several with which engineers should be made familiar. Here are some:

Mind everybody's business but your own.

Always butt in where you are not wanted.

If your boss happens to be a large man and tells you that you are not on your job, call him a liar.

Pick out a good husky fireman and kick him in the slats.

Fail to duck your nut when you pass under a low pipe line.

Come home at 2 a.m., stewed to the gills, and tell your wife that you had trouble at the plant and had to work overtime.

These few will no doubt direct a course of investigation which will result in digging up many more "formulas for bumped heads."

E. L. Aine.

Reading, Penn.

Laying Up Boilers

Some years ago I had the opportunity of experimenting in preparing boilers for a long period of idleness. The steam generators consisted of three horizontal-tubular boilers, 100-hp. each, and were in good condition. The feed water being badly incrusting, a boiler compound was used to prevent pitting and corrosion.

Before laying up the boilers they were cleaned inside and out and a coat of red lead spread on all accessible external parts. Boiler No. 1 received the following treatment: The inside was dried and a box of quicklime was put in to absorb any moisture remaining. Before closing, a pan of charcoal was burned to consume the oxygen of the air. The handhole plates were then replaced and the boiler made practically air-tight. Boiler No. 2 was filled with water and 150 lb. of soda dissolved in it, which is equal to 50 lb. to each 100 cu.ft. of water. All openings were then tightly closed. Boiler No. 3 was completely filled with feed water, and all the air was allowed to escape through a valve at the top. In each boiler was hung a polished wrought-iron bar.

Nine months later I was called back to prepare the plant for operation. On opening boiler No. 1, the iron bar was found to be slightly rusted, but the oxide was easily rubbed off with the finger. The bar hung in No. 2 was as bright as the day it was put in. Boiler No. 3 was found to have lost about half its water in some way, leaving the bar above the water line. This bar was badly rusted, the corrosion having eaten into the metal $\frac{1}{32}$ in. My opinion is that the dry method is the best and cheapest, there being no danger of freezing in extreme cold, and no water to leak out.

Reseating a Ball Engine Valve

The following shows what may be done in an out-of-the-way place when there is a will to do it. The valve and valve seat of a Ball engine, Fig. 1, being worn, the valve was sent to the shop and overhauled, but the engine could not be spared long enough to send the cylinder away.

The tool shown in Fig. 2 was made to true the upper seat after the lower one had been leveled and scraped.

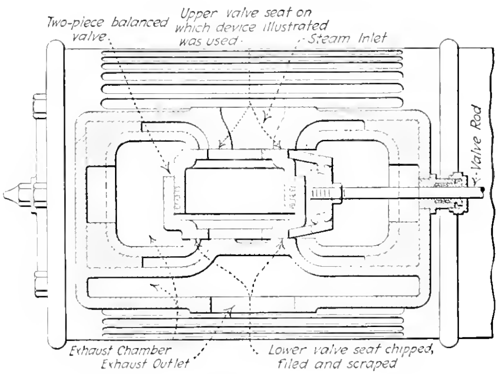

Fig. 1. Type of Valve Operated On

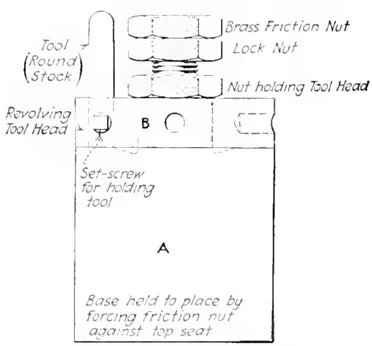

Fig. 2. Tool Used in Truing Valve Seat

It consists of a cast-iron block A for a base and a revolving tool head B. The cutting tool was set away from the center far enough to swing across the width of the face of the seat. Four holes were bored to receive the small bar used to rotate the tool head. The tool was set upon the lower seat and the adjusting nuts set up against the upper seat lightly; the tool was then adjusted to the desired cut, and the head rotated with the bar in one hand, while the base was held steady with the other. The adjusting nut required frequent changing at first, but as the work progressed only slight adjustments were necessary. A surface approximately 8x10 in. was gone over in about five hours, taking a cut from almost nothing to $^3/_{64}$ in. The tool cost $5, making a satisfactory job at a low cost.

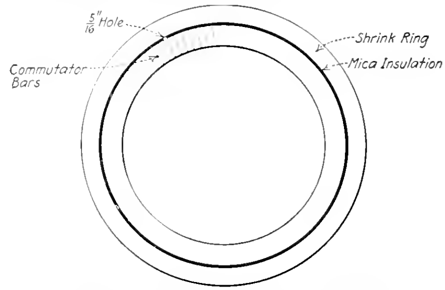
St. Joseph, Mo.

Quick Repair to Commutator

We have three 1500-kw., 600-volt, direct-current generators for operating a street-railway system. These run at 750 r.p.m., and the commutator bars are held in place by three shrink rings which are separated from the bars by mica insulation.

A short-circuit developed between two of the bars, and



Illustrating How Repair Was Made

investigation showed that it was directly under one of the shrink rings. To save the time and expense required to take off the shrink ring, a $\frac{5}{16}$-in. hole was bored between the two bars showing the short-circuit; it being necessary to drill nearly the whole depth of the shrink ring. After the short was cleared the hole was filled with a composition of mica and shellac, and the machine was put back in service after twelve hours' shutdown and has since been operating and carrying full load without difficulty.

Air Hose and Bucket as Ammonia Helmet

To be able to remain calm when there is a serious ammonia leak about the plant is a valuable asset to a refrigerating engineer.

The following is an excellent example of the engineer doing the right thing at the right time. He was operating an absorption plant when a serious break in the ammonia end of the aqua pump occurred. Before he could shut the valves the ammonia fumes had become so strong that he was compelled to leave the room. The engineer realized that the charge of ammonia would be lost unless the valves were shut immediately. Reaching in through a window he pulled the air hose loose from the air hoist. He then put the end of the hose into a three-gallon water bucket, and with the hose at the back pulled the bucket down over his head, and with his improvised helmet was able to get at the valves to save the ammonia. The air, which was at a fairly high pressure, blew the ammonia fumes from his face.

Selecting a Pump

Mr. Lent's criticism in the Mar. 9 issue, of the writer's article on pumps in the Feb. 9 number, seems to be devoted largely to deploring the latter's lack of knowledge upon the subject rather than to imparting useful information to replace that which he discredits.

The suggestion that the priming of a centrifugal pump should have been mentioned is a good one. The length of the article, however, did not allow of a discussion of many of the important details relating to the various types mentioned, and this was omitted, with others of a similar nature. Possibly a second reading will bring out the fact that the matter of distance was not the only factor noted regarding the selection of a pump for a given set of conditions.

A deep-well pump having an efficiency over 80 per cent. and no slip, is interesting as showing what can be done through good design and careful adjustment, but is hardly to be taken as current practice. The Deming Co., large manufacturers of this type of pump, give average efficiencies even lower than the ones criticized, while those for triplex pumps are practically the same as given by the writer.

Methods employed for increasing the flow of artesian wells are discussed in detail by Professor Turneaure, in "Water Supply," Part I, American School of Correspondence, and might be of interest to Mr. Lent. The use of the air lift for increasing the flow of artesian wells has been recommended to the writer by the consulting engineer of a large concern making a specialty of sinking wells and installing pumps of various kinds.

Gebhardt's "Steam Power Plant Engineering" gives the efficiency of direct-acting steam pumps as varying from 50 to 90 per cent., according to the conditions under which they are operated, with an average of about 65 per cent. for actual practice. The writer's estimate of 60 to 80 per cent. does not appear to be outside the usual limits. The Lawrence Machine Co. recommends efficiencies of 50 to 60 per cent. when estimating the power for driving centrifugal pumps of the type used for circulating hot water in heating systems, while tests of high-class machines, as given in standard works on pumps and published in the catalogs of the Worthington and De Laval companies, show efficiencies running from 70 to 80 per cent. The range of 60 to 80 per cent., as given in the article, does not seem unreasonable when compared with average results.

Regarding the statement relating to the action of volute and turbine pumps, Gebhardt's "Steam Power Plant Engineering," pages 630-631, may throw some light on the matter.

In brief, the writer has no desire to discredit the views of Mr. Lent or enter into any controversy, but he wishes to emphasize that the statements made in the original article seem to be well supported by authorities of high standing and to be based on average current practice.

CHARLES L. HUBBARD.

Boston, Mass.

Charles L. Hubbard's article, "Selecting a Pump for General Service," in the Feb. 9 issue is of interest, and may be modified and enlarged upon without limit. The following may be of additional interest.

It may be worth while to note that the usual steam consumption for this type of pump is more nearly 200 to 250 lb. per developed horsepower per hour than 80 to 160 lb. The latter would be difficult to obtain under ideal conditions of tight steam valves and pistons working on smooth, polished, well lubricated surfaces, the best hydraulic piston packing, fitting snugly to the water-cylinder barrel, and tight suction and discharge valves. Even this extravagant use of steam is not a serious disadvantage when the pump is installed under proper service conditions, as the exhaust steam can often be used advantageously.

Under normal operating conditions direct-acting steam pumps should not have a slippage of more than 5 per cent., and any pump having 15 to 20 per cent. should receive prompt attention from the operating engineer.

A normal speed of 100 ft. per min. is conservative. Boiler-feed pumps frequently operate at half this rate, while general-service pumps operate satisfactorily at 50 per cent. excess speed. The piston speed of a pump has little or no relation to its proper operation unless the valve area is restricted. The important consideration is the number of piston reversals, hence the number of times the flow of water is interrupted. The higher the speed the lower the steam consumption per indicated horsepower per hour, due to the reduced cylinder condensation.

A single, or simplex, pump is one having a single steam and water cylinder arranged along the same center line. A duplex pump is two single pumps placed side by side, the steam valves receiving their motions from the piston rods of the opposite sides. Owing to its simplicity, positive operation and even rate of discharge, the duplex type is often preferred, although the single pump has a slightly lower steam consumption.

Power Pumps

The power pump has more universal application than the steam pump, because of the extensive use of electricity and the gas and oil engine, to which it is either belted or directly connected. The belt drive is preferable, as it is quieter, more flexible, and provides a safety, which may prevent serious damage to the pump. It is frequently objected to where the pump is to be automatically started and stopped. In such cases, the belt should be selected with care and the drive carefully laid out.

The belt should not be allowed to run slack or slip, as this eventually results in its destruction, and interrupted service. A proper-sized belt, cut from the best hide, thoroughly stretched, carefully made and rightly installed, with an idler for maintaining a constant tension, is a most satisfactory drive and should operate for years. Where an idler pulley is not desired or where there is much moisture, a rubber belt will give more satisfactory service than leather. If the space is limited, a close-belted idler drive is to be preferred to a gear drive, and especially is this so in apartment houses and office buildings, where the noise of the gears may be transmitted through the piping system.

The power pump is much used for elevator, domestic and irrigation service, as it may be conveniently located and long lines of steam pipes are eliminated. The discharge is positive, hence a relief valve should always be placed in the discharge line, close to the pump, to prevent excessive pressure and damage to the pump.

In the larger sizes and where the plunger loads are reasonably large, the efficiency is from 80 to 90 per cent.

A slippage of 15 to 20 per cent., as stated by Mr. Hubbard, is excessive; it should not be more than 3 to 5 per cent. Most power pumps, especially the vertical triplex, are outside-packed and the slippage past the plungers is evident.

Power pumps are either horizontal or vertical; the larger sizes are usually horizontal. Both types are built single, duplex, triplex or quintuplex. The vertical triplex is the most popular high-grade power pump, because of its moderate cost, smooth discharge and generally satisfactory service.

Deep-Well Pumps

This class of pump performs the most severe kind of work, and there are indeed few deep-well pumps which render reliable service year in and year out. There is great difficulty in maintaining the well rods, which frequently reach five or six hundred feet to the water level below the ground, and in some cases of oil wells, three or four thousand feet below the surface. Because of their great length and the large inertia stresses due to the rising and falling column of water, the rods are frequently broken, and until the wreckage can be removed and the rods renewed the service is interrupted.

The vertical artesian steam engine is so cushioned that rod troubles are slight on wells up to 200 ft. deep. The power-well head has troubles all its own, especially on deep wells. The difficulties have, however, been largely eliminated by the triple-plunger barrel and well head, known as the "Glendora" deep-well pump, manufactured by the Deane Steam Pump Co. With this construction the column of water is always moving upward. There is no reversal of stress in the well rods, and the efficiency is 85 per cent. and more, as against 65 to 70 per cent. for the single-acting power-well head.

Mr. Hubbard states that deep-well pump efficiencies are 40 to 50 per cent. This is true only of the centrifugal type. There are installations where centrifugal deep-well pumps give better initial efficiencies, which are maintained only by frequent tuning up.

Centrifugal Pumps

Centrifugal pumps are most desirable for clear water and low heads. Efficiencies of 60 to 80 per cent. are normal, but appear absurd if the slippage is as great as 20 to 60 per cent., as given by Mr. Hubbard. The foregoing, of course, assumes that the pumps are of good design and construction, properly maintained and operating under suitable conditions. It is evident that the discharge head might be so great that there would be no discharge and the slippage would then be 100 per cent. A slippage of 20 to 40 per cent. would be reasonable for a well designed pump operating under the conditions for which it is designed.

A peculiar characteristic of a centrifugal pump is that, as the pressure on the discharge is increased above some fixed pressure for a particular pump, the required driving power is reduced, and, as the pressure is reduced the required driving power is increased. For this reason the centrifugal type is not adapted to fluctuating conditions of service.

Air Lifts

The air lift as a pump would be simple were it not necessarily complicated with compressors and air-storage tanks, which are more or less dangerous and in some states must be regularly inspected by a properly authorized inspector. The efficiencies given by Mr. Hubbard are misleading, as the net overall efficiency is generally between 20 and 30 per cent., with isolated cases of better efficiency.

Hydraulic Ram

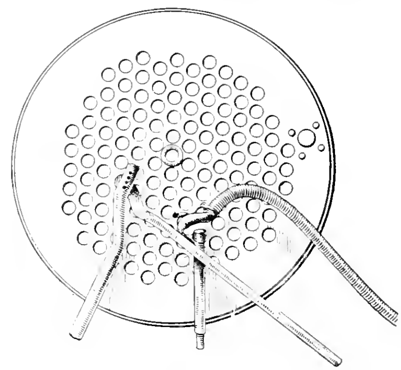
A hydraulic ram would hardly be considered as a pump for general service, and it may be located only where the supply of water is itself elevated.

Robert E. Newcomb,
Supt. Deane Steam Pump Co.

Holyoke, Mass.

An Ingenious Repair Job

A small vertical boiler on a locomotive crane at the works of the Champion Fibre Co. at Canton, N. C., required a new set of flues and an upper flue sheet. Time being the essence of the contract, a novel means was employed by the boiler maker. To avoid the necessity of removing the firebox in order to get inside to hold the "dolly" on the head of the rivets while driving, a piece



Dolly-Bar and Hammer Used on Repair Job

of 3-in. shafting, the right length to reach from the center flue hole to the rivet heads, was prepared, hinged and pinned to a lever put through the center flue opening (which was bushed to prevent injury to the edge).

The new head was fitted in place in the usual way and the riveting process was carried on in the following manner: The heated rivets were passed inside of the boiler to a pair of long, specially made tongs operated, through one of the tube holes in the lower head, by a man stationed in the firebox. He in turn placed the rivet in the proper hole. Then the end of the dolly-bar was brought to bear on the rivet head as described and the pneumatic riveter "turned loose" on the outer end. The cost of the job and the time consumed were, of course, materially less than they would have been if done in the ordinary way.

H. Kilday.

Canton, N. C.

[We presume there were "good and sufficient" reasons for not wishing to invert the heads and drive the rivets from the outside. The rather unsightly appearance of such a job is sometimes objectionable.—Editor.]

Inquiries of General Interest

Temperature for Pouring Babbitt Metal—How can the proper temperature for pouring babbitt metal be known?

F. L.

When a yellowish tinge has formed on the surface, or if a white-pine stick is heavily browned or slightly charred when inserted in the molten metal, then the proper temperature has been reached for pouring.

Disadvantage of Low Boiler Settings—What is the disadvantage of low, as compared with high settings for return-tubular boilers?

C. B. L.

Settings which are too low may be wasteful of fuel, for when a boiler is set too close to the grates the flame is cooled by coming in contact with the boiler surfaces before combustion has been completed.

Calculation of Calorific Value of Coal—How is the calorific value of coal determined from its analysis?

J. M. E.

The heat value of any coal may be calculated from its ultimate analysis, with a probable error not exceeding 2 per cent., by Dulong's formula,

$$\text{Heat value in B.t.u. per lb.} = 146\,C + 620\left(H - \frac{O}{8}\right) + 40\,S$$

in which C, H, O and S are the respective percentages of carbon, hydrogen, oxygen and sulphur present in the coal.

To Draw True Vacuum Line on Indicator Diagram—How is the true vacuum line drawn on a steam-engine indicator diagram?

M. G.

The line representing true vacuum would be below the atmospheric line a distance which represents atmospheric pressure. Therefore, at sea level the true vacuum line is to be drawn with a straightedge below the atmospheric line of the diagram, and parallel to it, at a distance which, according to the scale of the indicator spring, represents 14.7 lb. per sq.in.

Objections to Sulphur in Coal—What are the objections to the presence of sulphur in coal for steaming purposes?

C. R. S.

The calorific value of sulphur is less than $\frac{3}{10}$ that of carbon, and its presence in fuel is objectionable because the gases formed from its combustion attack the metal of the boiler, causing rapid corrosion, especially in the presence of moisture. Sulphur is also objectionable because it unites with the ash of the coal to form a fusible slag, or clinker, which chokes up grate bars, forming a solid mass having embedded in it considerable quantities of unconsumed carbon.

Absolute Temperature—What is meant by absolute temperature?

G. R.

Since substances can be cooled below the zero point of the ordinary thermometer, it does not represent the true zero of temperature at which there is an entire absence of heat; and while this has never been reached in cooling substances, experiments indicate that it is 460 deg. below the zero of the Fahrenheit scale. Hence, to change Fahrenheit degrees to absolute temperatures add 460 to, or to change from absolute to Fahrenheit degrees, subtract 460 from, the number of degrees.

Obtaining Length of Open Belt—What is the rule for finding the length required for an open belt?

R. B.

The best method is to measure the length directly by passing a tape line around the pulleys. When this cannot be done an approximate formula is

$$\text{Length} = 2\,L + 3.1416\,(R + r) + \frac{(R - r)^2}{L}$$

in which all dimensions being in feet or inches,

L = The distance between centers of the pulleys;
R = Radius of larger pulley;
r = Radius of smaller pulley.

Loss of Draft in Flues and Elbows—What is the relative loss of draft in round and square smoke flues and what allowance should be made for elbows and lengths of flues?

W. C.

The retarding effect of a square flue is about ⅛ greater than for a circular flue of the same area, and for brick flues is about ⅓ greater than for steel flues. Short right-angle turns reduce the force of draft about 0.05 in. for each turn and a circular steel flue the same size as the stack causes about 0.1 in. draft loss for each 100-ft. length of flue. In average power plants it is usually practical to reduce the loss of draft by providing a smoke flue with a cross-sectional area about 20 per cent. greater than the cross-sectional area of the stack.

Duty of Steam Pump—What is meant by the duty of a steam pump?

H. N. M.

The duty of a steam pump is the number of foot-pounds of useful work realized, or the equivalent number of pounds of water lifted 1 ft. high, per 1,000,000 heat units furnished by the boiler; i.e.,

$$\text{Duty} = \frac{\text{Foot-pounds of work done} \times 1{,}000{,}000}{\text{Total number of heat units consumed}}$$

The old unit of comparison was the number of foot-pounds of work realized per 100 lb. of coal, and this was inexact, as the amount of steam depended upon the quality of the coal and the evaporative efficiency of the boilers. The modern unit of comparison is not seriously at variance with the old unit, as in good boiler practice 1 lb. of coal will yield at least 10,000 B.t.u. in generation of steam.

Loss of Heat from Steam Pipe—What would be the loss of heat from an uncovered 6-in. steam pipe 80 ft. long, containing steam at 100 lb. gage pressure?

W. B.

Bare pipe will radiate approximately 3 B.t.u. per hour per square foot of exposed surface per 1 deg. of difference in temperature between the steam contained and the external air. The temperature of steam at 100 lb. gage pressure being 338 deg. F., and assuming the temperature of air surrounding the pipe to be 80 deg. F., then the loss of heat would be

$$(338 - 80) \times 3 = 774 \text{ B.t.u.}$$

per hour per square foot of exposed pipe surface, and as the external diameter of 6-in. pipe is 6.625 in., the total pipe area exposed would be

$$\frac{6.625}{12} \times 3.1416 \times 80 = 138.75 \text{ ft.}$$

and the loss of heat would amount to

$$138.75 \times 774 = 107{,}392.5 \text{ B.t.u. per hour.}$$

Equivalent Evaporation—With an average temperature of feed water of 136 deg. F., 2900 tons (each 2240 lb.) of coal were required to evaporate 38,000,000 lb. of water into steam at an average gage pressure of 137 lb. per sq.in. What was the equivalent evaporation from and at 212 deg. F. per pound of coal?

J. A. M.

The evaporation under the actual conditions was

$$\frac{38{,}000{,}000}{2900 \times 2240} = 5.849 \text{ lb.}$$

of water per pound of coal. The steam tables show that 1 lb. of steam at 137 lb. gage, or about 137 + 15 = 152 lb. absolute, contains 1193.6 B.t.u. above 32 deg. F., and as each pound of the feed water contained 136 — 32 = 104 B.t.u., then for conversion into steam at the stated pressure each pound of feed water received

$$1193.6 - 104 = 1089.6 \text{ B.t.u.}$$

As the latent heat of evaporation of a pound of water at 212 deg. F. is 970.4 B.t.u., the factor of evaporation was

$$1089.6 \div 970.4 = 1.1228$$

hence the actual evaporation was equivalent to an evaporation of

$$5.849 \times 1.1228 = 6.567 \text{ lb. of water}$$

from and at 212 deg. F., per pound of coal.

Testing Lubricating Oils*

SYNOPSIS—An enumeration of the various tests to determine the qualities of an oil. Results obtained are only approximate.

A brief description of a desirable lubricant is that its viscosity should be the least possible which will allow it to stay in place and do the work. Summarizing the commonly desirable characteristics, they are:

1. The oil should possess cohesion.
2. It should possess the maximum possible adhesion.
3. It should be as far as possible unchangeable.
4. It should be commercially free from acid.
5. It should be pure, that is, it should be what it purports to be.

TYPES OF VISCOSIMETER

The first to be discussed is the viscosity test, which is used to measure the internal friction of the oil, or, as an engineer might put it, the shearing modulus. This test is of value because a lubricant is really used to keep a shaft or journal and its bearing apart. The journal really revolves on a sheet of lubricant, an action which has been described as revolving on the molecules of the lubricant. The ease with which the molecules slide over one another therefore determines, to a certain extent, the friction loss in a bearing.

A fine example of the effect of the viscosity of lubricating oil is furnished by an experience in a certain spinning mill. This mill was operated with power derived from an engine carrying about the maximum load of which it was capable. The lubricant used on the spindles was changed to one which was supposed to be better. It was then found that the engine did not have power enough to drive the machinery in the mill; as a matter of fact, it was unable to start the machine in motion. Examination showed that the only essential difference between the two lubricants was the possession of higher viscosity by the new oil.

The measurement of viscosity of lubricating oils is in a certain sense unsatisfactory, because the results obtained with the different instruments which are available for making this test do not agree among themselves. It is therefore customary to state the instrument which was used in determining any quoted viscosity.

One of the most commonly used viscosimeters is the Saybolt instrument. This is of the pipette type, having a tall pipette of rather small diameter immersed in a jacket which may be used for maintaining any desired temperature during the test. The test is made by filling the pipette to a certain point and noting the time of efflux, in seconds, which is taken as the measure of the viscosity of the oil tested. Or the so called specific viscosity may be determined by dividing the time required for the efflux of the oil by the time required for the efflux of the corresponding volume of water. The Saybolt instrument was developed by the Standard Oil Co. and was used as a standard for many years, and is today.

The instrument most commonly used in Germany, and now coming into rapid use in this country by both the Government and individuals, is known as the Engler viscosimeter. This differs from the Saybolt principally in using a shorter pipette of larger diameter. It is used in the same way, but the specific viscosities as determined by the two instruments do not agree.

None of the commercial viscosimeters really measure the viscosity, becaues it can be shown that the tube through which a jet is discharged must have a length of from 175 to 200 times the diameter to give a true measure of viscosity. Any of the commercial instruments can, however, be standardized by measuring the times of efflux of standard solutions of cane sugar or of glycerin. By such means the readings of these instruments can be interpreted in terms of absolute viscosity in dynes.

Numerous viscosimeters made of glass have been tried, but unfortunately no two glass instruments can be made exactly alike except at prohibitive expense. For this reason, the glass pipette once used as a standard by the Pennsylvania R.R. was abandoned. It should, however, be noted that a glass pipette, calibrated with glycerin as above described, can be used.

The viscosimeters just mentioned are all of the efflux variety, but there are numerous other forms available, and some of them are particularly well adapted for testing the viscosity of certain commercial products other than oils. For instance, the retarding effect exerted on a paddle revolved in a viscous liquid may be used as a measure of the viscosity and is so used with varnishes, glue and paste. Another form consists of a cylinder suspended from a torsion wire. The retarding effect upon this cylinder when swinging back to normal position after a displacement can be used as a measure of viscosity.

It should be particularly noted that the viscosity varies rapidly with the temperature. It is therefore necessary to state the temperature at which any determination was made.

FRICTION TEST

There is really no satisfactory test of the adhesive quality of a lubricant. It is commonly supposed to be determined by a friction test. This is made by measuring the frictional resistance offered to the rotation of a standard journal in a standard bearing when lubricated with the oil in question. The results obtained depend partly upon the viscosity of the lubricant and partly upon its adhesion. Modern research shows that viscosity tests show about as much as do friction tests, but this is not necessarily so, and must not be assumed to be universally applicable.

GUMMING TEST

A third test, and one which is of great importance, is known as the gumming test. This is particularly applicable to petroleum oils and is used to indicate the extent to which the oil has been refined. It serves indirectly to indicate the extent to which the oil may be expected to change due to oxidation when in use. Numerous opportunities have been offered to check the results obtained with this test and results obtained in practice with the same oils, and all of this experience tends to show the great value of the gumming test.

This test is made by putting a small quantity of the oil to be tested in a small glass vessel, such as a cordial glass, and then mixing with it an equal quantity of nitrosulphuric acid. A properly refined oil will show little, if any, change, but a poorly refined oil will be indicated by the separation of large quantities of material of dark color. This color is due to the oxidation of the tarry matter contained in the lubricant. Experience has shown that oils containing large percentages of tar absorb the most oxygen, that is, they are mildly drying oils.

The results obtained by the gumming test agree well with carbon-residue tests made by distilling to dryness in a glass or a fused quartz flask. The carbon-residue test has been found of great assistance in choosing a satisfactory cylinder lubricant for gas engines, as a large amount of carbon means trouble in the engine cylinder. The lowest carbon content mentioned by the author was 0.11 per cent. The oil giving this test showed no tarry matter when tested with nitrosulphuric acid. In general, a gas-engine oil should not contain more than 0.5 per cent. carbon as determined by the carbon-residue test.

FLASH, FIRE AND EVAPORATION TESTS

When an oil has been found to have satisfactory viscosity and has given satisfactory results in a gumming test, it must next be checked for safety, that is, the flash and fire test must be made. The amount of volatile matter given off at the temperature at which the lubricant is to be used is often of great importance. A case is on record in which a serious mill fire was spread by vapors given off by the lubricant used in the various bearings. The oil used in this mill gave off 25 per cent. of volatile material when raised to 145 deg. F.

It is advisable to include an evaporation test with the flash test of lubricants. The evaporation test is made by exposing about 0.2 gram of oil at a proper temperature and determining the loss by weight in a given time.

The flash test is made by heating the oil slowly in a vessel surrounded by a proper bath and determining the lowest temperature at which a flame passed over the surface will ignite the vapors which are given off.

FREE ACID TEST

It is generally conceded that lubricants should be practically free from acid, and the so-called free acid test is made to determine the extent of acid content. The mineral oils are agitated with sulphuric acid during the refining process for the purpose of removing tarry materials, and this acid must be practically all removed from the oil before it is put on the market. Oils may become contaminated with acid from another source as well; namely, the animal or vegetable oils which are occasionally mixed with them for the purpose of

*Abstract of paper read by Prof. A. H. Gill before the Detroit Engineering Society, Mar. 19, 1915.

modifying their characteristics. A content of 0.3 per cent. of acid is generally considered the maximum allowable.

SPECIFIC GRAVITY

It is often desirable to determine the character of the raw material from which a given lubricant was made. This can be done in the case of oils refined from petroleum by means of the specific-gravity test. Experience has shown that lubricants made from petroleum with an asphaltic base run from 7 to 10 deg. Baumé heavier than similar lubricants made from petroleum with a paraffin base.

In examining oils, it is well to bear in mind that the viscosity is easily increased by the use of a material known as oil pulp or oil thickener. This is really oleate of alumina, and while it brings up the viscosity, it does not give the greasiness expected when that particular viscosity was specified. At ordinary temperatures, a small quantity of this material will greatly raise the viscosity.

COLD TEST

There is another test, known as the cold test, which is of value in some cases. If an oil is to lubricate a bearing, it must be fluid enough at the temperature of use to readily flow into that bearing. Many ruined bearings and some fires have resulted from the use of an oil which became too viscous to flow under the conditions of use. For such reasons, it is customary to chill samples of oil and to determine the temperatures at which they become too thick to flow readily.

IODINE TEST

Tests other than those already described are often made on animal and vegetable oils. They are generally made for the purpose of determining whether the oil under test is what it is supposed to be. It is a simple matter to mix different animal and vegetable oils in such a way that they will give a product capable of passing any one or possibly two given tests, but it is impossible to make such a mixture successfully pass all of the tests which would be passed by the pure oil for which the mixture is to serve as a substitute.

The chemist is often at a great disadvantage in testing such mixtures, because there are no exact specific tests for some of the animal and vegetable oils. The presence of some can be determined absolutely, but unfortunately, this is not true of all.

The iodine test, by which is meant the determination of percentage of iodine absorbed by the oil under set conditions, has long been used to indicate the character of vegetable and animal oils present in a sample. At one time it was believed that the so-called iodine number was a constant for any one oil and that this test was therefore perfect. It is now known that this is not true, the iodine number varying with the condition of the material from which the oil was made.

It is a simple matter to determine the presence of petroleum oils in a mixture of oils with animal or vegetable origin. This is done by saponification, which serves to separate the petroleum oil, which does not saponify, from the others which do.

MAUMENÉ TEST

There is a comparatively new test, known as the Maumené test, which gives results comparable with those obtained with the iodine test, but is much simpler and therefore more readily performed by the average individual. For this test, 50 grams of oil and 10 c.c. of sulphuric acid are placed in a beaker and slowly stirred with a thermometer. The maximum temperature rise which occurs is noted and used as an indication of the character of the oil.

TESTS ONLY APPROXIMATE

It should be appreciated by the practical man that the tests of lubricating oils give only approximate results. Thus any one viscosimeter as ordinarily made will give consistent results on the same material at the same temperature, but different instruments of the same type and apparently exactly alike will give results on the same material which vary several per cent. Similarly, large errors are often obtained when using friction machines. With tests otherwise properly conducted, it appears that the absorption of oil by the metal of the journal and bearing may be sufficient to cause appreciable errors. Tests have shown that it may take several hours to eliminate the effects of the last oil tested so as to get correct results with a given sample.

No rigid directions can be given for the choice of oils for given purposes. It is best to try various lubricants which can be purchased for any given lubricating problem until one is found which gives satisfactory results. This should then be completely tested and the results of the test should be used in writing specifications on the basis of which bids are to be asked. When the problem is handled in this way, the different prices asked for lubricants which will meet the same specifications will often be found most remarkable.

Wrought Iron and Steel Tubes*

By J. G. Stewart

When the British Engineering Standards Committee considered the question of screw threads for pipes they compared the merits of two well known forms of thread, viz., the Whitworth or British standard bolt thread, the Sellers, or U. S. A. standard, and another, not so well known—the Briggs American standard pipe thread. The committee decided by a majority (of which the writer was not a party) to accept the Whitworth thread, principally because the tools to make it were already in the hands of every engineer and plumber in this country, but also because taps and dies made to this form have little tendency to change by wear, which is not the case with the American standard forms of bolt and pipe joints.

However, any pipe joint, in order to be petroleum tight under high pressure (many oil lines work at 1000 lb. per sq.in.) must be of very special and accurate construction, and for this class of work the Briggs thread has alone proved satisfactory. It will be noticed that the crest of the thread is very sharp, much more so than the contour of the root. One result of this is that a difficulty occurs in maintaining the screwing tools to their correct shape. This is minimized by forming the tools to the correct profile by a single cutting tool which leaves the sharp crests on the master tap. As there is a considerable amount of cutting surface to be worn away on the master tap, the sharp edges stand up to their work for some time without losing appreciably the sharpness of the thread.

The difference in the power required to draw up a coupler with the Briggs thread, as compared with one with the Whitworth, is marked, particularly as such threads are made on a cone with a taper of $\frac{1}{16}$ in. per inch. With the Whitworth thread little movement can be given to the coupler with a heavy pipe wrench, after it has been drawn up by hand, as compared with that which can be obtained in a Briggs thread joint. There is little doubt that Briggs himself, in putting it forward in his paper which was read in America in 1886, fell into confusion. His description of his proposed thread, which was subsequently adopted as the American standard pipe thread, is as follows: "The thread employed has an angle of 60 deg.; it is rounded off top and bottom, so that the height or depth of the thread, instead of being exactly equal to the pitch, is only four-fifths of the pitch." But, having an angle of 60 deg., the depth could not be equal to the pitch. There can be no doubt that what he meant to say instead was "the depth appropriate to the pitch." This depth measures 0.866 and as the depth was to be 0.8 the amount to be taken off the sharp edge or crest was 0.066, as against 0.17 on the Whitworth standard.

The question arises, Can a joint be made in this manner—i.e., with the Briggs thread—be undone, and remade if occasion arises? The answer is that it depends upon the treatment given when the joint is first made. If the couplings are driven very hard upon the screwed ends of the pipes it may be found impossible to disengage without injury to the thread and again remake the joint. But if the joints are screwed up with proper care and with a liberal use of thick viscous oil, these joints with this form of thread can be unmade and remade five times at the least computation.

Many engineers are under the impression that a coarse thread is stronger than a fine one, but that the converse is the case may be readily demonstrated. Take a pipe or bolt, and screw it at one end with a fine thread and with a coarse thread at the other, with nuts to correspond; place a spiral spring between them and draw up until one of the threads strips. This will invariably be found to be the coarse thread.

An important item in drawing up a specification for steel pipes is the method of bending them to the required pattern. There are two ways in which a steel pipe may be bent. The straight length of pipe may be set on a table between supporting dogs and bent by drawing the free end of the pipe against the dogs. By this method the pipe is constantly under the observation of a skilled operator, who is careful to arrest any local drawing of the metal on the outside radius, by causing the pipe to thicken on the inside radius rather than to reduce on the outside. The other way is to bend the pipe between a pair of dies, each forming a half-mold of the bend to be made. Curiously enough, some engineers seem to be under the impression that the correct way to

*Abstracted from a paper read before the Institution of Engineers and Shipbuilders in Scotland, Feb. 16, 1915.

form a bend is by dies, whereas the two methods will not stand comparison.

When a piece of tube is bent into a curve, first, one side of the tube must stretch or become extended in length; secondly, the opposite side must, in a lesser degree, become shortened; and, thirdly, the cross-section of the tube must become an ellipse. Condition No. 2 is no disadvantage, and condition No. 3 can in most cases hardly matter, as the cross-sectional area is only slightly diminished. The consequences of No. 1 may seriously injure the bend, the result being a reduction of the thickness of the wall, even to the extent of rupture; this does actually take place frequently when the radius of the bend has a small ratio to that of the cross-section of the tube.

It follows that in making a bend it is desirable to control and relieve the stretching at the expense of the other two conditions. The only way of exercising this control is for an expert workman to watch the action and cool the part where he can detect thinning. Along the outside of the bend it will be more prevalent at one point than at others, and wherever it is apparent it will accentuate itself as the metal gets more attenuated and weaker. An experienced bender will stop the bending and cool the yielding part by a water jet before resuming. He may require to cool many parts many times before he completes the operation of forming his bend. This manipulation is quite impossible if the forming is done between a pair of dies.

No doubt, bending pipes in dies is a more expeditious process, suited to unskilled labor, and therefore cheaper, but the quality of the work is altogether inferior. Bending of pipes in dies should never be employed or sanctioned for anything but the sizes of pipes of, say 2-in. bore and under. To confirm this opinion one has only to drill holes in the back of two pipes bent by these two processes, when the difference in thickness of the metal will at once establish the superiority of the first mentioned method.

I have purposely avoided reference to the controversial subject of the relative merits of steel and cast iron for pipes. Some years ago, when steel pipes were introduced for the gas and water supply of our Colonial possessions and other markets far removed from the manufacturing centers, these light lap-welded tubes proved of inestimable value in developing new towns and colonies, which, had it not been for their low cost and the low freight on them, would in many cases have been without water supply to the present day. With very few exceptions these pipes have given every satisfaction, recent reports from all sides showing that they are practically as free from corrosion as when laid. This being so, there is a natural disinclination to pay the extra price and freight charges of the thicker hot-rolled weldless pipe.

As regards its application to water and gas pipes, the total value of steel pipes for that purpose manufactured last year in this country was about £7,000,000, or three times as much as it was 15 years ago. The steel pipe maker, therefore, has certainly nothing to complain about. I believe that during the same period, the production of cast-iron pipes has remained about stationary, but I have no definite statistics on this point.

A few representative cases may be cited as illustrating that the rapid transition from cast iron to steel indicated by the above figures is well warranted. For the water supply of Perth, Western Australia, a cast-iron pipe 12 in. diameter was laid about twenty-five years ago, and this was supplemented 17 years ago by a steel pipe 21 in. diameter. The former has been twice scraped to remove the internal nodular incrustation due to rust, some of these nodules being found to be from 2 to 3 in. thick. On the other hand, the steel pipe, on recent inspection, was found to be practically free from corrosion. This case is remarkable from the fact that the water is from the same source and practically identical with that pumped through the celebrated 350-mile line of 30-in. steel pipe for the water supply of Coolgardie, the internal corrosion of which in places (principally due to portions of this pipe line being allowed to run only half full, that is, between wind and water) has led to a good deal of extravagant comparison of the relative corrosion-resisting qualities of steel and cast iron coupled with the assertion that the laying of this main in steel was a false economy. The real facts of the case are that the local authorities knew full well from the above-cited experience in the Perth water supply that any trouble experienced with this main in steel would certainly have been very much worse in cast iron.

Sixteen years ago the town of Bradford laid about 15 miles of 36-in. steel pipes. At that time there was a difficulty in supplying bent pipes of this size, and the bends in the line were therefore furnished in cast iron. A recent landslide at one of these bends dislodged the leaded socket between the straight steel pipe and the cast-iron bend, when it was found that the surface of the cast-iron pipe was heavily incrusted, owing to corrosion, thus seriously reducing the capacity of the pipe, but the steel pipe was found to be in almost the same condition as when laid, with the glossy surface of the Angus Smith's solution practically intact as originally applied 16 years ago.

Twenty-two years ago Vancouver actually risked its water supply with a 16-in. steel main only ⅛ in. thick. Inspection of this main last year demonstrated that the estimate of steel was not exaggerated, this very thin pipe being so little affected by corrosion that the engineer estimated its life to be worth at least another twenty-five years.

Thirty-three years ago the Kimberley Water Co., South Africa, laid down a wrought-iron water-supply main 14-in. and 18-in. diam., and ¼ in. thick, of which the present manager stated early this year: "With the exception of the portion which runs through a salt marsh, and which was replaced some three years ago, the pipe line is in as good a condition as when it was put down, and we do not anticipate any trouble for at least another twenty-five years."

I have selected the above cases for citation, because they represent pioneer work in four continents, and have led to the very general adoption of steel pipes throughout Australasia, Canada and South Africa, while the favorable experience of Bradford is now leading to the adoption of steel for the water-supply mains of some of the largest industrial centers in the country.

Years ago steel established itself as the material for high-pressure steam-boiler feed, and all other high-pressure service. In addition to the large number of steel, steam, feed, boiler and general service tubes to be found on every modern steamship (the boilers of the "Lusitania," "Mauretania" and "Aquitania" alone contain 100,000 fire tubes), the saving in weight effected by tubular construction has led to its adoption on board ship for many purposes where other sections and materials were formerly used.

Upon the general question of whether the experience of the last few years would warrant the conclusion that the weldless processes of tube making have now been developed to the stage that they will, in the immediate future, in competition with the welded tube, emerge triumphant, and that after all the difficulties which for so many years have accompanied these efforts continuously, I can only say this: In Germany, where the weldless process has been most sedulously pursued, the older methods of making tubes have not been developed and improved in any degree approaching to the way in which these older systems have been advanced by the Americans, and in this country.

I have had many opportunities of seeing tube works in Germany and in the United States, and I am convinced of this—that if the Germans had devoted as much labor of mind and as much of money to the improvement of their welding plants as they have upon experiments on weldless processes, their competition would have been much more severely felt here.

To summarize, the question is this: Can we produce by the old-established, known method of making tubes a tube as reliable as one made by the weldless process, and produce it so as to be able to sell it at the same price? In this country we can, and in America it is still possible. Commercially, the two processes have nowhere met each other on equal ground.

There has also existed, very generally, a theoretic prejudice in favor of the word "weldless," which has proved strong. In Germany the weldless process is universal. In this country and in the United States it is almost non-existent. Of course we all know how often we have been told that the Germans are beating us in everything, and how miserably incompetent and antiquated in their methods our manufacturers are, but we do not often hear the Americans branded as prejudiced fools, unable to take care of their own interests. The question is sometimes put thus: Is a tube any better for having a weld? No one can pretend that it is, and when a weldless tube can be produced of as reliable material and at about the same cost as a welded tube, the days of the latter will be numbered. That that day has not yet arrived is manifest, but that it is always growing nearer is certain.

A Year's Boiler Explosions

The annual report of the Marine Department of the Board of Trade upon the working of the Boiler Explosions Acts during the year ending June 30, 1914, is now before us.

The number of explosions, 68, and the number of lives lost thereby, 22, are both below the average, but the number of people injured, 74, is above the average. This is an exact reversal of the state of affairs set out in the immediately preceding report. Twenty-eight of the "boiler" explosions reported upon resulted neither in loss of life nor in injury to limb. The 96 casualties are thus attributable to 40 explosions. The report is distinguished by the record of an unusually disastrous explosion. On Aug. 26, 1913, a Beesley boiler, 22 years old, failed at the works of Walter Scott, Limited, Hunslet, Leeds, killing 9 men and injuring 18. Investigation showed that the center flue tube had become worn out and that its first ring had collapsed for its full length and had fractured circumferentially. The insurance company, its assistant engineer and one of its inspectors were found to blame, and had to pay costs totaling £600.

Twenty-nine of the explosions occurred to "boilers" which were under the inspection of public bodies, but in 14 of these cases the explosions were not due to material defects, and therefore presumably could not have been guarded against by inspection. Of the causes of the explosions, deterioration or corrosion is most prominent, with 20 cases. Defective design or undue working pressure was responsible for 19, defective workmanship, material or construction for 12, ignorance or neglect of attendants for 9, and water hammer and miscellaneous causes for 4 each. As for the types of boilers which exploded, the horizontal multitubular was the greatest offender with 13 cases. Vertical boilers came next with 7. Tubes in steam ovens were responsible for 5, locomotive boilers for 4, while Lancashire, Cornish and other flue boilers resulted in 3 and water-tube boilers in 2 explosions. Steam pipes, stop-valve chests, etc., are classed as boilers in the acts, and these are debited with 11 explosions. There are three cases of pipes failing by fatigue caused by vibration. In one case it was a cast-iron feed-water pipe, 21 years old. In the two others the parts which failed were the main steam pipes, one being sixteen months old and the other but two months old. There are two cases of failure by fatigue caused by expansion and contraction. In one a cast-iron steam pipe 28 years old was concerned, and in the other the front end plate of a single-ended marine boiler 8½ years old was the part at fault.—"The Engineer," London.

ENGINEERING AFFAIRS

The Annual Dinners of The Atlantic City Association N. A. S. E. are always a success in point of attendance and speakers. The latest, given Mar. 20, was in keeping with all previous ones. The guests of the evening were Col. Lewis T. Bryant, Commissioner of Labor for New Jersey; George R. Starrs, of the Paterson, N. J., Board of Education; and A. L. Case, of the Engineers and Firemen's License Bureau. Other representative N. A. S. E. men and city officials were present.

Atlantic City N. A. S. E. and Guests at Dinner

Detroit Chief Engineers Dine—The second annual banquet of the Chief Engineers' Club of Detroit, Mich., was held at the Hotel St. Clair, Mar. 13, 1915.

This club, which has been in existence only three years, is composed solely of chief engineers, and to be eligible to membership one must occupy the position of chief engineer in some steam plant. At the first annual banquet there were 42 present. This year 86 attended.

Immediately following the banquet there was a vaudeville entertainment given by stars from some of the leading Detroit theaters. The affair was under the direction of the entertainment committee, J. H. Roberts, chairman.

Following is a copy of the menu card:

BILL OF MATERIAL

Exciter — Smooth On
Bleached Fiber — Ball Bearings
Center Punches
Feed Water Agitators

Detroit Chief Engineers' Club Dinner

Aggressor | Carbon Brushes
Electrified Voltage
Aëroplanes
Gas Producers | Aggregate
Silencer | Circuit Breakers
Cement Pats
Refrigerator | Assorted Gaskets
Treated Feed Water | Fuel Testers

The executive committee for 1915 is as follows: Past-president, Charles Mery; president, John Gretzinger; vice-president, Alex Warner; secretary, H. C. Hayes; financial secretary, Edward Kahl; treasurer, Alex Kothe; marshal, F. J. Linck; assistant marshal, J. P. Field; entertainment committee, J. H. Roberts.

Ohio Adopts the A. S. M. E. Code

The following "Special Notice" has been issued by the chairman of the Ohio Board of Boiler Rules.

The Ohio Board of Boiler Rules at their meeting on Mar. 25, 1915, adopted the following resolution:

Until further notice, an Inspector holding a Certificate of Competency and a Commission authorizing him to inspect steam or hot-water boilers which are to be installed within the State of Ohio, is hereby authorized to inspect during construction and on completion stamp "OHIO STD" with Serial Number any boiler constructed in accordance with Rules formulated by the Boiler Code Committee as submitted to the Council of the American Society of Mechanical Engineers on February 13, 1915.

OHIO BOARD OF BOILER RULES,
H. V. NEFF, Chairman.

Mar. 29, 1915.

New Orleans Likely to Have Municipal Plant

That the City of New Orleans will have a municipal lighting plant, involving an ultimate outlay of from five to six million dollars, became apparent Mar. 15, when it was announced that engineers sent by George F. Bishop, of Cleveland, to make a survey of the proposition had completed their work and would soon make a report. There has been organized agitation for a municipally owned plant in the Southern city for many months and the New Orleans Railway & Light Co., which is at present supplying electrical energy for the city and private consumers, apparently isn't so powerful a factor in the city and state affairs as it used to be. The present street-lighting contract with the company expires Sept. 30 but, according to Commissioner E. E. Lafaye, whose department would have jurisdiction over the municipally owned plant, it will not be necessary to execute a new contract on that date or to make other arrangements, as the contract may be extended so as to give sufficient time for the construction of the municipal plant should that be decided upon.

BUSINESS ITEMS

Arthur D. Little, Inc., chemists and engineers, of Boston, are establishing an office in the Chemists' Building, 50 E. 31st St., New York.

Harry B. Aller now has charge of the Chicago territory of the Ohio Injector Co. He will handle its complete line of stationary power-plant equipment.

The Southwark Foundry & Machine Co., Philadelphia, Penn., is now actively engaged in the manufacture of hydraulic and steam hydraulic presses and has a considerable volume of this work in hand at the present time.

A correction—The advertisement of the Girtanner-Daviess Engr. & Contr. Co., St. Louis, Mo., in the Mar. 16 issue read "Sixteen installations since Jan. 1, 1915." This should have read "Twenty-two installations since Jan. 1, 1915."

G. L. Simonds & Co., 500 Gaff Bldg., Chicago, Ill., sales department of the Vulcan Soot Cleaner Co., has been awarded the contract for 18 Vulcan soot cleaners to be applied to 18 Keeler boilers to be furnished for the Illinois State Board of Administration.

A souvenir card being sent out by Yarnall-Waring Co., Chestnut Hill, Philadelphia, is a moving picture of the Simplex seatless blow-off valve. It is really a valve model and shows the construction and operation of the valve in detail. Sent on request.

The Hoppes Manufacturing Co., of Springfield, Ohio, recently made a sale of two 1,000,000 lb. per hr. Hoppes V-notch recording meters to the West Penn Traction Co., Pittsburgh, Penn. This is believed to be the largest installation of feed water metering equipment in the world and will be operated in connection with Hoppes feed water heaters.

The Lagonda Manufacturing Co., Springfield, Ohio, has just published a booklet entitled, "Lagonda Boiler Room Specialties." This booklet describes and illustrates the several types of Lagonda boiler tube cleaners with latest improvements and boiler quick repair tools. It also covers the Lagonda automatic cut-off valve and multiple strainers. Copy may be had on request.

The American Pulley Co., of Philadelphia, Penn., manufacturer of the celebrated "American" wrought-steel split pulley, has just completed arrangements for the opening of its own store at 119 Jackson St., Seattle, Wash., where it will carry a large and complete stock of pulleys for the accommodation of dealers in the Northwest. Archie Chandler, of Seattle, will represent the company in the distribution of its product among dealers on the Pacific Coast.

The Buffalo Forge Co., Buffalo, N. Y., has recently received contracts for heating and ventilating apparatus for the following public buildings: Private Ward Hospital, Wilkes-Barre, Penn.; Southwark Public School, Philadelphia, Penn.; Merchants National Bank, Richmond, Va.; Union High School, Alhambra, Calif.; High School, Compton, Calif.; El Paso Telephone Co., El Paso, Tex.; public school, Garden City, S. D.; Concordia Club, San Francisco, Calif.; Bloomsburg church, Bloomsburg, Penn.

Practically all the sizes and types of Edison Mazda multiple lamps are affected by reductions in list prices that were put into effect Apr. 1, by the Edison Lamp Works of General Electric Co. On the regular straight side and round bulb lamps, from the 10-watt to the 250-watt sizes, also on sign lamps, stereopticon lamps, etc., the reductions range from 3 to 20c. per lamp, according to the size.

On the gas-filled, multiple lamp of 100- to 1000-watt sizes, the reductions range from 50c. to $1 per lamp, the average reductions being between 20 and 25 per cent.

On Jan. 1, Lee H. Parker became president of the Spray Engineering Co., 93 Federal St., Boston, Mass., maker of Spray cooling equipment and air washers. Mr. Parker's experience in the engineering field has been unusually broad, he having severed a connection of 10 years with the Stone & Webster Co. to assume his new duties. Previous to this connection Mr. Parker had been for six years with the General Electric Co. and had also for some time represented large English engineering interests in South America. Mr. Parker was graduated from Cornell University in 1889 with the degree of M. E.

For the territory comprised by Kansas, Nebraska, southern part of Iowa and western part of Missouri, the McIntosh & Seymour Corporation, of Auburn, N. Y., has appointed as its agent Stanton A. Hadley, 621 Delaware St., Kansas City, Mo. Mr. Hadley is interested in the machinery-supply business of Hadley-Hudson Co., Kansas City, but in the future wil devote his whole time to the sale of McIntosh & Seymour Diesel type engines and steam engines and Gould pumps. Previously district manager for the Griscom-Russel Co., of New York, Mr. Hadley was prior thereto contractor, machinery salesman, erecting man and earlier with the A., T. & S. F. Ry.

The Manati Sugar Co., in the Province of Oriente, Cuba, with offices in New York City, has recently placed an order with the Westinghouse Electric & Manufacturing Co., East Pittsburgh, Penn., for electric motors to drive all of its machinery in its new mill with the exception of the engine-driven rolls. This order covers a total of 32 alternating-current motors, having a total capacity of 1042 hp. All of the auxiliaries in this next extension of the Manati Sugar Co. will be motor driven, these auxiliaries including cane and bagasse conveyors, centrifugal pumps, crystalizers, agitators, etc. All of the new material will be in operation for the 1915-1916 grinding, and the electrical equipment will be delivered in time for this operation.

STATEMENT OF THE OWNERSHIP, MANAGEMENT, CIRCULATION, ETC., APR. 1, 1915,

of Power, published weekly at New York, N. Y., required by the Act of August 24, 1912.

Editor, Fred R. Low, 10th Ave. at 36th St., New York, N. Y.

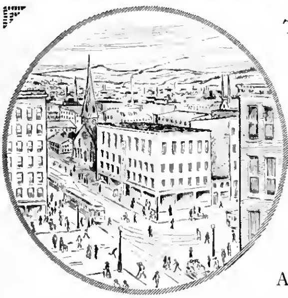
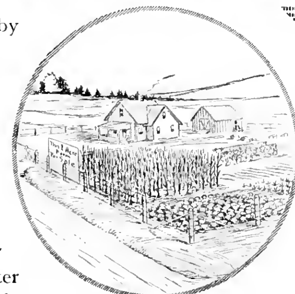
POWER

Vol. 41 NEW YORK, APRIL 20, 1915 No. 16

The Seventy-Fourth St. Turbine





The condensing water daily required by the turbine is as great as the daily water consumption of any one of the following cities: Hoboken, N.J.; Manchester, N.H.; Saginaw, Mich.; Binghampton, N. Y.; Charleston, S. C.; Galveston, Tex.; Norfolk, Va.; Stamford, Conn.; Chattanooga, Tenn.; Woonsocket, R. I.; Superior, Wis.

Approximately 100,000,000 gal. of water would be required for the condenser for a 24-hr. run at the rated load of 30,000 kw. The cross-sectional area of the intake tunnel is more than 138 sq. ft.

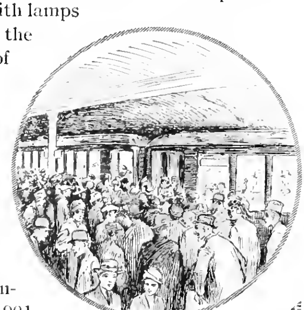
At 1.30 lb. coal per kw.-hr. and 24 hr. a day service, the turbine will use 504 tons of coal. It would require a train of 14 cars, each carrying about 35 tons, to haul a day's supply. A good miner would be 51 days getting out enough coal to last the turbine unit one day.

One of the Westinghouse "Cross-Compound" Turbines for the 74th Street Station of the Interborough Rapid Transit Co., New York City.

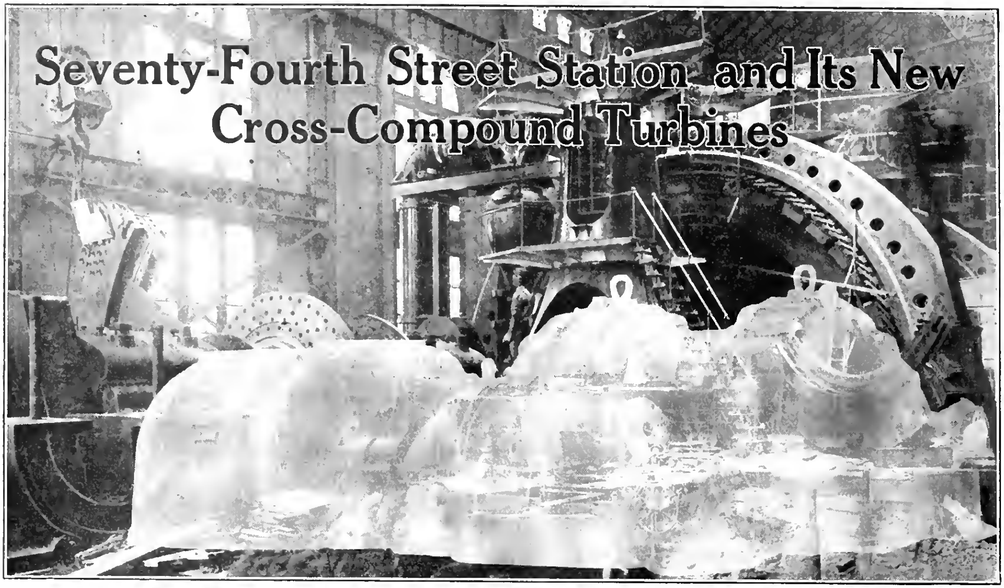
The turbine will furnish power for electric railway traffic. It can haul at one time a line of people 36 miles long, allowing a space of only two feet between each person. Used solely for illumination with arc lamps it could light an area of 40 sq. miles with lamps arranged as in lighting city streets. For the same output the higher economy of each of these turbines would effect a saving of approximately 240 tons (2000 lb. each) of coal every 24 hr. over the consumption by the engines which they displace.

Based on 24-hr. operation and with coal at $3.00 per ton this would mean a saving of over $700 a day for each turbine. The old Manhattan-type engines were installed in 1901.

If the condenser tubes were slit and flattened out there would be enough metal to completely cover over an acre of ground. Placed end to end the tubes would extend 36 miles. The tubes are each 1 in. diameter, No. 18 gage and are all of admiralty composition.



Seventy-Fourth Street Station and Its New Cross-Compound Turbines



By Charles H. Bromley

SYNOPSIS—What the installation of 30,000-kw. cross-compound turbines has meant for the Seventy-Fourth Street station of the Interborough Rapid Transit Co., New York City. Many excellent views of the turbines, and of the station during their installation, are shown. A table of ratios and important data concerning the station forms a valuable part of the article. See also the Foreword in this issue.

"The 5000-kw., direct-connected units now being built by the E. P. Allis Co., of Milwaukee, for the main power station of the Manhattan Railway Co., at Seventy-Fourth and Seventy-Fifth streets on the East River, New York City, are the most powerful steam-operated machines of which we have any knowledge outside of the engines of the great ocean steamers."

So reads the opening paragraph of the leading article in Power for June, 1901, which describes the units installed in the Seventy-Fourth Street station of the present Interborough Rapid Transit Co. These units were the last word in large stationary steam engines. Yet three have been, and a fourth is being, broken up for junk despite the fact that they were in as perfect physical condition and that their economy was as good, as a month after installation.

A Notable Example of Obsolescence

Amid the din of rock drills, hammer blows, rumbling cranes, the hum of turbines and the clack of releasing valve gears, this station is rapidly developing from the old to the new. Yet it is little more than a decade since these units were installed. Such is the rapidity of power-plant progress, such the ruthlessness of obsolescence.

As is generally known, these old units have two cross-compound engines each—the low-pressure vertical, the high-pressure horizontal—connected to a common crankshaft. The rated capacity of each is 8000 hp., but at one-third cutoff, 150 lb. initial pressure, 26 in. vacuum and 75 r.p.m., each can develop a maximum of 12,000 hp. The guaranteed steam consumption (dry saturated), under the above condition but for normal rating, was 13 lb. per i.hp.-hr. Today the consumption is nearly the same, being 17.3 lb. per kw.-hr.

Why Low-Pressure Turbines Were Not Installed

The economy and the excellent physical condition of the units have caused many to wonder why low-pressure turbines were not connected to them, as practiced with such satisfactory results at the company's Fifty-Ninth Street station. Briefly, the chief reasons are these: First, the economy of the turbine as a prime mover at the time of the Fifty-Ninth Street installation was not nearly as good as at present. Secondly, the engines at Fifty-Ninth Street, in addition to being in excellent physical condition, were designed for a higher pressure than those at Seventy-Fourth Street, and, quite important, they have poppet valves in the high-pressure cylinders, adapting them to high-pressure superheated steam, while this advantage is not possessed by the Corliss-valve units at Seventy-Fourth Street. Thirdly, the complete expansion turbines (turbine and generator combined) now going in at Seventy-Fourth Street were bought at a comparatively low figure—about one-third the price per kilowatt paid for the engine units. Fourthly, it is necessary to economize on space at Seventy-Fourth Street, and complete expansion turbines accomplish this far better than combination units. For a more exhaustive analysis of the reasons for the selection of low-pressure turbines for the Fifty-Ninth Street station and of complete expansion turbines for Seventy-Fourth Street, see the article by the writer in Power, Mar. 24, 1914, page 398.

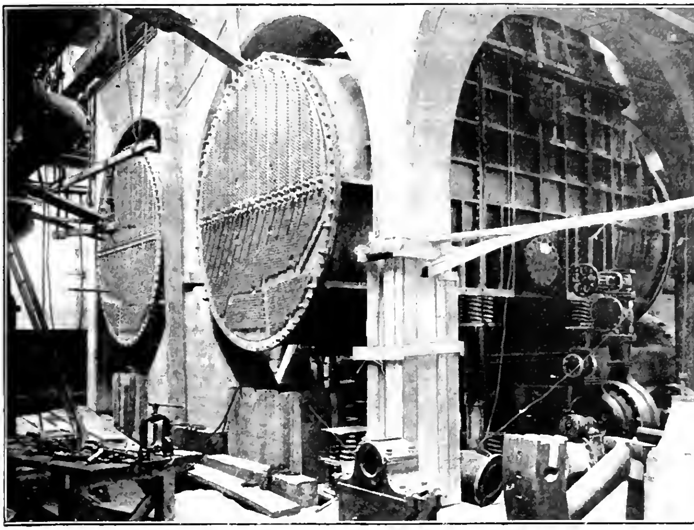

FIG. 1. NOTE THE STEAM PASSAGES IN THE TUBE BANK. CONDENSERS SUPPORTED ON SPRINGS MOUNTED ON SCREW JACKS

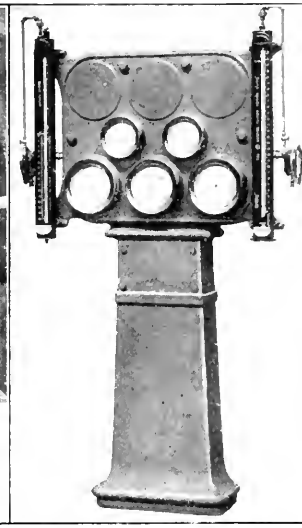

FIG. 2. THE GAGE BOARD FOR ONE OF THE 30,000-KW. TURBINES

As an indication of the advance in the economy of prime movers in recent years, the water rate of the new turbines for Seventy-Fourth Street is 30 per cent. better than for the engines they displace. For 30,000 kw. output per day of 24 hr., the turbine would save about $700 in coal alone.

WHY CROSS-COMPOUND TURBINES WERE SELECTED

The chief feature of these 30,000-kw. units is that they consist of two turbines, a high- and a low-pressure, erected side by side. Each half drives a generator, the high-pressure running 1500 r.p.m. and the low-pressure 750; the generators are tied together electrically. The turbine is of the reaction type throughout, no impulse wheel being used. The high-pressure element is single-flow, while the low-pressure is a double-flow machine. By dividing the unit into two unconnected parts the heat drop in each casing is also divided, which eliminates the distortions and the consequent severe stresses feared in large turbines having single casings. Most important, however, is the fact that by using two speeds the relations of steam velocities to blade speeds may be correctly met in both the high- and the low-pressure ends. The double-flow principle as applied to the low-pressure end also obviates the necessity of dummy pistons to balance the end thrust. The advantages of the cross-compound principle from the designers' standpoint have been so well brought out in an article written especially for POWER (Sept. 11, 1914, page 374) by Francis Hodgkinson,* designer of these units, that the reader is referred to it for further particulars.

BOILER PRESSURE INCREASED AFTER THIRTEEN YEARS' SERVICE

Until shortly before the installation of the new turbines, the Seventy-Fourth Street station furnished dry saturated steam to the engines at 160 lb. pressure. As the turbines are to have an exhaust pressure maintained at 97 per cent. vacuum (29.1 in., or 0.442 lb. absolute), it

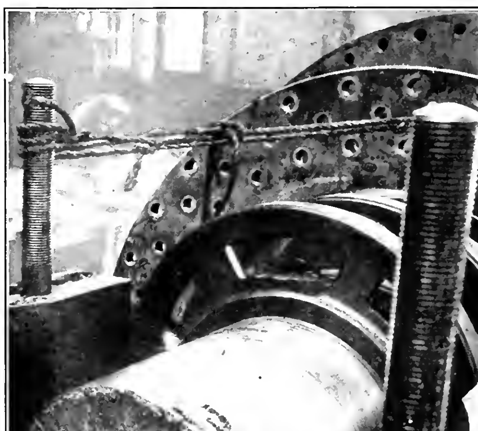

FIG. 3. THIS 32-IN. SHAFT, 16-IN. HOLE, CUT THROUGH IN THREE HOURS WITH OXYACETYLENE TORCH

was desired to obtain the advantages of a higher initial pressure than 160 lb. So the advisability of increasing it to 215 lb. was considered. The boilers had been designed

*Engineer, turbine department, Westinghouse Machine Co.

for 212 lb., with a factor of safety of 5, though never worked at that pressure, and had given thirteen years' service.

Pieces were cut from the steam drums and subjected to physical tests, which showed that the tensile strength is greater now than called for in the original specifications, 55,000 lb. having been specified, while the tests showed the present strength to be from 64,000 to 69,000 lb.

It is interesting to know that micrometer measurements of the plates show them to be from 0.01 to 0.02 in. thicker than the original specified dimensions.

After an investigation of all factors affecting safety, the owners and the Police Department decided that 215 lb. pressure was permissible, and a well-known insurance company assumed the risk at normal premium rates. In the calculations used to determine if 215 lb. would be an allowable working pressure, a factor of safety of 5 was used. All cast-iron mud drums were replaced with wrought steel, and steel fittings were put in to replace the cast-iron ones removed.

Changes Made in the Boiler Room

The need for higher rating of the boilers at greater economy was the deciding factor in the removal of the overfeed stokers and the installation of those of the underfeed type. With the former and the old engines 1150 kw. per stoker was the permissible maximum attainable, while with the latter and the new turbine 3750 kw., or 225 per cent. more, may be satisfactorily carried. The engineers for the purchaser state that the furnace efficiency for the underfeed stoker is 10 per cent. greater than for the overfeed in average running. The boilers will operate at 300 per cent. rating during the peaks, which come twice a day, each lasting about two hours.

As the boilers run at higher rating than formerly and, consequently, need more flue cross-sectional area, and partly because the feed temperature is high with all-steam auxiliaries, the economizers were removed. This enlarged the effective flue area enough to increase the natural draft from 0.7 to 1.25 in.

May Attempt to Cool Firebrick

It is the company's practice to set the firebrick in the furnace side walls from the grate to a point a little above the fire line, so that they may be renewed without disturbing the rest of the brick. This is true of all refractory material in contact with the fire. Heretofore, the same quality brick has been used below and above the fire line. But as the furnace and fuel-bed temperatures with the underfeed stokers will be higher than with the overfeed, it may be found expedient to use a better grade below the fire line. In the hope of using a low-grade, low-priced brick without experiencing the usual troubles, the experiment of embedding in each side wall a pipe carrying exhaust steam and air which will be discharged through small holes in the walls, is being tried out.

Ratio Kilowatts to Boiler Horsepower

There are 70 boilers in the Seventy-Fourth Street station, six of 600 hp. each, the remainder, 520 hp. Eight of the latter were allowed for each of the 7500 kw. maximum capacity, reciprocating engines, giving a ratio of 1.8 kw. per rated boiler horsepower, installed capacity. It is worthy of note that eight of these boilers will be allowed for each 30,000-kw. turbine unit (see footnote under table, page 531), a ratio of 7.2 kw. per rated boiler horsepower installed, during peaks—the highest yet practiced, though it should be understood, of course, that an equivalent output is sometimes reached in other large plants during peaks. Unfortunately, at this time an economy,

or performance-at-different-load, curve of this turbine is not available for publication. It may be said, however, that it is liberally designed, for tests show that the consumption at full load is but little higher than that at the most economical load. Also, the turbines—three are to be installed for the present—will each easily carry 32,000 to 33,000 kw. with but a slight increase in steam consumption. The two now in service each carry this load nearly every morning.

Rubber Expansion Joints in Circulating Water Pipes

There are two condensers, one connected to each low-pressure exhaust outlet, and each is in three sections. The total tube surface is 50,000 sq.ft., in 4780 admiralty tubes, each 20 ft. 3⅜ in. long, 1 in. diameter and of 18 gage. The chief guarantee is 350,000 lb. steam condensed per hour with water at 60 deg. F., maintaining a vacuum of 97 per cent. (29.1 in., or 0.442 lb. absolute). The steam opening into each condenser is 142 sq.ft. in area. The openings in the bank of tubes to assure steam getting down around the bottom tubes are plainly shown in Fig. 1. Fig. 2 shows the gage board used.

The circulating-water pipes which supply both condensers are 60 in. diameter. A novel feature of construction is that there are no expansion joints between the turbine and condenser, each condenser being rigidly bolted to one of the exhaust flanges of the double-flow low-pressure turbine, there being provided a 36-in. connection with a copper expansion joint between the two condensers to maintain equilibrium of pressure. Hence, to provide for the expansion and contraction of the turbine under different operating conditions, it is necessary that the condensers be able to translate themselves with reference to each other. This necessitates quite flexible expansion joints between the circulating pipes and the water chambers. Copper expansion joints were first installed, but it was found that these held the condensers too rigidly and that they would not move with the expansion and contraction of the turbine. This difficulty was overcome by substituting rubber expansion joints. Inasmuch as the piping was in place, the joint must be so designed as to make use of the flanges and, to avoid special rubber work, must admit of using plain sheet rubber instead of a molded piece. The rubber is of a good grade and is five-ply, ½ in. thick and made up similar to belting.

Reference to Fig. 1 will show that the condensers are supported on heavy springs resting on screw jacks.

The air pump is of the reciprocating kind, being 14x39x30 in.

Fig. 4 shows one of the circulating pumps and Fig. 5 the revolving type of screen used at the intake.

Structural-Steel Supports

The economy in the use of concrete by using structural-steel supports for turbines over the old solid engine foundations is well demonstrated at Seventy-Fourth Street. The foundations for each of the 7500-kw. engine units required 1500 cu.yd., while for each 30,000-kw. turbine supported on structural steel, but 275 cu.yd. is needed and this chiefly to stiffen the supports against vibration. This is the heaviest turbine yet to be supported on structural steelwork. Although the tandem-compound, 30,000-kw. unit in Waterside No. 2 is so supported, it weighs less. The condenser support of the Waterside structural work has a system of spring beams to avoid the necessity of an expansion joint between the turbine exhaust opening and the condenser steam inlet.

In the removal of the large engines it was found expedient to cut the main shafts. These are each 37 in. diameter with a 16-in. hole, and by employing the oxy-acetylene torch it took but three hours to make a cut. See Fig. 3.

The Construction of the Turbine

The high-pressure side contains 38 rows of blades and differs but little from any other single-cylinder reaction turbine. The first 8 rows are mounted on a ring bolted to the casing. Following this are 19 rows mounted on a second and longer ring, or barrel. The remaining 11 rows are mounted directly on the casing. The rotor is 20 ft. 4⅝ in. long. The views on the insert give a good idea of the construction and size of one of the units.

The low-pressure turbine is double-flow. The casing is a simple shell affair except that it has some interesting reinforcing members. There is no blading mounted directly on the casing, but instead, it is all put on rings or barrels bolted to the casing. One of the intermediate-pressure rings for the low-pressure machine having the blading mounted is also shown in the insert.

The low-pressure rotor is made up chiefly of a hollow drum secured to two spindles, one at each end. The intermediate-pressure blades are mounted directly on the drum, and the low-pressure blades are put on rings which slip up over the spindles and are bolted fast. The spindle castings with the risers weigh 72,500 lb. each and are of steel. The rough ends without the risers weigh 38,500 lb. each.

A Cement for Leather

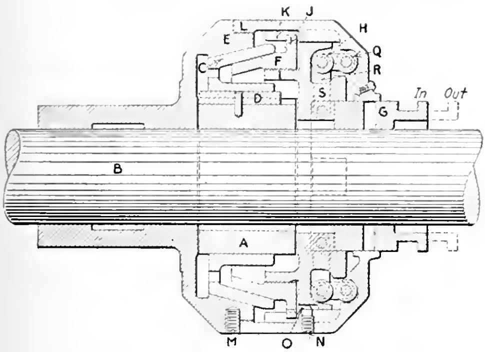
To prepare a cement suitable for leather belts or for fastening paper covering to pulleys, get the best cabinet maker's glue, in a quantity suitable to your requirements. A large quantity can be prepared if desired, for it will keep for some time after being mixed, if not permitted to dry out. Break the glue into pieces and put in a dish, with water just sufficient to cover it, and let stand twelve to fourteen hours, or until all of the water has been soaked up. Then melt the glue in a water or steam bath and add strong vinegar to thin it. It should then be evaporated until it will appear quite stringy from the stick or spoon used to stir it while hot.

A leather belt should be roughed or furred with sandpaper or a coarse file, which will make the joint stronger than if the leather were left smooth. If the leather is warmed before applying the glue, a better joint can be made. The laps should be scraped down to a thin edge and their length should be equal to the width of the belt. In making the joint, lay the belt on a board so that the parts come even, then fasten with a couple of nails through the leather a foot or more from the joint on each side, so that when one piece is raised from the other to apply the glue, it will fall back into the proper position. Apply the glue warm and pound the joint all over with a hammer and a block laid on the leather. A few tacks driven through the joint will assist in holding it together properly until the cement has set.

The same preparation can be used for fastening paper, cloth or split leather to a pulley to increase the driving power of the belt. If of iron, the pulley should be well cleaned by scraping and then washed with strong vinegar or a weak solution of sulphuric acid in water. Wipe dry and apply the paper, which has previously been covered with the hot glue. Two or three thicknesses of heavy straw paper will be found sufficient, and each layer should be firmly glued on. As soon as the first layer is applied and before the glue has had a chance to cool, roll or hammer the paper to bring it in contact with the pulley. Each layer should be treated in the same way. A belt should remain undisturbed for about five hours after the joint is made, before an attempt is made to use it. Three or four hours will be sufficient for the paper covering on the pulley.

Ideal Multi-Cone Clutch

This clutch, which is manufactured by the Akron Gear & Engineering Co., Akron, Ohio, might be termed a multi-disk cone clutch. In its design it retains the simplicity of the two-cone clutch, allows smooth engagement due to momentary slipping, and will release instantly. To avoid a too sudden engagement of the cones their face an-



Ideal Multi-Cone Clutch

gles are greater than those of the ordinary two-cone type, and the clutching force and pulling power so lost are more than compensated for by the addition of a third cone, which practically doubles the pulling power. The cones run in an oil bath which leaves a film between them and permits a slippage before being broken down by the pressure of coming into engagement. Owing to the face angles and the small unit pressure on them, as well as the oil bath, immediate disengagement occurs when the clutch is thrown out.

Means are provided to prevent the oil from escaping to the outer surfaces where it would be thrown off by centrifugal force. The horizontal pressure exerted by the throw in the mechanism is distributed equally around the circumference and does not distort the cones from a true circle.

When the clutch is out the throwing mechanism is still and centrifugal force cannot throw it in. When it is in centrifugal force cannot throw it out, but will tend rather to keep it in.

Referring to the illustration, the driving ring *A* is keyed to the shaft at *B*. The middle or driving cone *C* is driven by the ring *A* through two feathers *D;* both friction surfaces of this cone contain oil grooves. The driven cones *E* and *F* are brought into contact with *C* when the shifter sleeve *G* is pushed in, thus throwing the rollers *H* outward and forward against the adjustment ring *I*, which carries the cone *F* forward into contact with *C*, and the latter into contact with *E*. As the cones come into contact singly, too sudden clutching is prevented. The cone *F* is caused to revolve with *E* by means of the lugs *J* projecting outward on *F*, which lie between the lugs *K* on the casing *L*. The inner faces of the lugs *K* are turned true and hold the ring *I* central. The casing screws on the cone *E* and is locked by the screw *M*. The inner end of the locking screw *N* projects into one end of the numerous slots *O* in the outside periphery of the ring *I* and causes it to revolve within the casing *L*. The adjustment of the clutch is made by inserting the screw into one of the slots. The rollers *H* and *Q* and their pivot pins are large in diameter and in bearing area. The links *R* straddle the lugs *S*, the ends of which are raised slightly.

In throwing the clutch out, the rollers *H* strike the lugs *S* and pull the cone *F* forward, which gives the maximum clearance for the oil films between the cones. The throwing mechanism is powerful, the multiplication between the horizontal force on the shifter sleeve *G* and the pressure on the cone faces being approximately 100 to 1 on all sizes.

⁂

Large Buffalo Transformer Blower

An unusually large fan for cooling air-blast transformers has recently been installed at the Blue Island Power Station, Public Service Co. of Northern Illinois, by the Buffalo Forge Co., Buffalo, N. Y. The installation was made under the direction of Sargent & Lundy, engineers. It consists of a direct-connected blower handling continuously 40,000 cu.ft. of air per min. at 70 deg. F. and 29.92 in. bar., with a static increase in pressure of 2.6 in. water gage. The blower is directly connected to a 30-hp., 25-cycle, three-phase, 470 r.p.m. motor. Aside from the size of the unit, the interesting feature is the operating speed.

Most transformer cooling units are 20,000 cu.ft. per min. capacity or below, and although direct connection is desirable, it has heretofore involved prohibitive expense for the slow-speed motors necessary on larger units. The blower in this case is a turbo conoidal high-speed type,

Motor-Driven Fan of 40,000 Cu.Ft. of Air per Min.

such as has been used in connection with motor and steam-turbine-driven forced-draft units for underfeed-stoker work. Although the air pressures required for cooling air-blast transformers are considerably less than for stoker work, the speed of this fan is high enough to permit the use of a motor at a price which is not excessive. The fan is of the multiblade type with compact housing. The photograph shows the relative sizes of the fan and the motor. The fan has a static efficiency of 60 per cent. and requires 27 b.hp

Theoretical Efficiency of Heat Engines

By R. C. H. Heck

SYNOPSIS—Distinction between "actual" and "ideal" efficiencies, explanation of the Carnot efficiency and when it should be applied, also the error involved in using the "air standard" in connection with the Carnot efficiency in internal-combustion engines.

The term "heat engine" covers all forms of apparatus for converting heat into work, and the only practical way of making this conversion is by means of an expansive medium which may be either a liquid (alternately vaporized and condensed) or a dry gas mixture. In judging the performance of a heat engine there are three efficiencies to be considered—actual, ideal and relative.

Actual efficiency is the ratio of the heat converted into work (or work output measured in heat units) to the heat supplied, these quantities being determined by test or experiment. No heat engine converts into work more than a minor portion of the heat energy which it receives. This is due largely to the inherent nature of the heat-engine process and in lesser degree to imperfections of actual material and operations. For any set of limiting conditions it is possible to calculate, from thermodynamic theory, the efficiency of an ideal heat engine, free from all secondary imperfections.

This ideal efficiency is the proper basis for judgment of actual performance. Thus, a conversion ratio of 0.24 for the best steam turbine may seem a poor showing, but when theory determines that an ideal apparatus under the same conditions could convert only 0.34 of the heat received, it appears that the real engine is doing about 70 per cent. as well as the ideally perfect one. In medium to very good practice this relative efficiency, the ratio of actual to ideal, ranges from 50 to 75 per cent.

The Carnot Engine

Any heat engine operates by receiving heat at high temperature, converting a part of it into work, and rejecting the remainder as heat at low temperature. The simplest possible scheme, thermally, is that of the ideal Carnot engine, in which the temperatures of heat reception and heat rejection are constant throughout the respective operations, and in which there are no losses by radiation, cylinder-wall action or machine friction.

The temperature-entropy diagram in Fig. 1 represents the working of the Carnot cycle. The expansive medium is confined in a suitable cylinder with a piston, and at A it has the upper temperature and a high pressure. Receiving heat at the constant absolute temperature T_1, it changes to state B by isothermal expansion. The quantity of heat Q_1 received is represented by the area $ABFEA$: which has the width $EF = Q_1 \div T_1$. This horizontal distance EF is known as the "difference in entropy" and will be represented by N. Applied to steam, EA represents the absolute temperature corresponding to the given pressure: the condition at A would be hot water at

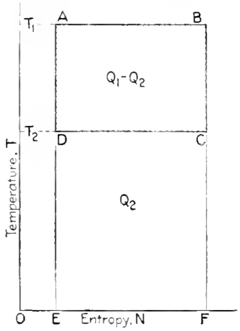


Fig. 1

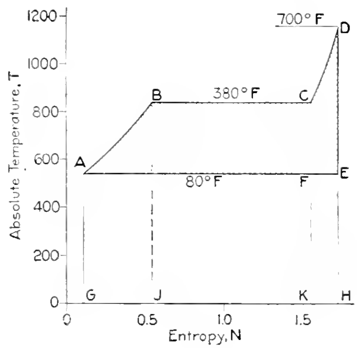

Fig. 2

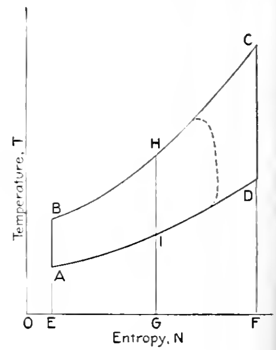

Fig. 3

this temperature, and the area $ABFEA$ would represent the latent heat necessary to change the water into dry saturated steam, which condition is represented at B; finally, AB ($= EF = N$) is the distance necessary to make the area $ABEFA$ proportional to the latent heat at temperature T_1.

At B in Fig. 1 the supply of heat is shut off and expansion continues in the perfectly nonconducting cylinder until the temperature is lowered to T_2 at C. The drop in temperature is due to the expenditure of heat energy in the work of expansion; but since no energy is transferred in thermal form, there is no change of entropy. A no-heat-transfer operation is called adiabatic.

From C to D the medium is compressed isothermally (at constant temperature) at T_2, surrendering the heat $Q_2 = NT_2 =$ area $DCFED$, and adiabatic compression from D up A completes the cycle. With a heat input Q_1 and heat, $Q_1 - Q_2$, converted, the efficiency is

$$E = \frac{Q_1 - Q_2}{Q_1} \qquad (1)$$

which is a general expression applicable to all heat engines. Here $Q_1 = NT_1$ and $Q_2 = NT_2$, so that the efficiency of this cycle may also be expressed by

$$E = \frac{T_1 - T_2}{T_1} = \frac{t_1 - t_2}{t_1 + 460} \qquad (2)$$

in which t_1 and t_2 are the Fahrenheit temperatures corresponding to the absolute temperatures T_1 and T_2.

Sometimes this Carnot efficiency is used erroneously as a standard when it does not fit the conditions of the actual plant. A notable example is found in the issue of June 9 last, in the abstract of a lecture by F. G. Gasche, on "Power for Steel Mills." For a steam turbine using steam superheated to 700 deg. F. and with exhaust at 80 deg., the ideal efficiency is there computed as

$$E = \frac{700 - 80}{700 + 460} = \frac{620}{1160} = 0.535$$

As a matter of fact, this result is about 60 per cent. in excess of the correct value.

Ideal Steam Cycle

Fig. 2 shows the ideal cycle for the steam engine or turbine, within the limits just named and with the additional datum that vaporization shall take place at 380 deg., or that the boiler pressure shall be about 195 lb. absolute. The cycle begins at A with 1 lb. of feed water at exhaust temperature pumped into the boiler. Curve AB represents the heating of the water up to the boiling point of 380 deg. F., or 840 deg. absolute; it receives heat and acquires entropy as the temperature rises. The horizontal line BC represents the isothermal, or constant-temperature, operation of vaporization. At C the steam is dry saturated, and its superheating from 380 to 700 deg. is represented by curve CD. At D the total heat of the steam is 1370 B.t.u., and the heat imparted, beginning with water at 80 deg. F. (540 absolute), is 1322 B.t.u., represented by area $GABCDHG$.

The operation $ABCD$ is performed in the boiler, and we assume that the steam is carried over to the engine or turbine without loss of heat by radiation or of pressure by pipe resistance. Then adiabatic expansion, whether in the ideal non-conducting cylinder or in the formation and utilization of a perfect steam jet, lowers it to state E. Abstraction, of heat in the condenser, of the exhaust heat Q_2 (area $EAGHE$ = 879 B.t.u.), is represented by the isothermal line EA. The ideal efficiency is now, as against the 0.535 previously figured, only

$$E = \frac{Q_1 - Q_2}{Q_1} = \frac{1322 - 879}{1322} = \frac{443}{1322} = 0.335$$

The diagram shows clearly the error involved in using for T_1 in the Carnot expression, equation (2), the highest temperature reached by the medium, instead of making it the temperature of heat reception. When the latter temperature varies, as here, it might be replaced by a mean value of equivalent effect, although that is not the direct or the better way of calculating E. Just to see how nearly the vaporization temperature of 380 deg. would come to serving as such an effective average value, try it in equation (2), from which will be found

$$E = \frac{380 - 80}{380 + 460} = \frac{300}{840} = 0.357$$

Evidently $t_1 = 380$, or $T_1 = 840$, is a little too high for this purpose.

Because so much of its heat reception is at T_1 and all of its heat rejection at T_2, the steam cycle is fairly near the Carnot in general form. The practical reason for this is that the constant-pressure operations of vaporization and condensation are characterized also by constant temperature. But in no scheme of gas-engine working do isothermal operations find place.

Otto Gas-Engine Cycle

Consider the Otto cycle outlined in Fig. 3. The operation begins at A with a charge of gas mixture under atmospheric pressure and of a little higher than atmospheric temperature. Line AB shows adiabatic compression, followed by the reception, at practically constant volume and with a rapidly rising temperature, of the heat of combustion. This heating along curve BC is followed by the ideal adiabatic expansion CD, and exhaust is taken to be equivalent to constant-volume cooling along curve DA. The actual performance, in an actively conducting cylinder and with combustion more or less retarded, is somewhat of the form sketched by the dotted line.

It has been usual, for a simple calculation of theoretical efficiency, to assume that the gas mixture is practically the same as air in properties and that its specific heat is constant, not rising with temperature. Under the latter assumption the ratio of low to high temperature is the same on any ordinate in Fig. 3, whether at the extreme lines BE and CF or on any vertical HG. If then

$$\frac{T_A}{T_B} = \frac{T_D}{T_C} = \frac{T_I}{T_H}, \textit{ etc.}$$

it is evident that the conversion area $ABCDA$ will be to total heat area $EBCFE$ as $T_B - T_A$ is to T_B, or that the Carnot ratio will apply if the limiting temperatures of either adiabatic are used in place of certain constant temperatures.

The principal purpose in writing this article has been to lay before the readers the fact, to be found only in the more recent textbooks, that the use of this simple air standard involves a large error. Computed results from a typical example are laid out in Figs. 5 and 6, where the dotted diagrams marked a are for ideal air and the full-line diagrams b represent the behavior of an actual gas mixture.

The medium selected in the example is a blast-furnace gas with a moderate excess of air in the combustible mixture. Its heat value is such that perfect combustion generates just 1000 B.t.u. per pound of mixture, the diagrams being drawn for that quantity. The specific heat rises with the temperature according to the constant-rate law shown by straight lines Nos. 2 and 3 in Fig. 4, of which No. 2 is for the original mixture and No. 3 for the products of combustion; line No. 1 shows the uniform value, C_v = 0.169, for the ideal air medium.

One main determinant is the pressure of 175 lb. absolute at the end of compression in Fig. 5 (points B and B'). This and the initial atmospheric pressure and an assumed temperature of 80 deg. F., or 540 deg. absolute, at A and A' are the only conditions common to the two cases, although the compression curves AB and $A'B'$ are very much alike. The greatest difference is seen in the temperature rise from B to C and B' to C', with the resulting expansion lines CD and $C'D'$. Curve c is a rough guess at the probable actual indicator diagram.

Of course, such a tremendous rise of temperature as that which carries C' up to more than 7000 deg. in Fig. 6 and the corresponding pressure to 1100 lb. in Fig. 5 is physically impossible. Even the more reasonable height of point C runs into a region where dissociation is probably a potent influence and where our knowledge of specific heat is vague. But disregarding the fact that the conditions of diagram a are largely imaginary and those of b in some degree doubtful, the results of calculation may be summed up as follows:

In diagram a, Fig. 6, the four corner temperatures are: $T_A = 540$ deg., $T_B = 1104$ deg., $T_C = 7021$ deg., and $T_D = 3434$ deg. Then the efficiency is

$$E = \frac{1104 - 540}{1104} = \frac{7021 - 3434}{7021} = 0.511$$

In diagram b the corresponding temperatures are: $T_A = 540$ deg., $T_B = 1092$ deg., $T_C = 4818$ deg., and $T_D = 3315$ deg. With these the Carnot ratios at the limiting ordinates BA and CD are very different, being

$$\frac{1092 - 540}{1092} = 0.505 \quad \text{and} \quad \frac{4818 - 3315}{4818} = 0.312$$

A notable effect of higher specific heat is the relatively smaller vertical width of the effective area $ABCDA$, as

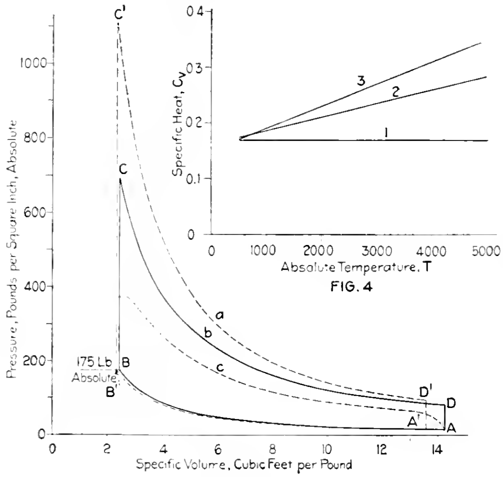

FIG. 5

compared with $A'B'C'D'A'$ (Fig. 5). Efficiency is found, however, not from temperatures but from heat quantities, as referred to in the method of equation (1). Along curve BC (Fig. 6) the heat received from combustion is 1000 B.t.u., while that rejected along DA is 632 B.t.u.; then the efficiency is

$$E = \frac{1000 - 632}{1000} = 0.368$$

The physical data for a calculation such as is represented by diagrams b, Figs. 5 and 6, are not complete in full accuracy. The methods of calculation are more directly related to Fig. 5, involving data as to pressure, volume and specific heat; and the heat converted, 368 B.t.u., is strictly equivalent to the work area $ABCDA$ in Fig. 5. When entropy is calculated, rather as a secondary quantity, a discrepancy develops; the diagram in Fig. 6 failing to close by the amount A_1A.

USEFULNESS OF IDEAL EFFICIENCY

Ideal efficiency, or the performance and output of the Rankine cycle represented by Fig. 2, is regularly used as a standard of comparison for steam action; but with internal-combustion engines it is little used. The simple air standard is so much in error as to be worthless, and the more correct method requires complicated and difficult calculations. For one thing, it must start in each case with the proportions of the particular gas mixture, upon which the average fundamental physical properties of the medium are dependent; and even with the simple straight-line law for variation of specific heat with temperature (itself probably no more than an approximation), the change of temperature in an adiabatic operation can be found only by a troublesome trial solution. Merely to state and outline the calculations for Figs. 5 and 6, including a number of intermediate points on each curve, would take considerable space, with no explanations or proofs; and while the direct calculation of ideal efficiency alone is much shorter, it is yet rather beyond the scope of ordinary use. Therefore, gas-power engineers will probably continue to be satisfied with actual efficiency as a measure of performance.

The really important result from the example here set

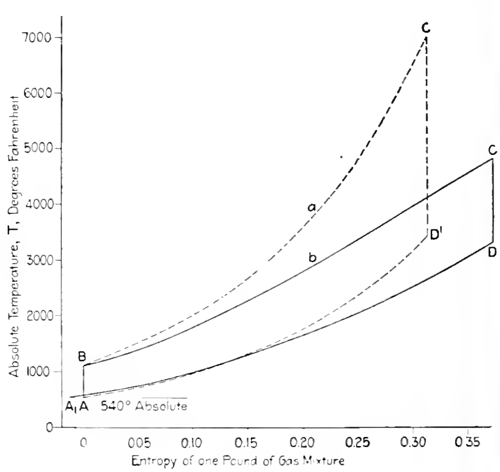

FIG. 6

forth is the relatively low value, 0.37, for true ideal efficiency, as against 0.51 under the assumption of constant specific heat. Considering the intense action of the cylinder walls in a gas engine, the relative efficiency is not likely to be over 0.6. Applying this to 0.37, we get a probable actual value of 0.22, and see that so far as the conversion of the heat supplied to it is concerned, an engine using blast-furnace gas is much in the same class with good steam engines and turbines. This does not, of course, deny the great economy of using such gas directly in the engine instead of burning it under steam boilers.

*

Coal for Coke—In the last five years the coal used in metallurgical coke manufacture has averaged around 65,577,000 tons, yielding 43,983,000 tons of coke, valued at $111,736,000. Of this total, 14,767,000 tons were used in byproduct coke ovens, yielding, besides the coke 54,491,000 cubic feet of gas 94,306,000 gallons of tar, and $9,190,000 worth of ammonia. When it is considered that every year approximately four times these enormous totals of byproducts are absolutely wasted through the use of non-byproduct ovens, the vital importance to the country of a general use of the modern, scientific byproduct ovens will be appreciated.—"Journal of the Franklin Institute."

A Forty-Million-Revolution Compressor-Valve Test

In the endeavor to test to destruction one of the feather valves now being used by the Laidlaw-Dunn-Gordon plant of the International Steam Pump Co., for air and gas compressors, the builders fitted a small vertical compressor with one of the standard-type feather valves and with an annular valve of the so called low-lift, plate type, the latter being of standard German manu-

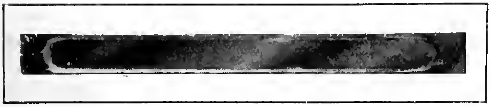

FIG. 1. SEATING SURFACE OF FEATHER VALVE. THE LIGHTER PORTION SHOWS THE SURFACE AFTER FORTY MILLION REVOLUTIONS OF THE PUMP

facture. The valves were used alternately for intake and discharge. The compressor was operated at a speed of 560 r.p.m. against a pressure of 40 lb. during each working day of ten hours, for a period of six months, aggregating in that time something over forty million revolutions. During this period three of the annular valves gave out, while the original feather valve at the end of the period had gone no further than to perfect its seat. Fig. 1 is a photograph of one of the blades used, the lighter portion indicating the polished surface of the seating area.

Forty million revolutions represents about a year's operation at 225 r.p.m. The speed of 560 r.p.m. should, on the basis of ordinarily accepted practice, result in destructive action four times as fast as a speed of 280 revolutions, which represents about the limit of commercial practice at present. The builders claim, therefore, that this run of forty million revolutions at 560 r.p.m. is the equivalent of at least four years' normal running, and the valves, judging from their appearance, had not even begun to deteriorate.

The valve on which this test was made is designated by its builders as the Laidlaw feather valve (patented),

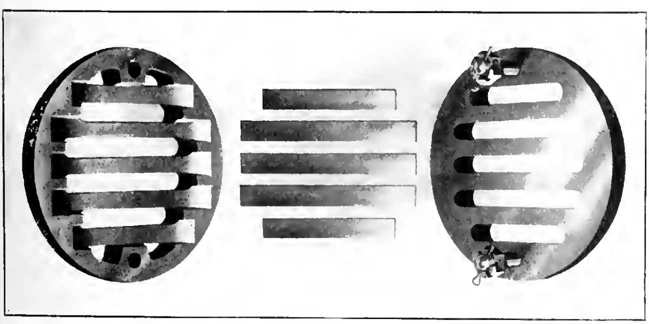

FIG. 2. THREE ELEMENTS COMPRISE THE FEATHER VALVE

Fig. 2. The complete contrivance consists of three elements only. The valves proper are strips of light flexible flat steel stock similar in appearance to ordinary clock-spring stock, but more flexible and of a much lower temper. These strips, which in the average valve are about ½ in. wide and vary in length from 4 to 12 in., seat on the ground face of a slotted casting, the slots being slightly smaller than the strips. The valves are not held rigidly at any point, but are restrained in movement by a curved guard with slots staggered to the slots in the seat, the spaces between being milled out on a curve against which the valve bows up when in an open

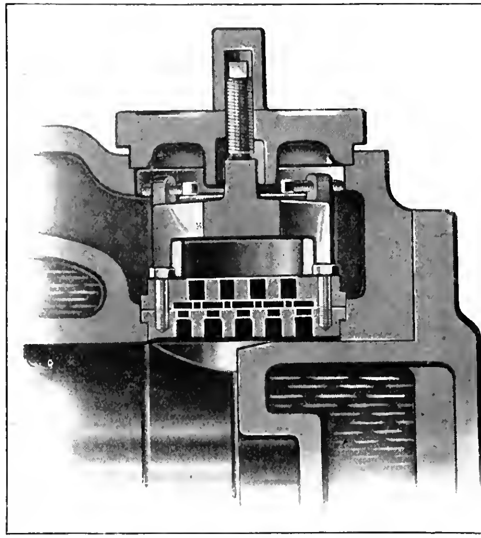

FIG. 3. DETAILS OF THE VALVE ASSEMBLED

position, to allow the passage of air. The ports are shown in Fig. 3.

The guard is lightly bolted to the seat, the strips being thus held between, free to bend up and down in the middle, their ends always remaining in contact with the seat, giving a breathing rather than a slapping action. The movement of the valve is controlled by the air flow, the valves themselves having negligible spring action, the best results being obtained with the highest flexibility. They are so light as to respond instantly to change in air flow, their flexibility not only permitting air to flow through them with a minimum of spring resistance, but also resulting, with the reversal of air travel, in almost perfect contact with the seat. The notable feature of this valve as compared with the older type of poppet or with the newer type of low-lift plate valve, is the fact that it seats not by impact of the entire valve, but by increasing contact from the ends to the center. This characteristic, in combination with extreme lightness and flexibility, not only results in the marked durability demonstrated by the test carried out, but also permits a lift area greatly in excess of that obtainable with the annular low-lift type, seating by impact. The valve as applied to a compressor is shown in Fig. 4.

In efficiency of performance the valve shows actual measured volumetric efficiency approaching within less

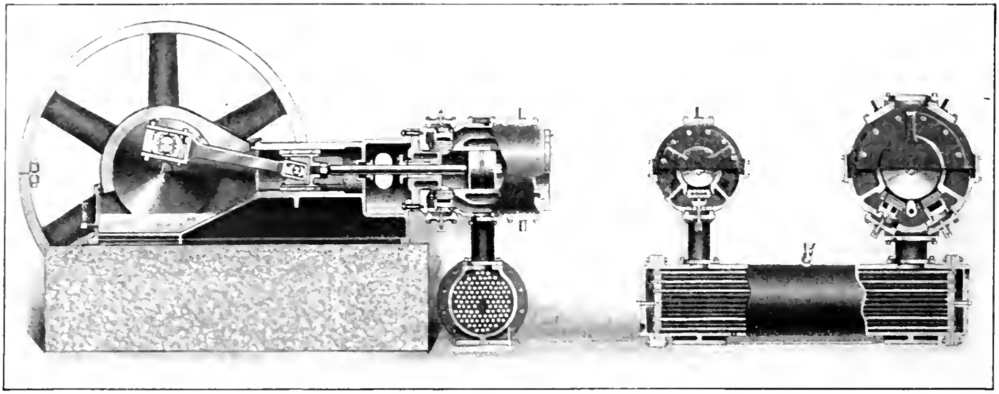

Fig. 1. Feather Valves Applied to an Air Compressor

than 1 per cent. of the efficiency indicated by a diagram, which latter indicated efficiency shows only the reëxpansion loss from clearance. This close approach of the actual to the indicated efficiency is a significant check on the valve performance, inasmuch as the clearance reëxpansion indicated by the card, and which is inevitable in any practicable air compressor, is not an economical loss, the energy return of the clearance reëxpansion being practically identical with the energy absorbed in its compression.

Contact seating, in addition to contributing to a high degree of durability and permitting the high lift which gives the valve its exceptional efficiency, also accounts for its remarkably quiet action.

Extreme simplicity of makeup permits the valve to be made reversible as regards seat and guard, so that the same valve can be used in its cylinder optionally as an intake or a discharge valve, the construction of both being identical and their function being determined only by the relation of the seat to the cylinder bore.

Nugent's Indicator Reducing Motion

A simple indicator reducing motion has been designed recently by Wm. W. Nugent & Co., of Chicago. It may be attached to any Nugent telescopic crosshead-pin oiling device or to a special stand on the floor. The former

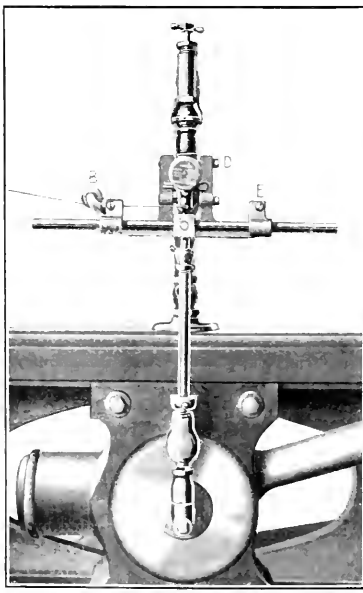

Fig. 1. Nugent Reducing Motion Attached to Crosshead-Pin Oiling Device

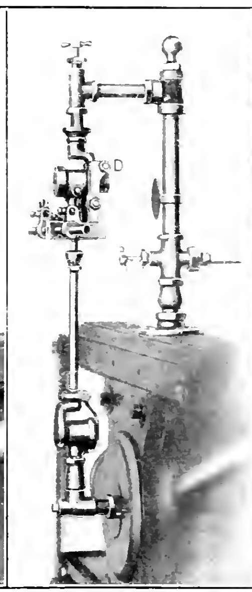

Fig. 2. Side View of Reducing Motion and Oiling Device

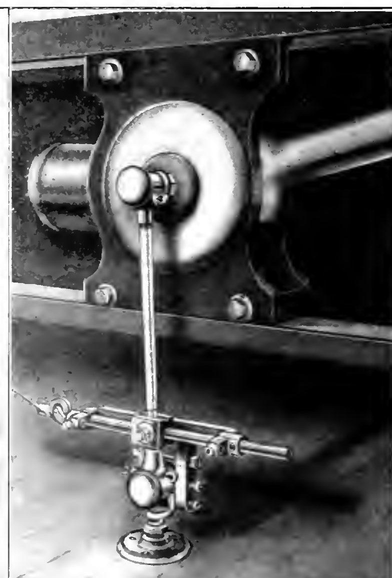

Fig. 3. Reducing Motion Supported by Stand Secured to the Floor

method of attachment is shown in Figs. 1 and 2 and the floor stand in Fig. 3. Either is mounted at the center of the stroke.

As shown in the first two illustrations, the reducing motion consists of a forked member which straddles and is clamped to the oiling device mounted on the top guide to the crosshead. The forked member just referred to supports two horizontal tubular guides for an oscillating block which reproduces on a smaller scale the motion of the piston. The block is moved back and forth by the telescopic tube of the oiling device. A pin that is free to turn passes horizontally through the block. The former is bored radially to allow the telescopic tube to pass through.

A given point on the tube naturally moves in the arc of a circle, but the arrangement allows the block to travel horizontally, as it may slide along the tube away from or toward the fulcrum, as it moves either side of the central position. As the pin is free to turn, there is no binding action on the tube. The cord is attached to this same pin and on its way to the indicator passes through a swivel guide pulley. The device accurately reproduces the motion of the piston and can be easily attached to or removed from the supporting element.

A Question Puzzling to Some

Many of our very practical engineers do not understand the reason for the greater efficiency or economy of a compound condensing over a simple condensing engine. The prevailing idea seems to be that power and efficiency are derived only from a greater number of cylinders. The principal difference in the two engines is entirely overlooked—the difference in the loss of heat through cylinder condensation; otherwise the greater number of cylinders would be of no advantage, but a disadvantage.

Consider the diagram of a 300-hp. simple condensing engine, admitting steam at a pressure of 200 lb. absolute and a temperature of 287.2 deg. F. and expanding down to 1 lb. absolute and 102.9 deg. F., thus losing 284.4 deg. F.; or, in other words, admitting steam at the high temperature of 387.3 deg. F. into a cylinder which has been cooled to some extent by the expanded steam at 102.9 deg. F., thus condensing and losing a large percentage of the incoming steam in reheating the cylinder.

With a compound engine with steam at the same pressure and temperature, and the high-pressure cylinder expanding it down to 27 lb. absolute at 245.1 deg. F., the temperature difference between the admission and exhaust is only 142.2 deg. F. This exhaust from the high-pressure cylinder is admitted into the low-pressure cylinder at practically the same pressure and temperature, and expanding in its turn to 1 lb. absolute and 102.9 deg. This makes a difference of 142.2 deg., the same difference of temperature between the admission and exhaust in the high- and low-pressure cylinders.

By having two cylinders, as in the compound engine, the extreme difference in temperature met with at admission in each cylinder is reduced.

Rate of Combustion is the amount of fuel burned per hour per square foot of grate surface. It varies from about 5 lb. in small furnaces to 100 in large furnaces under forced draft. The ordinary rate for anthracite is from 5 to 15 lb. and for bituminous coal 5 to 25 lb.; in locomotives, from 45 to 90 lb.

Just for Fun

A foreigner who spoke very little English was second fireman in a plant of eight 150-hp. horizontal return-tubular boilers. The so called "Hunkie" was told one day to take one of the boilers out of service for cleaning and repairs. He shut the header valve all right, and when the steam pressure had fallen to 60 lb. he went to blow down the boiler, but the blowoff pipe was completely stopped up. He then took the blind flange off the cross on the end of the pipe and commenced poking at the obstruction with a rod while there was still 60 lb. pressure on the boiler. Somebody caught him before he completed the "suicide act."—*F. F. Jorgensen, Gillespie, Ill.*

In a plant where I was employed a man who was interested in the plant and was supposed to understand electricity came in one evening during the peak-load period. There were two machines, and No. 1 was permanently connected up, but No. 2 was only temporarily connected, and in such a manner that one main circuit-breaker served both machines, although only one could be run at a time. The feeder switches were all of the quick-break type. These switches were something new to the gentleman, and I showed him how they worked, and remarked that the large one was the main switch for the idle machine. At this time I turned to a storage-battery panel, and bang went the circuit-breaker and everything went out. He had simply tried that large quick-break switch, but when things were in order again he remarked: "I guess it is a good idea to leave things alone that we are not acquainted with."

In this same plant we were required to take ground readings from all of the circuits once a day, before the evening load came on. The "boss" had a habit of coming in frequently and pulling out and putting in switches and watching the effect on the ground indicator. On one occasion he came in before I had tried the circuits and proceeded as usual. It happened that I went over to the engine while he was engaged with the switches and coincident with my move he threw in a switch which had been open, and started a commotion. I was innocent of any connection with the short-circuit, which was on that line, but circumstantial evidence was against me. Our "friendly relations" were not "strained" at all, but the "boss" sort of lost interest in grounds.—*H. L. Strong, Yarmouthville, Me.*

The fellow who painted the commutator has nothing on a painting stunt pulled off by one of my men last fall. I decided to give the machinery a coat of paint. The boys prided themselves on the appearance of the lagging, valve-gear and especially the well polished cylinder head of a Corliss engine. One afternoon all the painting was completed with the exception of an oil guard on this engine. The middle-watch man was told not to run the machine that night, but to finish the painting job.

The following morning I found our nice lagging, cylinder head, bonnets and valve-gear, including the sole plate and dashpots, all painted green, and it had begun to run and then baked. The color of the atmosphere was "some variegated" while we were scraping paint.—*E. B. Mertens, Milwaukee, Wis.*

Automatic Electric Elevator Dispatcher

By Norman G. Meade

Dispatching of passenger elevators in large office buildings has received considerable attention recently, and it has been the aim to obviate the human element as far as possible. The engineering staff of the Insurance Exchange Building, Chicago, has designed and installed an automatic electric dispatcher which times the starting of the elevators from both the bottom and the top floors. This building is a modern 18-story office structure covering half a city block and is equipped with sixteen electric passenger elevators arranged in four banks on four sides of the building.

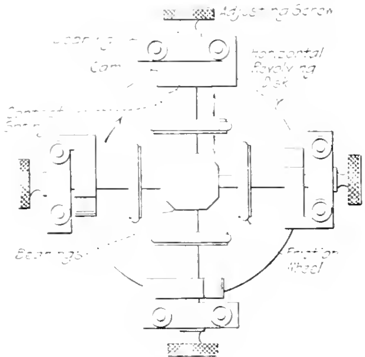

Fig. 1. Plan of Dispatcher

These elevators are of the Otis traction type, operated by 25-hp., 220-volt direct-current motors controlled by Otis type MF4 controllers. Eight operate as express cars and eight as locals. The floor signals for the former normally do not operate below the twelfth floor, but on occasions such as Sundays and holidays, a switching arrangement is provided which throws in the signals for all floors. The automatic dispatcher presents several novel features and signals the starting of the elevators independently of the hall men, who merely direct persons to their desired destination in the building.

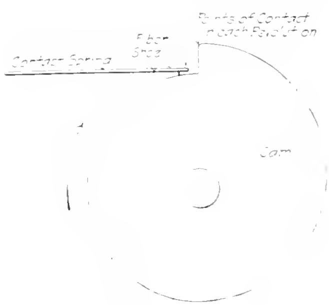

Fig. 2. Cam and Spring Contact

There is a bell located at the top and at the bottom of each bank of elevators, operated by the dispatcher. This bell is adjustable so that the timing of the cars may range from 20 to 60 sec. A 220-volt to 15-volt motor-generator set, with an auxiliary storage battery, furnishes energy for the dispatcher.

Fig. 1 is a plan view of the dispatcher, which consists essentially of a horizontal revolving disk operated through reducing gears by a $1/6$-hp. motor at a constant speed. Four vertical columns attached to the slate base support four independent hollow shafts to which are attached friction wheels and cams; a contact spring rests on each cam, but is normally out of electrical contact except once in each revolution. The horizontal shafts are hollow and inclose a threaded rod which engages with a central projection from the friction wheel that passes through a slot in the shaft. Hence, the position of the friction wheel on the shaft can be varied by turning the adjusting screw one way or the other. Moving the friction wheel toward the center of the revolving disk decreases the speed and moving it toward the outer edge increases it.

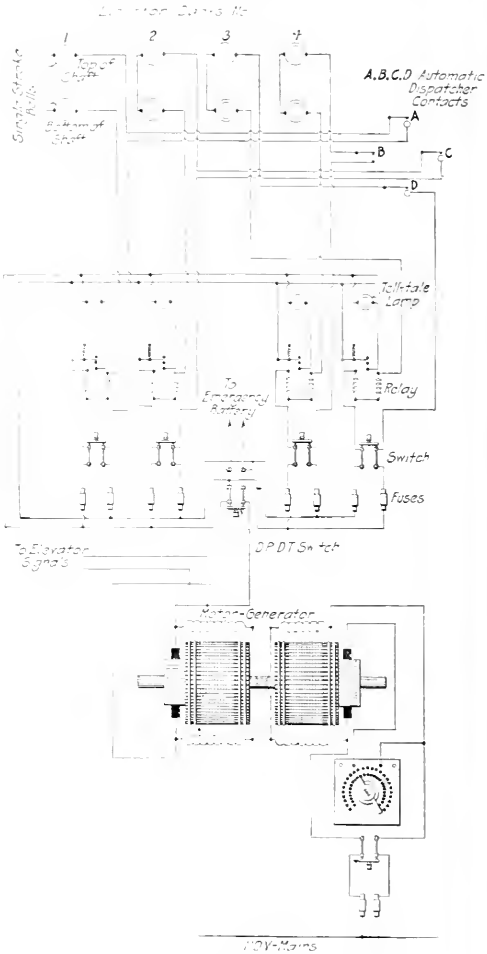

Fig. 3. Wiring Diagram of System

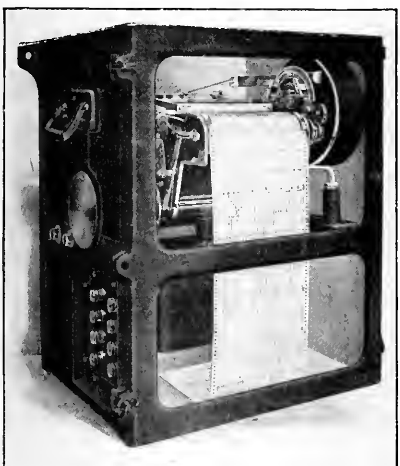
Details of the cam and spring-contact arrangement are shown in Fig. 2. The former is insulated from the latter by a fiber shoe, except when the spring escapes over the lip of the cam, and an open circuit normally exists. Fig. 3 is a wiring diagram of the motor-generator set and the dispatcher with its switchboard. The double-pole, double-throw switch in the center of the board is for disconnecting the motor-generator set and connecting the batteries in case of emergency. A relay is connected in the generator circuit and in case of failure of the latter, releases its armature which closes a local circuit and lights a telltale lamp, warning the attendant.

The dispatcher equipment on the board consists f four sets of fuses, four double-pole switches, four telltale lamps, and four relays—one o tfit for each bank of elevators. As the horizontal shafts of the dispatcher revolve, contact is made each revolution as the contact springs slip over the lips of the cams, closing the circuit through the relay coils and the single-stroke bells which are connected in series. The relay draws down its armature and closes the circuit through the telltale lamp, which lights, indicating that the signal has been given. Cars start in order in each bank of elevators, one after the other at the signal, and return from the top in the same order on receiving the signal.

Recording Pyrometer

The recording pyrometer shown is of a new type developed by the Wilson-Maeulen Co., 1 East Forty-Second St., New York City, and is to be marketed under the trade name of "Tapalog."



"TAPALOG" AUTOGRAPHIC PYROMETER

A special feature of this instrument is that the carriage containing the record paper, typewriter ribbon and other recording mechanism is pivoted to drop away from the galvanometer so that the paper and ribbon can be changed without danger of injuring the galvanometer.

The record is taken on the under side of the strip. The tracing paper used is visible from both sides and the speed of the record is 1 in. an hour. A dot is made every 12 seconds, and during the intervening period the pointer is free to swing to its true position.

The depressing member which makes the dot is operated by a three-cell dry battery; the clock merely shows the time. The indicating scale is mounted on the front of a chopper bar that is pulled down by an electromagnet, with a blow to make the record, and this bar is over-counterbalanced so that it tends to rise quickly after the downward stroke, at the bottom of which the electromagnetic circuit is opened.

The Tapalog will take a single record of one temperature in one color, but it is generally furnished with an automatic switch which, every minute and a half, switches the Tapalog from one thermocouple to the next and brings another portion of the multi-color typewriter ribbon under the pointer, so that the different records are taken in as many as four distinctive colors.

Multiple recording is important, for instance, in a large furnace where thermocouples are inserted at different points: the r cords, all being on one sheet, show definitely whether the furnace is evenly heated or just what the degree of uneven heating may be—the whole graphically set forth in a multiple record. The ribbon that passes under the record paper is made in the form of an endless belt so that it is not necessary to employ any mechanism to reverse the direction of travel.

This pyrometer may be located a long distance from the furnace, and to overcome shrinkage it is provided throughout with bakelite disks, washers, plates and other working parts.

Steam-Turbine Rolling-Mill Drive

The rolling mill has been one of the last stands of the large reciprocating engine. The Carpenter Steel Co., of Reading, Penn., has, however, recently installed a low-pressure steam turbine for driving two stands of 18-in. three-high mills. The turbine is of the De Laval multi-stage impulse type, in nine stages. It runs at 5000 r.p.m., and the speed is reduced by double helical involute gears, first to 600 and then to 100 r.p.m. The Jahns governor, with which it is supplied, may be adjusted while the machine is in operation, to vary the speed from 100 to 70 r.p.m. on the mill shaft.

The turbine will operate normally with 3 lb. gage pressure at the turbine throttle, and with 3 in. absolute pressure in the turbine wheel case at the exhaust end, under which conditions it will carry 350 hp. at the speeds mentioned and require not more than 26 lb. of steam per hour per brake horsepower, the power being measured at the end of the second gear reduction. It may be run low-pressure condensing, mixed-pressure condensing, high-pressure condensing, and high-pressure noncondensing.

With 120 lb. pressure at the throttle and 3 in. absolute pressure in the turbine wheel case, it is guaranteed not to require more than 17½ lb. of steam per brake horsepower-hour. As a mixed-pressure turbine, with the same pressure conditions, it will carry 600 b.hp. continuously, and is also designed to carry the full load of 600 hp. on the high-pressure steam alone, under which condition it is guaranteed to take not more than 15.7 lb. of steam per brake horsepower-hour.

American Cigar Co.'s Plant—We have been informed by Clark, MacMullen & Riley, 101 Park Ave., New York City, that the plant of the American Cigar Co., Garfield, N. J., described by W. L. Durand in Apr. 6 issue was designed and installed by them. This building is the first in the country used exclusively for cigar manufacturing to put in an air-washing system.

Vacuum Fluid Cooler

This device has been designed for the purpose of reducing the temperature of water below that of the surrounding atmosphere. Referring to Fig. 1, where the

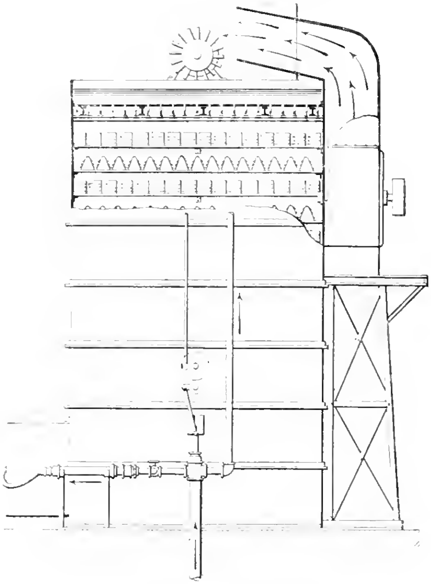


Fig. 1. Cooling Tower

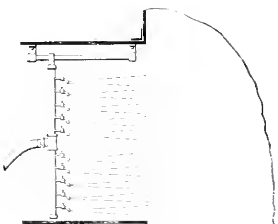

FIG.2

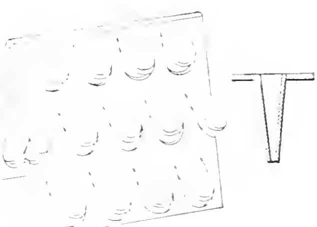

FIG 4

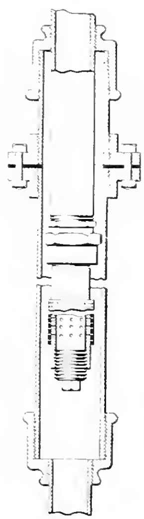

FIG 3

Fig. 2. Air-Cooling Chamber. Fig. 3. Strainer. Fig. 4. Tongued Baffle Plates

cooler is shown in the form of a rectangular tower, the air is taken through the air-cooling chamber, details of which are shown in Fig. 2, at a velocity of about 2000 ft. per min. In this chamber is a manifold sprayer which subdivides the water after it has passed through a strainer, Fig. 3. As the air enters through the cooling chamber it is compressed by passing through a smaller orifice at a high velocity, and is thereby reduced to about 65 deg., at which temperature it is drawn through the cooler and comes in direct contact with the falling water. The method of baffling the water and the air by means of tongued baffle plates, Fig. 4, causes the drops of water to

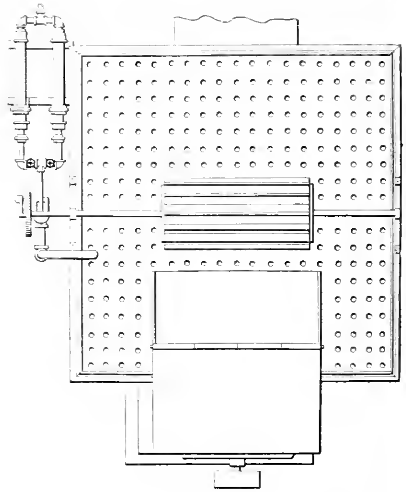

Fig. 5. Perforated Steel Pan

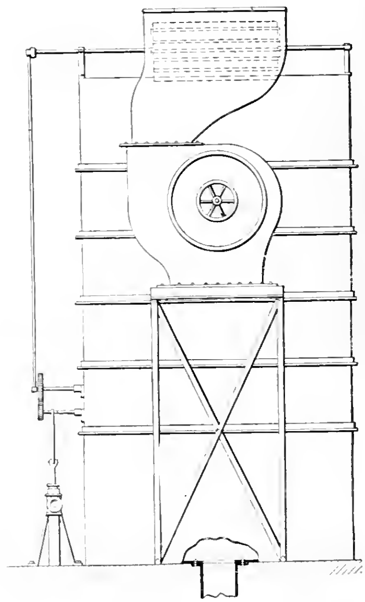

Fig. 6. End View of Cooling Tower

come in contact with the cooler air twelve or fourteen times during their fall from the inlet to the outlet.

At the top of the cooler is a steel pan about twenty inches deep (Fig. 5), into which the hot water from the condenser is pumped and the bottom of which is perforated at regular intervals with 1-in. holes. Each hole is connected to a funnel-shaped tube, Fig. 4, which tapers to 1/4 in. diameter at the base, thus forming sprayers. These tubes are so designed that with the weight of water which passes through it is impossible for them to become clogged or to retain any foreign matter that may be in the water.

The water is distributed to the tubes in the form of a spray, and when sufficient is in the pan to cover the holes, the exhaust fan, Fig. 6, placed under the tube, forms a partial vacuum into which is precipitated the falling hot water and vapor.

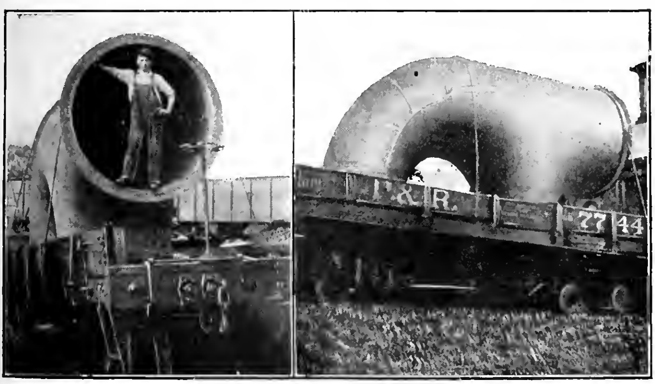
The exhaust is under the top pan. By circulating the water through the cooler after it has been heated from 90 to 160 deg. F. in passing through a condenser, it is brought back to be used again at a temperature of 70 to 75 deg. F. after passing through the cooler.

This cooling tower is manufactured by the Vacuum Flue & Cooler Co., 205 Highland Bldg., South Highland Ave., Pittsburgh, Penn.

Large Double Exhaust Fitting

The accompanying illustration shows a 72-in., cast-iron, double exhaust fitting which was recently made in the shops of the Hunsicker Engineering Co., Lebanon, Penn. So far as known this is the largest fitting of its kind ever made in the East.

It is used in connection with a 5000-kv.-a. turbine, 1500 r.p.m., at 80 lb. boiler pressure. The condenser used in the equipment is a No. 23 barometric type. The double outlets connect with the expansion joints of the turbine and the large end connects with a 72-in. exhaust line. It weighs 14 tons and is 18 ft. in length over all.



Two Views of 72-In. Double Exhaust Fitting

The Efficiency of Compressed Air can be greatly increased by reheating. The gains are both direct and indirect, the chief direct gain being in the greatly increased efficiency of fuel used in the heating stoves as compared with the effect when coal is burned under boilers. It is commonly stated, and the statement is fairly correct, that when 1 lb. of coal is burned in a reheater stove the commercial effect is as great as when 3 lb. are burned under a boiler. The increase in commercial efficiency when reheating air from 60 deg. F. to 400 deg. F. may be put at 35 per cent. The indirect gains are better lubrication of the compressed-air engine, less investment required, as a smaller plant will be needed, reduction of compressor-engine friction as compared with the useful work done.—Exchange.

Belting Calculations

By E. O. Waters

The theory of belting, as presented in standard handbooks, does not seem to harmonize with examples taken from everyday practice. There appears to be conflict between textbook theory and machine-shop practice, but this conflict is more apparent than real.

Primarily, a belt is made in such a length that it will be stretched enough to give it an initial tension. When the driving pulley starts it will cause one-half of the belt to tighten and the other half to become more or less slack. When the difference in tensions becomes slightly greater than the resistance of the driven pulley, it, in turn, will start up, provided the resistance does not exceed the maximum value determined by the coefficient of friction between the belt and pulley surface and the arc of contact made by the belt. This maximum ratio is that number whose common logarithm is $0.00758\mu\theta$, where μ is the coefficient of friction and θ is the arc of contact measured in degrees. For any proposed installation of belting θ is known (it is usually about 180°); and μ was determined many years ago by hanging pieces of belting with weights attached to the ends, over fixed sheaves, and finding out what excess weight hanging from one end was required to produce slipping. Accordingly, our maximum limit for $\frac{T_t}{T_s}$ is fixed, and since $T_t - T_s$ is determined by the power to be transmitted and the belt speed, we have only to make T_t and T_s large enough so that their ratio will be within the required limit, and to choose a belt sufficiently wide and thick to stand this maximum pull.

Suppose, for example, that it is desired to transmit 100 hp. between two 30-in. cast-iron pulleys, 30 ft. apart and on the same level, at a belt speed of 2500 ft. per minute. The resistance of the driven pulley will be 1320 lb. at the rim, and this same figure will represent the excess of T_t over T_s. Since the arc of contact is 180 deg., and μ, according to the experiments referred to above, is about 0.3, $\frac{T_t}{T_s}$ must be greater than 2161 lb. and T_s greater than 841 lb. Of course, the excess will be made as small as possible in order to avoid undue pressure on the shaft bearings and an unnecessarily large belt; but there must be an actual excess, or the belt will soon stretch permanently—so much so that it will be necessary to shorten it by cutting out a piece, so as to keep it from slipping. As for the size of belt to be used, the standard rule of 111 lb. maximum tension per inch width of double belt, corresponding to a maximum tension of about 375 lb. per sq.in., gives us a belt having 5.75 sq.in. sectional area, which would probably mean a double belt 20 in. wide. According to F. W. Taylor's recommendations, the maximum tension should be only 54 lb. per inch width of double belt, if it is desired to have belts which will give the least expense for repairs and lost time on machinery. In that case, our calculations show that a 30-in. double belt or, preferably, a 20-in. quadruple belt must be used.

So much for the design of belting transmissions by theoretical formulas. On the other side of the question, our own observation tells us, first, that for transmitting 100 hp. at 2500 ft. per min., very few factories use belts much over 20 in. wide and 3/8 in. thick, and second, that such belts, when running between pulleys a considerable distance apart, will often sag on the loose side anywhere from one-third to three-quarters of the mean diameter of the pulleys. Now we can very easily find the tension at the two ends of the loose portion of the belt by means of a little mechanics and the use of the well-known fact that a belt or rope, when suspended between two points, hangs approximately in a parabolic curve whose equation is

$$y = \frac{wx^2}{2H}$$

in which

y = Vertical distance of any part of the belt from the lowest point;

x = Horizontal distance of the same point from the lowest point;

w = Weight per unit length, and

H = Tension at the lowest point.

Taking $y = 2$ ft. and $x = 15$ ft., corresponding to a point on the loose side of the belt just as it is leaving one of the pulleys, and assuming the weight of leather as 0.036 lb. per cu.in., we have, for the 20-in. double belt, $w = 2.47$ lb. per ft. and $H = 139$ lb. At one end of the span the tension T_s will consist of a horizontal component equal to 139 lb. and a vertical component equal to the weight of half the span, or approximately 37 lb. This gives us $T_s = 143.8$ lb., which, to say the least, does not check very well with the minimum value of 841 lb. obtained by theoretical deductions. Even if the heavier belt were used, according to Taylor's recommendations, w and H would merely be doubled, and T_s would then be 288 lb.

In the opinion of the writer this discrepancy is due to two things—the arc of contact and the coefficient of friction assumed in the theoretical formula $\log \frac{T_t}{T_s} = 0.00758\mu\theta$. The arc is increased very materially by a slight sag in the loose side of the belt, if that side is the upper one. In our problem a sag of 2 ft. at the middle of the span means an increase of about 15 deg. in the arc of contact, and this difference alone is enough to increase the allowable ratio of $\frac{T_t}{T_s}$ from 2.57 to 2.78. However, a much greater change is caused by the second factor. It is not generally known that the coefficient of friction is very decidedly increased by slippage between the belt and pulley surfaces, although this fact seems to have been recognized many years ago by several investigators of the practical mechanics of belting. Unwin gives the equation $\mu = 0.2 + 0.001\sqrt{V}$, where V is the belt velocity in feet per minute, on the assumption that the amount of slip will increase as the speed of a belt becomes greater. Barth, after making a very careful analysis of some tests carried out by Wilfred Lewis for Wm. Sellers & Co., deduced the two following equations: $\mu = 0.6 - \frac{2}{4 + v}$ where v is the velocity of slippage of the belt relative to one of the pulleys, in feet per minute, and in the other $\mu = 0.54 - \frac{140}{500 + V}$.

The last of these, like Unwin's equation, depends only on the velocity of the belt, and is supposed to be used for ordinary belt transmissions where the total slip between the driving and driven pulleys is about 1½ per cent. Now a slip of 3 per cent. is very common in belting practice, and for belts that are running at all loose it may easily reach 6 per cent. In such a case, a belt running at 2500 ft. per min. will slip over each pulley with a velocity of 75 ft. per min., and μ, according to Barth's first formula, = 0.575. At that rate, the ratio $\frac{T_t}{T_s}$, as figured by the same equation that gave us $\frac{T_t}{T_s} = 2.57$, may be increased to 7.1, and T_t and T_s, instead of being, respectively, 2161 lb. and 841 lb., are reduced to 1536 lb. and 216 lb. This value of the tension in the loose side of the belt lies about half way between the tension which it was figured would be required to support a 20-in. double belt with a 2-ft. sag between the pulleys, and that required for a 20-in. quadruple or 40-in. double belt with the same sag. In other words, a 20-in. triple belt can be used in the transmission which we have been figuring, and allowed to sag 2 ft. on the loose side, in spite of the preliminary calculations which showed that such a heavy initial tension would be needed that the belt would pass from pulley to pulley in practically straight lines.

The upshot of the whole matter seems to be this: Almost any value within reason for the ratio $\frac{T_t}{T_s}$ may be obtained by calculation, simply by juggling with the coefficient of friction; it is therefore worse than useless to use the standard formulas for the design of belt transmissions, unless we take into account such factors as the belt's speed and slip, which are usually neglected. If, however, we can get a pretty accurate value for the coefficient of friction, we can figure belt tensions which will agree quite satisfactorily with those which we observe in practice. It should be noted that this can be done without in any way taking into account the effects of centrifugal force, which, in the opinion of some, should be given the entire credit for making it possible to run slack belts.

Economy of Heating Feed Water

By C. E. Anderson

Notwithstanding the economy of using exhaust steam for heating water for boiler feed and other purposes and the widespread information on the subject, the writer is constantly coming in contact with cases where live steam is used for heating water and for other purposes where exhaust steam might readily be employed.

Theory and practice prove beyond a doubt that a saving of 10 to 20 per cent. in coal consumption may be effected by heating feed water, the amount varying according to conditions. Where large quantities of hot water are used for other purposes a much greater saving may be made by using exhaust instead of live steam to heat it. In some cases it is more economical to run noncondensing, but if the exhaust furnished by the pumps and other auxiliary machinery is nearly enough, it is good practice to make up the deficiency by bleeding the intermediate receiver.

The following calculations may be of interest, showing the value of the feed-water heater. For convenience, assume a heater working continuously at its full capacity for ten hours a day and supplied with exhaust steam from the average noncondensing engine developing about 75 hp. Taking water at 60 deg. F., the heater will deliver about 1200 gal. per hour, or 12,000 gal. per day at about 210 deg. F. One gallon of water weighs about $8\frac{1}{3}$ lb., and 12,000 gal. will weigh 100,000 lb. Since it requires 150 heat units (B.t.u.) to heat one pound of water from 60 deg. F. to 210 deg. F., 100,000 lb. requires 15,000,000 heat units.

Roughly speaking, one pound (weight) of live steam will furnish 1000 heat units, therefore, 15,000 lb. of live steam would be required to do the work. Under good conditions one pound of coal will evaporate 10 lb. of water. This figure may be exceeded in some instances, but probably the majority of cases fall below it. On this basis no less than 1500 lb. of coal per day will be required. Assuming a working year of 300 days, this gives a total of 450,000 lb., or 225 tons, of coal burned, which at $4 per ton would cost $900.

This sum represents the saving by the use of a heater with exhaust steam. Of course, these figures are arbitrary and the result will be more or less fully realized in practice, according to circumstances.

Curnon Steam Meter

The Curnon Steam Meter is nothing more than the familiar low-pressure recording gage of the diaphragm type, and its pressure regulator which utilizes the Bourdon tube. The meter is sensitive and fairly accurate. The charts used with the instrument are directly calibrated in pounds of steam per hour, so that no calculations are necessary to secure the desired data. The installation is simplified by the use of double cocks both on the test plug and on the meter.

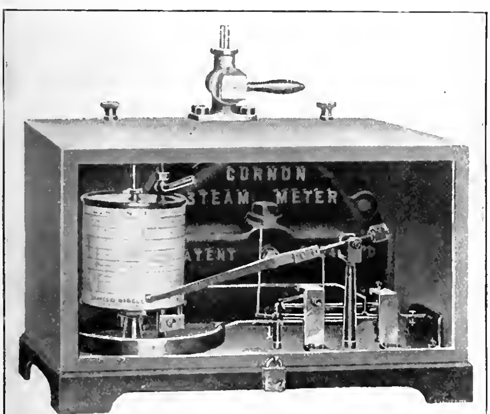


Fig. 1. Curnon Steam Meter

The principle employed in this meter, Fig. 1, is that of the Pitot tube, consisting of two small tubes with their ends bent at right angles and inserted in the pipe in which the steam is flowing in such manner that the end of one faces against, and that of the other with, the direction of flow. The rush of steam past the tubes causes in one a slight increase, and in the other a corresponding decrease, in the static pressure in the pipe. The difference in pressure is a measure of the velocity of the steam, and by connecting the two tubes to a sensitive differential pressure recorder a record is obtained of the quantity of steam passing through the pipe to which it is attached. Fig. 2 shows the Pitot tube mounted in the Curnon plug. The special feature is that the tubes are of such length

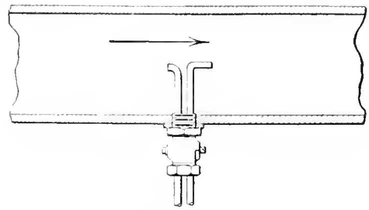

Fig. 2. Arrangement of the Pitot Tube

as to reach exactly to the center of the pipe, where the speed of the flow is highest and where eddy currents are least likely to interfere with the accuracy of the measurements. The low-pressure tube has a long elbow, which further increases the pressure difference and the motive power available to secure clear records of small variation in load. A single three-way cross controls both tubes and enables steam to be blown through them for cleaning purposes.

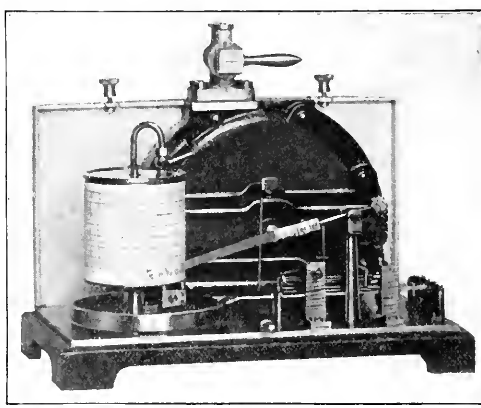

Fig. 3. Meter without Casing

All of the moving parts are mounted on a cast-iron base, as shown in Fig. 1. The outside dimensions when mounted in a box are 15x9x9 in. and the weight is about fifty pounds. Fig. 4 is a view of the diaphragm box, which is arranged in the back plate of the meter case. The two pressures in the test plug act upon the sides of a sensitive diaphragm, which is stiffened by two plates and controlled by a strong flat spring. The movements of the diaphragm are conveyed to the pen through a system of levers which multiply and rectify the movement in such a way that the curves traced upon the paper chart directly represent the weight of steam passing through the pipes.

As the accuracy of the instrument would be affected by any variation in boiler pressure, each is fitted with an automatic pressure regulator consisting mainly of a hollow spring of the Bourdon type, arranged centrally below the recording drum and linked at its free end to the multiplying gear. This is shown in Figs. 1 and 3. The interior of the Bourdon tube is in communication with the steam pressure in the pipe, and the movement of the free end so acts upon the pin gear as to automatically correct the reading for any fluctuation in pressure.

The connection between the meter and the 3/8-in. copper test tube may be any reasonable distance away, either above or below the pipe.

The double cock, shown in Figs. 1 and 3, at the top, is constructed so that both ports are opened and closed simultaneously. In the closed position the meter is connected to the atmosphere and the pen must always stand at zero on the chart. This enables the operator to check the adjustments at any time. Between the plug and the meter are the condenser coils, which consist of 3/8-in. copper tubing fitted to the plug horizontally and on an exact level with the Pitot tube in the steam space. The

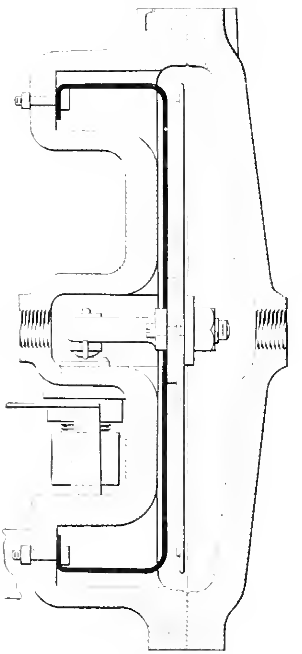

Fig. 1. Diaphragm Box in Section

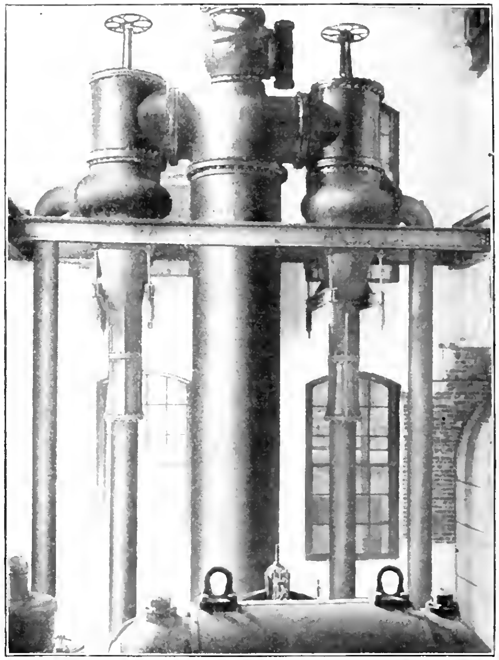
condensing coils insure that the meter, as well as the connecting pipe, is always filled with comparatively cold water, regardless of the displacement due to the movement of the diaphragm.

The meter is manufactured by the James Biddle Co., 1211 Arch St., Philadelphia, Penn. Each one is supplied with a test book, condenser coil, two 10-ft. copper connecting tubes and 100 charts and ink. The standard charts are calibrated in pounds of steam power and are available in various ranges for each size of pipe. The instrument is fitted with a 24-hr. chart and an 8-day clock.

Deane Ejector Condenser

The illustration shows a pair of 34-in. ejector condensers recently installed by the Deane Steam Pump Co. in the city electric generating plant of Holyoke, Mass. The apparatus serves a 3500-kw. horizontal double-flow turbine and maintains 28 to 28½ in. of vacuum in the turbine exhaust chamber.



A Pair of 34-In. Ejector Condensers

In the construction a lifting device has been provided to permit the cone to be raised to discharge any trash which may stop the annular opening in the condenser after passing through the strainer. The tees shown at the top of the condenser are so designed that the cone can be lifted through the tee in case of desired changes, repairs or alterations. A pointer on the cone-raising spindle indicates the amount of opening around the cone. A device has also been incorporated to center the cone and prevent vibration of the lower edge when it is in its working position. The long run of 50-in. exhaust-steam riser and the 16-in. injection pipes are noticeable. These are both made of lap-welded steel tubing. The exhaust-steam riser is in one piece 25 ft. 8¾ in. long and the injection risers and the drop pipes are also each in one piece. Expansion and contraction of the piping under varying temperatures are taken care of by spring suspensions.

Formidable Looking Formulas—Many engineers will go down without a struggle before a formula which has a logarithm, entropy or a sine, cosine or tangent in it. It is just as simple to look up one of these quantities and to substitute the value given in the table for the letters of the formula as it is to hunt up the steam temperature corresponding to a given pressure, or the area corresponding to a given diameter, and the same book which contains the tables of the properties of steam and of circumferences and areas will usually have the other things, too.

Editorials

Changes at Seventy-Fourth Street

There are few more forceful examples of what the economy of the large steam turbine means in the generation of power than the recent changes in the Seventy-Fourth Street station of the Interborough Rapid Transit Company, New York City, which are described in this issue. When it pays to discard to the junk pile engines of large power, nearly as good as new, to make room for turbo-generator units, it shows that designers have been accomplishing things. And yet, in doing so they undo their admirable work of but a short time ago.

These great engines should not go into oblivion without a word being recorded of their life's history, too much of which has perhaps already been forgotten. The installation in the Seventy-Fourth Street station in 1901, beside being one of the most notable, was virtually the last stand of the large reciprocating engine for electric generating units.

They were designed by that Connecticut farmer boy, Edwin Reynolds, who became one of the eminent figures in the steam-engineering history of the country. It is told that Mr. Reynolds was invited to New York to discuss with the Manhattan Railway Company's engineers the subject of selecting the type of engine for the Seventy-Fourth Street station. When he left the E. P. Allis works in Milwaukee, the question was unsettled. At Albany a telegram informed him that a committee representing the railway company would meet him at the Grand Central station. When he reached Harlem, the story goes, he had sketched on the back of a letter the design ultimately adopted, the sizes of cylinders and principal parts being indicated. And the problem was to crowd 12,000 horsepower in each engine, which had to go in a limited space.

It seems that Fate had decided that this daring stroke should be about the last, for the turbine was beginning to demonstrate its possibilities. The first important installation was in 1899, when some 400-kilowatt machines were put in the plant of the Westinghouse Air Brake Company. About a year later attention here and abroad was centered in the two 2000-kilowatt units of the Electric Light & Power Company, Hartford, Conn. This was the most notable installation in point of capacity and because the expansion was completed in one cylinder. Then came the announcement that several 5000-kilowatt units were being built for the combined station of the Metropolitan and District roads, London.

The fact was being established that the larger the capacity of the turbine the more favorable was its performance, and 1905 saw contracts closed for a 10,000-kilowatt Brown-Boveri-Parsons machine for the Westphalian Electricity Works, Essen, Germany. At this time the Brooklyn Heights Railroad Company got two 7500-kilowatt units, which were then the largest turbines in this country.

There next followed the first real tryout of the turbine on a large scale, when in 1905 about 10,000 kilowatts in turbines were run in competition with a nearly equal capacity of reciprocating engines in the L-Street station of the Boston Edison Company. The results of these competitive trials do not need to be told.

And all this truly remarkable advance had been made almost simultaneously with the installation of large reciprocating engines in such stations as the Seventy-Fourth Street of the Interborough Rapid Transit Company; Waterside, No. 2, of the New York Edison Company, new in 1902; and the Fifty-Ninth Street station of the Interborough Rapid Transit Company, new in 1904. This is the most conclusive evidence that the early development of the turbine was rapid beyond the expectations of the best engineering talent of the time.

"Elbow Room" in Power-Station Design

If power-plant designers generally were experienced in station operation, more consideration would be given to adequate space for equipment and attendance. The temptation to cut down on space is great, to save in the amount of material required to inclose the plant and in the fixed charges per horsepower of capacity. This consideration limits stations built in country districts as well as those on valuable city land, and the operating staff frequently finds itself lacking in room.

Some of the difficulties of attempting to operate in a cramped location may well be considered as an offset to the demands of an initial layout extremely economical in structural material. The importance of adequate clearance will be conceded by any student of "safety first." Where bare conductors are to carry high voltage, the designer generally appreciates the element of clearance. It is fully as important in many low-voltage plants to provide adequate spacing between conductors and metal work and between lines and horizontal or vertical passages. The commercial value of the loads carried, even if there were no personal hazard in the crowding of live conductors into restricted spaces, often makes it inadvisable to take chances of interruptions. It should never be possible for an engineer, climbing an iron ladder and momentarily losing his grip, to swing outward so far as to touch the exposed contacts of an instrument transformer. Designers who will properly separate circuits carrying high voltages sometimes neglect to spend enough money on low-tension bus structures and switch cells to protect the service and the operator from mischances.

A thorough investigation of the relation between the labor cost of station service and the space requirements of the plants covered would be of much interest. Equipment arrangement is important, but accessibility and freedom to reach apparatus without traversing circuitous paths are also. Main units are rarely so crowded today in new stations as to hamper removing sections of machinery, but in the placing of auxiliaries and in the arrangement of piping, valves and platforms, much is often to be desired. A construction engineer who rose to a high place in a consulting organization recently remarked that few things in his early experience had proved of greater value than several months of service as a substation operator after the close of each day's work in the drafting department. The actual handling of the equipment gave him a knowledge of space requirements that was reflected in his later work. He knew what room the switchboard operator needed to manipulate manually connected switch levers in critical moments; he appreciated the desirability of being able to read instruments easily from all apparatus-controlling points; and he realized the handicap of crowded motor-generator sets and transformers closely adjacent to railings or too near aisles for rapid movement.

In order to get the benefit of the reduced labor cost per kilowatt of capacity of modern generating units, it is worth while to make sure that subordinate equipment is sufficiently separated to enable it to be operated and maintained without adding needlessly to the station payroll through the comparative inaccessibility or obstructive features of the apparatus and its arrangement. Ample space in which to use tools specially adapted to the adjustment of complex machinery and fittings is of enough value to justify, usually, at least a moderate increase in building cost. In other words, flexibility and compactness are not always synonymous in first-class designing.

Unreasonable License Laws

Nobody would deny that it is the duty of the state to see that boilers are safe and that they are safely operated.

If a factory inspector makes you provide fire escapes and put guards around gears and belts, if a plumbing inspector insists that the plumbing, even of your dwelling, shall be sanitarily installed, if the fire and insurance authorities can dictate how much combustible or explosive material you can have around and how you must keep it, surely somebody should pass upon the adequacy of steam boilers, to the consequences of the failure of which not only industrial workers, but occupants of office buildings, customers of department stores, guests of hotels, and even the pedestrian upon the street, are subjected.

Nobody would deny that the state—which is the people—should provide for the safety of the people by the inspection of these boilers and of the man who runs them—if that were all that there is of it.

The man who owns boilers and hires men to run them is afraid that this will not be all.

When he sees laws passed, denying to a man the privilege of working at his vocation because he was not born and brought up in the town where the job is—

When he sees rules adopted, denying to an engineer coming into a community, be he the best engineer in the world, anything except a chance to work in a subordinate capacity, with the lowest grade of license—

When he sees examiners acting in collusion with organized labor, to keep down the supply of engineers by refusing men licenses to run steam plants because they cannot design triple-expansion engines—

When he sees engineers' organizations straining the interpretation of existing laws so as to require every laborer about a steam plant to be a licensed man—

He is afraid that the legislation, however beneficent in its declared purpose, however innocent in its seeming intent, is of sinister design and hostile to his interests.

Most of the opposition to the passage of engineers' license laws is inspired by this fear. Most of the difficulties experienced by the A. S. M. E. committee appointed to formulate standard specifications for the construction of steam boilers and other pressure vessels and for the care of the same in service came because it included in its report a recommended form of license law. As one member put it, "this committee, appointed to get up a blueprint of a horizontal return-tubular boiler, tried to involve the society in objectionable legislation." The only way that the report could be gotten through at all was by leaving out all reference to legislation and all suggestions for laws which would bring about the adoption of the Code by the various states.

As we started in by saying, nobody has any tenable objection to the adoption of boiler inspection and engineers' examination laws, when he is satisfied that they are not excuses to add to the difficulties of the employer and subterfuges to obtain unnatural and unfair advantages for the present holders of jobs in power plants under a specious anxiety for the public safety.

The real effort for such laws is sincere and honest, and those who are making it should most forcibly disavow any ulterior purpose in their agitation and frame their proposed legislation so that it cannot be abused.

It is hoped that the American Society of Mechanical Engineers' Code, above referred to, will come into universal use in this country. Its adoption by the various states, for which powerful interests are striving, opens the way to, if it does not go hand in hand with, the examination and licensing of engineers. Those who are seeking legislation to bring this about should unite their efforts with those who are striving for the boiler-inspection laws and make their demand so reasonable and so sensible that they cannot reasonably be denied.

Effect of High Steam Pressure on Flywheel Risks

In the days when seventy pounds was so usual a steam pressure that it was taken by the committee on boiler trials of the Centennial Exposition as representing average practice, such an occurrence as a flywheel explosion was almost unheard of. The maximum mean effective pressure which could possibly be gotten was that which would result from carrying seventy pounds full stroke. With an initial pressure of one hundred and fifty pounds, the attainable mean effective pressure in case something goes wrong with the governor is more than twice as great. This means that the velocity generated in a given time would be more than twice as great; but since the centrifugal force increases as the square of the velocity, the stress generated in the flywheel in a given time would be over four times as great. An accident which prompt action, under the less strenuous conditions of twoscore years ago, would have headed off, would be likely to be all over now before the attendant could gather his wits, get into motion, and close the throttle.

Rate Discrimination in Massachusetts

In the Feb. 23 issue there appeared an item dealing with the attempt of the New England Power League to get a bill through the Massachusetts Legislature tending to make more equitable the rates for electricity. Perhaps it would be interesting to your readers to learn more as to why the League takes this attitude.

The schedule of the Boston Edison Co. appears to be the only one which is susceptible of having curves plotted which mean anything; but the conditions existing in most of the other electric companies in the state are the same as shown by the curves of the Edison company. There is no difference, so far as results are concerned, between a charge for the privilege of being connected to the lines plus a charge for the power delivered, and charging a high price to the small consumer and a low price to the large consumer. Twelve cents a kilowatt-hour to a small consumer and one cent to the large one represent the range in power costs in Massachusetts. This applies to both demand plus a current charge and a straight charge.

To illustrate the Boston Edison schedule, Fig. 1 has been drawn, which shows that from 0 to 15 kw. there is a demand charge of $60 per kilowatt per year. From 15 kw. upward, this demand charge decreases, and at 10,000

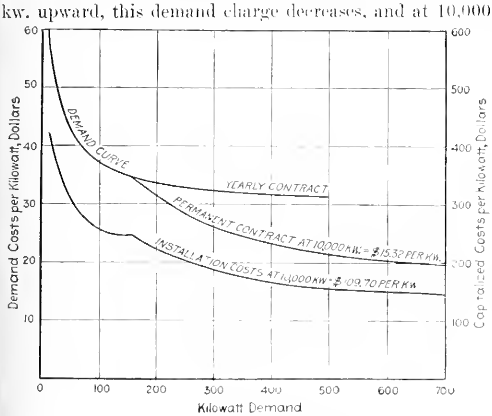

Fig. 1. Demand Charges

kw. demand is $15.32 per year. This applies to permanent rates, that is, to those who make a permanent contract for more than one year. If the contract is only for a year, the reduction is not so great; but even under these conditions, at 500 kw. the demand charge is only $31.20.

Capitalizing these charges, the lower curve is obtained, which would indicate that from 0 to 15 kw., the cost per kilowatt of demand is $128; whereas at 10,000 kw. it is only $109.70. This in itself is rank discrimination, because it is impossible that a city plant could be built with the necessary distributing lines at $109.70 per kilowatt. It is even worse than it appears on the surface, because of the diversity factor.

It has been proved by one of the largest companies that the diversity factor of the large load is practically unity, whereas that of the small load ranges between 3 and 4; that is, a large consumer will usually require in the power

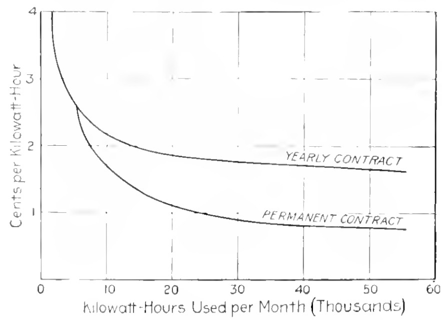

Fig. 2. Prices for Energy Used

plant a capacity equal to his maximum demand, whereas the small consumer will require an installation in the power plant equivalent to only one-third or one-quarter of his maximum demand. As the large consumer is charged for a value less than one-third of the actual cost of the apparatus, the small one on the other hand is charged at a value of three to four times those shown on the capitalized demand costs, or from $1282 to $1712 per kilowatt of actual station capacity.

These figures alone are sufficient to make the New England Power League and others feel that it is time some laws were passed which would make an equitable division of the power costs.

Another item of discrimination is the division between yearly and permanent contracts. It will be noted from Fig. 1 that from 15 to 155 kw., yearly and permanent contracts are the same, but that above 155 kw. there is a decided difference. To my mind this is discrimination, because there should be no point at which these two contracts should be the same if there is any reason for a division between the two characters of contract. If it costs more to handle yearly customers than it does permanent ones, it will cost more for any character of load.

So far attention has been called only to the demand, and it will be noted that there is a wide variation in demand charges. Let us look now at the energy used. Fig. 2 shows the variation in these charges for various consumptions in kilowatt-hours per month. It will be noted that here again there is a marked decrease in cost solely for an increase in the amount of current used. It would seem that if there were a large difference in the cost for the demand, there should be a uniform price for the current, for certainly the demand charges as laid out cover much more than the fixed charges on the small load, and do not cover nearly as much as the fixed charges on the large load. Therefore, in order to even matters up, it would seem as though the power charges for current delivered should be uniform. They are not, and again the small consumer gets the worst of it. Up to 1500 kw.-hr., he has to pay 5c. per kw.-hr. From this point on, the rate decreases to a marked extent, until at 55,500 kw.-hr. the price is under 2c. for permanent rates. For yearly rates, however, the price is approximately 2.6c. Here again there is a division between the yearly and the permanent rates. As has been stated before, if there is any reason for a division, it should apply to all characters of load; but it does not. The division takes place at 5500 kw.-hr. per month.

In my opinion there is no question as to the injustice and discriminatory feature of the demand charge as outlined, as well as the current charge; and I am heartily in favor of any attempt which may be made to bring about a more uniform and just arrangement of charges for electric light and power.

HENRY D. JACKSON.

Boston, Mass.

Priming a Centrifugal Pump

This is a problem which confronts many operators of centrifugal pumps. In the Mar. 2 issue there is an article on this subject by J. F. Jones, in which he describes the trouble he had in priming a 30-in. pump. While his method is all right, it does not exhaust all of the air from inside the casing, and no doubt there is considerable "rumbling" in the pump while it is in operation, with a possible chance of injuring the impeller. By referring to Fig. 2 of Mr. Jones' article, it will be seen that it is impossible to remove all the air from inside of that part of the casing which is above the point where the ejector suction enters the suction elbow on the pump. By running with air entrapped inside the casing, the delivery is no doubt reduced.

When a pump such as that shown by Mr. Jones is started with air inside the casing, it is difficult to get rid of all of it through the discharge pipe. What might be a more satisfactory way to prime this pump would be to connect the ejector as shown in Fig. 2 of Mr. Jones' arti-

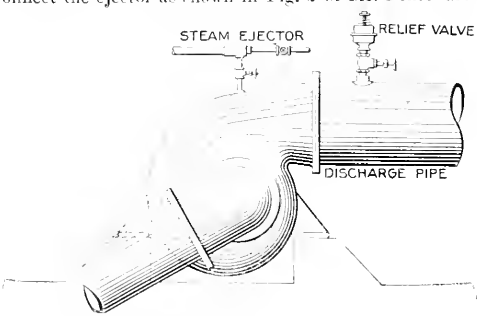

FIG. 1. POSITIONS OF EJECTOR AND RELIEF VALVE

cle, except that the suction should be cross-connected to the top of the casing. The method of starting would be the same as that adopted by Mr. Jones, except that after the pump is running and before stopping the ejector, the latter's suction to the top of the pump should be opened and that to the elbow closed. This will exhaust the air from the top of the casing. In this way the delivery should be better than if there were some air in the casing.

It is not always best to leave off the flap valve, and it is often necessary to have one on the end of the discharge pipe. When a flap valve is used it is necessary when shutting down, to have some way of breaking the vacuum in the discharge pipe which is due to the water running back down the pipe and through the pump.

The possibility of collapsing the discharge pipe on a pump such as that described by Mr. Jones, can be avoided by placing a relief valve near the flap valve on the discharge pipe. The position of this relief valve is shown in Fig. 1. It should be placed on the highest point of the discharge pipe.

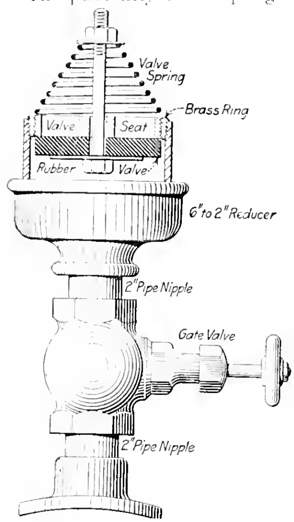

FIG. 2. RELIEF VALVE

A suitable relief valve can be made as shown in Fig. 2. The spring for holding the valve on its seat should be of such strength as to allow the valve to open when a vacuum of about 20 in. of mercury is produced inside the discharge pipe. The opening will permit air to enter, thus breaking the vacuum and preventing the possibility of collapsing the discharge pipe. An ordinary rubber pump valve and seat are shown as making up this relief valve. A gate valve should be placed as shown. This is left open while the pump is running, and if for any reason the pump should stop and the flap valve close, the relief valve would open automatically when the vacuum inside the discharge pipe became great enough to overcome the pressure of the spring.

J. E. POCHE.

New Orleans, La.

Some Reasons for Different Rates

In the issue of Mar. 16, Mr. Seed has an interesting article showing the reasons for different rates and using the cutting and delivery of ice as an illustration.

In his figures it appears that the cost of labor decreases much too rapidly in the handling of the various quantities of ice; also the investment cost. It is hard to conceive that the investment will decrease from $1.50 a ton to 45c. with an increase of four times the amount handled. It costs more to add a story to an icehouse than just the labor and material. Furthermore, the reduction in prices to the various large consumers is not as great as will probably take place in actual conditions, and nothing like as great as in electric sales, where the ratio of the small to the very large consumers' rate is often 10 to 1, and the small consumers' rate to the average, about 6 to 1. Mr. Seed's greatest variation is 4 to 1, when the largest consumer has no delivery cost at all.

In answering his question, "If Jones found it necessary to give up a part of his business and had his choice, which part would he drop?" it all depends on the figures. If he sold two tons at $8 per ton, and they cost delivered $12.30, there would be a gross profit of $3.70. If he sold the next three tons at $4 a ton and they cost him $13.45, he would have a loss of $1.45. If he sold five tons at $2.50 a ton and they cost him $15.75, he would have a loss of $3.25. If he sold ten tons at $1 and they cost him $11.50, he would have a loss of $1.50. Under these conditions which would he choose? These figures correspond more closely with actual electric prices, as is shown by the following table. One of the large companies sold power as follows:

	Kilowatt-Hours	Receipts	Cost
Motor service	25,471,000	$1,114,624	$743,000
Street railway	8,319,000	142,987	242,200
Street lights	17,739,000	781,792	516,500
Commercial lighting, small	24,568,000	2,457,000	715,000
Commercial lighting, large	42,495,000	1,792,000	1,249,000
Other companies	4,248,000	121,530	123,700

These costs, like those shown in Mr. Seed's illustration, are the average operating costs of the plant and do not take into account interest or depreciation. If the company had to choose which class of customer it would drop, which would seem the more probable—the small one, paying 10c., or the large one, paying considerably less?

I realize that the figures given here do not recognize many differences in expense to the various characters of load, the cost being the average as shown by the Public Service Commission's report. At the same time, I believe that this illustration shows the absolute futility of trying to compare the manufacture and sale of electricity with ice.

Electricity must be sold as it is manufactured, because it is not possible to store it commercially. This being the case, if we have a customer or group of customers who will demand a certain definite load all day, giving unity power factor, the investment is used to its maximum and therefore the price of the power should be low. If, however, another customer comes along who requires power for only a short period, an additional investment is compelled; and as the power is used but a short time, the investment is used but a short time and the fixed charges are high; and also, as the machinery is used but a short time, the labor charges are large, which means increased cost. This latter is to all intents and purposes the condition which exists with the large power users. During the summer they can be run very largely from the plant which is installed to handle the lighting load; but during the winter they cannot, and apparatus which is idle during the rest of the year has to be put into the plant to meet the power load. This being the case, the investment charges against these power users are very large. This will counterbalance any inaccuracy of the figures given above when taken in the sense of neglecting the interest and depreciation charges; they are comparable and accurate if these charges are taken into account.

HENRY D. JACKSON.

Boston, Mass.

That all do not reach the same conclusion from the same starting point is well illustrated in the letter of Mr. Seed on page 383. Using the same figures given, if Jones supplied only one of the classes of customers and could take his pick it would be as follows:

To consumers taking 50 to 100 lb.:

Two tons at $8 per ton		$16.00
Cost of two tons at $2.50	$5.00	
Cost of team	5.00	
Cost of two men	5.00	
		15.00
Gross profit		$1.00
Profit per ton, $0.50.		

To markets, etc., 200 to 500 lb. per delivery:

Three tons at $6 per ton		$18.00
Cost of three tons at $2.50	$7.50	
Cost of team	5.00	
Cost of men	5.00	
		17.50
Gross profit		$0.50
Profit per ton, $0.16⅔.		

For ice-cream factories, etc., 1000 to 2000 lb.:

Five tons at $4 per ton		$20.00
Cost of five tons at $2.50	$12.50	
Cost of team	5.00	
Cost of two men	5.00	
		22.50
Gross loss		$2.50
Loss per ton, $0.50.		

To Smith & Brown, 10 tons at icehouse:

Ten tons at $2 per ton	$20.00
Cost of ten tons at $2.50	25.00
Gross loss	$5.00
Loss per ton, $0.50.	

It is seen that the small consumer is the only one who pays much profit alone. Whom woeld Jones serve if he could get only one class?

Using the figures exactly as Mr. Seed gives them and supplying all classes, the profit per ton is

Small consumer	2 tons, proﬁt $3.70,	per ton	$1.85
Markets, etc.	3 tons, profit 4.55,	per ton	1.51⅔
Ice-cream factories	5 tons, profit 4.25,	per ton	0.85
Smith & Brown	10 tons, profit 8.50,	per ton	0.85

Jones will sell more ice to small consumers than to the other classes, and if he could only sell 1000 tons it is easily seen to which class he would prefer to sell.

I still fail to see why the large consumer should get all the benefit of cheaper production or pay so much less profit per unit.

HARRY D. EVERETT.

Washington, D. C.

Testing Small Centrifugal Pumps

In the Mar. 16 issue M. R. Blish makes two mistakes in defining the method of computing the head on a centrifugal pump. On page 372 he states that the total head is the sum of "the suction head, pressure head, and the vertical distance between the center of the pressure gage and the point of attachment of the mercury gage." The first error is the omission of a velocity-head correction. It is quite common for the suction pipe on a centrifugal pump to be a size larger than the discharge pipe, in which event we should have to include the difference between the velocity heads in the suction and discharge piping at the points where the gages are attached. This may be proved in various ways, but may readily be seen if we but realize that it requires power to increase the kinetic energy of the water as well as to increase its pressure. Only where the two pipes are of the same diameter, so that the velocity-head correction is zero, would Mr. Blish's definition apply.

The second error is that here, as well as on page 371, he implies that the indication of the mercury manometer is the value of the pressure at the point of its attachment to the suction gage. It is well known that a pressure gage reads the pressure found within itself and that its height must be considered in finding the value of the pressure at the point of attachment. The same is true of a suction gage. If the suction head is read by means of a vacuum gage, the definition of total head should be corrected to read, *and the vertical distance between the centers of the pressure and vacuum gages.* If the suction head is read by a mercury manometer, the point corresponding to the center of the vacuum gage will be the top of the mercury column on the side of the U-tube that is connected to the pump.

The words in italics are based upon the assumption that there is a continuous column of water between the vacuum gage or the mercury manometer and the point of attachment to the suction pipe. Such a condition may be realized if the connecting tubing be filled with water before the pump is started and if the point of attachment is not at a place where a pocket of air may accumulate. If the connecting tubing contains air only, then Mr. Blish's method of computation would be correct. This is because the weight of the column of air between the mercury manometer and the suction pipe is negligible and hence the manometer reading would be the value of the pressure at the point of attachment. In order to maintain this condition, however, it is necessary to have some means of permitting air to be drawn into the connecting tubing during a test, allowing water that has accumulated to be drawn back into the suction pipe. The figure shown in the article does not indicate any such provision. Unless one does have some means of admitting a small quantity of air during the test, it is better to fill the connecting tubing with water. Otherwise, if the tubing contains water and air both, it will be difficult to properly compute the true suction pressure. In the case of a pump delivering water under a high head and where the vertical distance from the suction gage to the suction pipe is small, the error introduced may be negligible, but under other circumstances it might be appreciable.

Objection must also be raised to the arrangement of suction piping shown in Fig. 3, on page 371. It is a fundamental principle that a suction pipe must contain no summits, otherwise air will accumulate and finally interfere with the flow of water or cause it to cease.

Mr. Blish seems to have the impression that the insertion of bafflles in a weir box is to "prevent a serious velocity of approach." Baffles are used to quiet the water and cause it to flow uniformly, but have no effect upon the velocity of approach. The latter is determined solely by the dimensions of the cross-section of the box.

In connection with measuring the rate of discharge of the pump, the author might have mentioned the most common method used in testing, which is by means of a calibrated nozzle on the end of the pipe. Also the venturi meter is a valuable device for such purposes.

In starting a centrifugal pump, the author states that after priming, "open the throttle valve in the delivery pipe and start the motor." While this may be permissible with proper starting devices at the motor, a better procedure would be to bring the pump up to speed before opening the discharge valve. In that way a smaller load would be thrown on the motor at starting, since the horsepower with the valve closed is about one-third that required with the valve wide open.

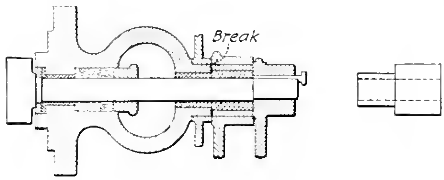
The efficiency curves shown in Fig. 7 for speeds of 1200, 1400 and 1650 r.p.m. are consistent with one another, but the curve for a speed of 1700 r.p.m. is somewhat doubtful. When there is an increase in the maximum efficiency of only about 3 per cent. for a range of speed from 1200 to 1650, it is hardly likely that there will be a drop of about 8 per cent. in passing from 1650 to 1700 r.p.m. Further, it will be noted that the maximum efficiency at each speed is attained at greater values of the rate of discharge as the speed increases for the first three speeds, but for 1700 r.p.m. the maximum efficiency is shown as occurring at a smaller rate of discharge than at 1650 r.p.m. This is hardly reasonable and makes one suspicious of the accuracy of the test data used.

R. L. DAUGHERTY.

Ithaca, N. Y.

Repairing Corliss Valve Bonnet

One of the admission-valve stems and bonnet bearings on a Corliss engine got overheated from running dry, until it gripped and broke the bonnet, as shown. A good repair job was done by boring out the bonnet and making a



VALVE BONNET WITH BUSHING

sleeve, or bushing, a driving fit. After forcing it into the bonnet it was turned down and bored out to fit the valve stem.

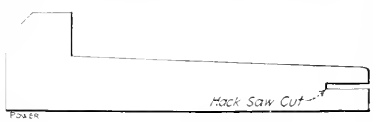
When the parts were reassembled very little adjustment was needed to set the valve to the builder's marks. The job was done in four hours by two men.

JOHN POWERS.

New Bedford, Mass.

Putting Liners in with Keys

When a key is too loose and it is necessary to put a liner in with it, there is sometimes difficulty in getting the liner to go in with the key, or if the liner is put in first, to get it to stay in place while the key is being driven. To overcome the foregoing, I saw the end of the key, as shown, and insert the end of the liner, doubled



SLOT IN KEY FOR LINER

if necessary, and bend it back along one face of the key. Whether the liner should be placed on the one face or the other depends on the depth and relative smoothness of the keyways.

CHARLES HERMAN.

Replacing Broken Capscrews

Referring to the subject of the letter by A. G. Solomon, page 414, Mar. 23, this difficulty seems to be quite common. Three years ago I had some trouble with a small ammonia-compressor cylinder held in place by eight ⅞-in. capscrews. The screws would become loose and the cylinder would slip on the bedplate at each stroke.

I overcame the trouble in a way similar to that described by Mr. Solomon, but more simple. I drilled a ¾-in. hole 2 in. deep at the joint of the cylinder flange and the frame, then fitted a dowel pin and drove it in tight. Since then there has been no difficulty in keeping the cylinder rigid.

L. M. Johnson.

Emsworth, Penn.

In the issue of Mar. 23, page 414, I notice an account of a method used to prevent the breaking of the capscrews used to secure the cylinder of an ammonia compressor to the base.

No doubt, putting in tight-fitting keys would prevent breaking more bolts, but if this means were used on a steam cylinder, I am afraid that before a great while the base would be broken, unless some provision were made for the expansion and contraction of the cylinder, which apparently was not done in the case of the ammonia cylinder.

To fit bolts snugly into the holes is wrong, in my opinion, for the cylinder is heated and expands, while the base remains practically cool and expands very little, thereby putting a shearing stress on the bolts. If the bolt holes had been elongated about ⅛ in., I believe the trouble would have been overcome without the expense of putting in the keys. I would advise using only one key in any case, and enlarging the holes in the other end to allow for expansion, as stated.

Philadelphia, Penn.

Gas Explosions in Boiler Furnaces

I would like to bring to your attention a recent accident in one of our boiler rooms, with the suggestion that it be published, and commented on by readers.

The boilers were of the vertical water-tube type, provided with two sets of fire-doors with automatic stokers (underfeed) between them. Forced draft for all the boilers was furnished by an automatically regulated engine-driven blower, supplemented by natural draft from the stack.

Owing to some minor troubles it had been necessary to cut out one of the two boilers in operation the night before the accident and it, together with the third boiler, had both the natural and the forced draft cut off by the dampers, leaving only one boiler in service to carry the load. This was being forced, with the stack damper wide open, the blower running at full capacity and the stoker rapidly feeding coal. The fireman in cleaning the fire (with only one fire-door open) found a clinker had formed over the tuyeres. As he loosened this an explosion occurred in the firebox, precipitating him backward against the coal bunker and burning him severely. The engineer, who was standing directly in front of the other fire-door of the same boiler, was not injured, as the safety latches on the latter (which had been installed after two similar occurrences of a minor nature) prevented its opening, thus justifying their adoption. But the cleaning-out door at the base of the stack was blown open by the force of the explosion, which appears to have been considerable.

Presumably, this was a carbon-monoxide explosion facilitated by the sudden inflow of air through the tuyeres when the latter were cleared. The lower limit of the explosive range of carbon monoxide in air is in the neighborhood of 15 per cent., and it is difficult to understand how such a rich mixture as this could have remained in the firebox with one fire-door open and the stack draft in operation. We might add that all ashpit doors were sealed and that it is the practice at this works to keep all stack dampers wide open on boilers which have fires under them. When it is necessary to cut out a boiler the forced draft is shut off, and as soon as the fire is dead the damper is closed.

We referred a description of this accident to three prominent companies, one of them supplying forced-draft equipment with turbine blowers, one supplying forced-draft equipment with steam blowers, and the third a well-known boiler insurance company; also calling their attention to a letter in Power of Mar. 18, 1913, on a carbon-monoxide explosion. Their comments are in part as follows:

First Letter—

We never had any experience of this sort, nor have we ever heard of any with the exception of one case in the writer's early experience with forced draft.

The power plant consisted of six water-tube boilers with which, on account of poor draft, it was difficult at times to keep up steam pressure. The ashpit doors had been removed. The writer recommended forced draft and made a test on one boiler with a turbine blower which was very noisy. To reduce the noise we decided to build a duct around the blower and run it up to within 10 ft. of the boiler-house roof, but as we were not sure that this would give the desired results, we built it of wood and had it lined with shoddy and used cardboard to keep it in place.

During the night the fireman was not able to keep down the steam pressure even with all dampers closed, something which had never happened before, and he closed the ashpit doors of the one boiler which was equipped with the blower, and no doubt also opened the fire-doors of all the boilers. After a while there was an explosion, and the duct caught fire and also set fire to the roof of the boiler room. The writer's explanation of this explosion was as follows: The ashpit doors were closed and the fire-doors open. The damper of the boiler was closed. The duct acted as a chimney and the air went through the fuel bed, caused the formation of carbon monoxide, which went into the ashpit through the blower and up the duct. This heated up the duct, and through leaks around the blower enough air got into the duct to mix with the carbon monoxide and cause the explosion. This experience and other trouble with this particular blower were among the causes that led to the inception of our present type of blower.

We have in the neighborhood of a thousand installations and, as stated before, we have never had trouble on account of carbon monoxide, though many of our installations are operated automatically, so that when the steam pressure goes up both the blower and the damper close and finally shut down completely. Many other forced-draft systems are operated in the same manner.

The letter to "Power" to which you refer is quite interesting, and the only explanation that the writer can give for such an occurrence is that a steam-jet blower was used. This type of blower is small in diameter and the air goes through at a high velocity, and consequently, when shut down little air goes through it by the draft of the chimney. No doubt the damper was also closed, and perhaps just prior to the blower being shut down there was a high rate of combustion and a high temperature of the fuel bed. On account of all this the combustion continued, but not enough air being present, it was incomplete, and carbon monoxide was produced.

With a turbine blower conditions are different. When it is shut down there is enough air going through the fan casing through natural draft to cause complete combustion provided the damper is not entirely closed. We do not recommend stopping the blower, but we have never thought of the carbon-monoxide danger, but simply do not recommend it on account of believing it desirable to change as little as possible the temperature of the fuel bed. In other words, we recommend that the blowers be run at the slowest rate for the lightest load and be speeded up when the load increases.

We do not think it possible that a high percentage of carbon monoxide can be reached with the dampers open and the fire-doors and ashpit doors closed, and we do not think it possible even with the damper closed provided the blower is not being run at full speed at one time and shut down completely afterward. It should be run at as near as possible the same speed all the time, this speed of course depending upon the variation in demand for steam. We have never considered it unsafe to automatically close off the blower when the boiler pressure reaches a certain point, though, as stated before, we do not recommend it. But in view of the two experiences mentioned in your letter we would not now consider it safe to shut the blower completely and the damper at the same time when the temperature of the fire is high. If the damper is open there will be no danger when the blower is stopped provided the blower is large enough so that the air can pass through it by natural draft.

Second Letter—

We have your favor referring to the explosion in a boiler at one of your works. We have heard of this occurring. The case we have in mind was one in which the damper in the stack or main breeching was closed at the time the explosion took place. We can readily conceive of such a condition, that is, damper closed and gases being given off by the coal with insufficient air supply, with the result that a large volume of CO forms. Then when more air is admitted, although the blower is started, it may be possible for an explosion to occur from the higher temperature resulting with a renewal of combustion, particularly if the stack damper is closed and the gases confined.

Apparently, in your case the damper was open, since you point out that the clean-out door in the base of the stack was forced open by the explosion. This would appear to indicate that your stack was small and that the suction was insufficient.

Such explosions are much more likely to occur in the combustion of soft than of hard coal, on account of the presence of the hydrocarbon gases, which are so much more volatile. We are not inclined to believe that so high a percentage of CO can be formed with the damper open, even though both the ash- and fire-doors be closed.

With regard to operation, the method we recommend is the automatic action of the main blower line by means of a balanced valve and automatic regulator, with a bypass around the former so as to keep the blowers going continuously, the regulator taking care of the slight fluctuations in the load. If the load is extremely variable, then it may be possible to install a balanced valve in the bypass where the throttle valve is, this balanced valve being controlled by another regulator to shut off at a point, say 5 lb. higher than the first regulator. If, on the other hand, the periods of high and of low loads are known and are not too frequent, then this condition can be best corrected by opening, more or less, the throttle valve in the bypass to the balanced valve in the blower line.

Third Letter—

We have had considerable experience on gas explosions, due to carbon monoxide from soft coal, from natural gas, etc., but are unable to advise you definitely as to the lowest range or percentage of carbon monoxide and air that would result in an explosion. While this particular feature is worth investigation as of scientific interest, yet the percentage of such air and gas mixtures in a furnace will, of course, vary widely.

Assuming conditions as described in your letter, we presume the fire-doors, etc., were so arranged that no air was permitted to enter above the fire, the supply being from the blower system. Therefore, with the tuyere openings blocked with clinkers and no air admitted above the fire, carbon monoxide would be generated faster than it could escape, and the furnace, and even the chimney (with one boiler chimney), would be filled with carbon monoxide, which would rapidly be built up to a point where it would be explosive.

It seems if the damper had been open, say 50 per cent., when the fireman opened the fire-door the draft would have quickly carried away the carbon monoxide and thus averted the accident. The matter of closing dampers from 75 to 95 per cent. while the furnace is loaded with coal which is setting free its volatile constituents strikes us as wrong. In our opinion the damper should have a limit closure when a boiler is in service.

In the last comment it is evident that the writer overlooked the points that the opening of the fire-door supplied air above the fire and that if the clean-out door in the base of the stack was blown open, the damper must necessarily have been open—as was actually the case. As for the amount of CO necessary for explosion, Von Schwartz, in "Fire and Explosion Risks," cites Professor Bunte, of Carlsruhe, as authority for 16.6 per cent. and 74.8 per cent. as the lower and upper limits of the amount of CO in admixture with air which will permit explosion when ignited by an electric spark, at the same time stating that the explosion of such can be prevented by the addition of 7½ to 10 per cent. CO_2. Von Schwartz also gives the approximate figures of 13 to 75 per cent. for ignition by flame and 636 to 814 deg. C. as the temperature at which pure CO will explode without air.

From a preventive standpoint the comments quoted do not give much information, and we are at a loss to know how to guard against explosions of this character with this particular installation. We have experienced dust explosions from the loosening of deposits of soot in the flues, oil-gas explosions with oil-fired systems, carbon-monoxide explosions from negligence in completely closing stack dampers and also severe accidents from flarebacks from boilers equipped with steam-blower systems—the latter caused by too high steam pressure or by firing the coal too far back in the furnace, where it obstructed the draft. For all these there seem to have been reasonable remedies, but for a case such as that mentioned we see no cure other than instructions to keep the tuyere openings clear of clinkers, which was, after all, what the fireman was trying to do.

A general discussion by qualified persons would be appreciated.

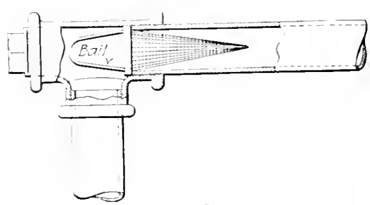
L. A. De Blois,
E. I. du Pont de Nemours Powder Co.

Wilmington, Del.

Strainer in Pump Suction

I have found that a strainer, made as shown in the illustration saves a lot of trouble by preventing small sticks and stones entering the pump and lodging under the valves.

The strainer is made fast to a brass ring, which will hold against the end of the pipe and keep the screen from



Removable Strainer

being drawn into the pump. A handle, or bail, is convenient to pull the strainer out for cleaning. A tee is used in the suction pipe instead of an elbow, and the strainer put in as shown, and a plug is used to close the end of the tee and to make the appliance easily accessible. The mesh of the screen should be suitable to the size of the pump and the kind of service. Brass or copper wire is preferable, but galvanized wire will answer in some cases.

Ithaca, N. Y. John P. Kolar.

Inquiries of General Interest

Side for Connecting Equalizing Switch—On which side of an electric generator should the equalizing switch be connected?

W. H. M.

An equalizing switch is to be connected on whichever side of the generator the series field winding is placed.

Vacuum Not Ascertainable from Temperature—Would determination of temperature of the condensate discharged from a condenser be an accurate method of measuring condenser pressure by ascertaining pressures corresponding to temperatures given in the steam tables?

A. J. F.

The temperature of the condensate would not be a true indication of the pressure, on account of the presence of air in the condenser.

Backfiring Trouble—Would placing a wire screen in the intake pipe of a gasoline engine between the carburetor and cylinder prevent backfiring?

C. E. S.

A screen would undoubtedly prevent backfiring through the intake pipe, but would not remove the cause of imperfect operation of the engine. The backfiring may be due to wrong timing of the ignition, improper seating of the inlet valve, thus allowing the exploding mixture to get by it into the intake pipe, or a combination of a lean mixture and too early ignition.

Measure of Ductility—What is the measure of the ductility of a metal?

E. H.

The percentage elongation and the percentage reduction of area are usually considered together as the measure of the ductility of a metal. After a bar of the material under tensile stress has passed its elastic limit it begins to be permanently elongated in the direction of the pull. The increase in length multiplied by 100 and divided by the original length is the "percentage elongation." When a bar is elongated it shrinks in cross-section, and just before it breaks it usually "necks down" at the point of fracture. The original cross-sectional area minus the area of smallest cross-section after fracture is called the "reduction area," and this difference multiplied by 100 and divided by the original area is the "percentage reduction of area."

Increase of Bolt Tension after Cooling—If a 1½-in. diameter steel bolt is drawn up tight when at the temperature of 160 deg. F., how much will its tension be increased after it has cooled to 70 deg. F.?

R. B. N.

If there is no yielding of the head, nut or screw from compressive stresses, the additional tensile stress in the bolt due to cooling will be the same as that required for elongating the bolt as much as it would elongate or contract for the same change of temperature. The coefficient of lineal expansion or contraction of steel is 0.0000065 of its length per degree change of temperature, and therefore the elongation or contraction per inch of length for a change of 160 — 70 = 90 deg. F. would be

$$0.0000065 \times 90 = 0.000585 \text{ in.}$$

As for steel, the modulus of elasticity, or load per square inch of cross-sectional area divided by the extension per inch of length, is 30,000,000, then for an extension of 0.000585 in. the stress would be

$$0.000585 \times 30{,}000{,}000 = 17{,}550 \text{ lb.}$$

per square inch of cross-sectional area, and for 1½-in. bolt, or a cross-sectional area of

$$1\tfrac{1}{2} \times 1\tfrac{1}{2} \times 0.7854 = 1.767 \text{ sq.in.,}$$

the stress would be

$$17{,}550 \times 1.767 = 31{,}010.85 \text{ lb.}$$

Size of Feed Pump—What size of single feed pump should be employed for a boiler which requires 3850 lb. of feed water per hour?

W. H. M.

A uniform feed-water supply would be equivalent to

$$3850 \div 8\tfrac{1}{3} = 462 \text{ gal.}$$

per hour, requiring a pump displacement of

$$(462 \times 231) \div 60 = 1778.7 \text{ cu.in. per min.}$$

But to meet emergencies the rated capacity should be about double the delivery required for uniform rate of feeding, i.e., neglecting slippage and reduction of piston area due to the piston rod, the displacement capacity should be about 3558 cu.in. per min. Allowing a maximum speed of 60 strokes per minute the piston displacement should be $\frac{3558}{60}$, or about 60 cu.in. per stroke.

To determine the size of water cylinder, either the area of the piston or the length of the stroke must be selected. Neglecting slippage and reduction of the area of piston due to the piston rod and assuming the diameter of water cylinder as 3¼ in., the area of the piston would be

$$3\tfrac{1}{4} \times 3\tfrac{1}{4} \times 0.7854 = 8.2958 \text{ sq.in.}$$

requiring a stroke of

$$\frac{60}{8.2958} = 7.23 \text{ in.}$$

and for most practical purposes the commercial size, 5½x3¼x7 in. (5½-in. diameter of steam cylinder, 3¼-in. diameter of water cylinder, 7-in. stroke) would answer.

Pressure Required for Running Noncondensing—If an engine, operated with steam at an initial pressure of 120 lb. absolute, ¼ cutoff and 26 in. vacuum, loses its vacuum, what initial pressure would be required to operate the engine noncondensing with the same length of cutoff, the valve setting and load remaining unchanged?

S. S.

The mean forward pressure per pound of initial is given approximately by the formula

$$P_m = (1 + \log_e R)\ (f + c) - c$$

in which

P_m = Mean forward pressure per pound of initial (absolute);

$\log_e R$ = Hyperbolic logarithm of the ratio of expansion;

R = Ratio of expansion $= \frac{1+c}{f+c}$

f = Fraction of stroke completed at cutoff;

c = Clearance per cent. of piston displacement.

Assuming 5 per cent. clearance, the ratio of expansion would be

$$\frac{1+c}{f+c} = \frac{1+0.05}{0.25+0.05} = 3.5$$

and as the hyperbolic logarithm of 3.5 is 1.2528, the mean forward pressure per pound of initial would be

$$(1 + 1.2528)\ (0.25 + 0.05) - 0.05 = 0.6258 \text{ lb.}$$

and for 120 lb. initial absolute the mean forward pressure would be

$$120 \times 0.6258 = 75.1 \text{ lb.}$$

When running condensing with 26-in. vacuum the back pressure would be

$$30 - 26 = 4 \text{ in. mercury,}$$

or

$$4 \times 0.491 = 1.964 \text{ lb. absolute,}$$

and the m.e.p. of an ideal diagram would be

$$75.1 - 1.964 = 73.136 \text{ lb. m.e.p.}$$

but when running noncondensing the back pressure would be about 1.5 lb. gage, or about

$$15 + 1.5 = 16.5 \text{ lb. absolute}$$

and to obtain the same m.e.p. (73.136 lb.) for the ideal diagram the mean forward pressure would need to be

$$73.136 + 16.5 = 89.636 \text{ lb.}$$

If in each instance the actual is the same per cent. of the ideal diagram, and as the mean forward pressure when cutting off at ¼ stroke is 0.6258 lb. per pound initial absolute, then to realize a mean forward pressure of 89.636 lb. absolute would require

$$89.636 \div 0.6258 = 143.2 \text{ lb. absolute,}$$

or about

$$143.2 - 15 = 128.2 \text{ gage pressure.}$$

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Convertible Combustion Engines*

By Alan E. L. Chorlton

One might at first sight say that the combustion engine most ready to work on different fuels would be of the self-ignition type, in which the heat of compression is sufficient to ignite the incoming fuel, and the only change necessary in going from liquid to solid fuel would be in the fuel-injection device. In practice, however, owing to the difficulty with solid-fuel injection, such a type would not prove workable, and even when the fuel is first gasified the results do not justify the complication. The problem of designing an engine is better met by trying to combine known types for gas and oil, in which good results are obtained at present and which in general principles show the same characteristics.

In the normal engines for both gas and oil the chief difference lies in the degree of compression. Thus, the compression of a modern gas engine may vary from 90 lb. when using coke-oven gas, to 150 lb. for producer gas; while for the liquid-fuel engine using crude or residual oils the compression pressure may exceed 500 lb., but may be considerably less if the temperature of ignition is obtained by uncooled surfaces or auxiliary or pocket firing is used.

As there is no fundamental difference in engines for gaseous or liquid fuels except in their conventional cycles, it follows that any schemes of convertibility must provide means whereby the requisite compressions can be readily obtained, but as there is a great gap between 500 and 150 lb., the tendency is to combine the lower-compression oil engine and the higher-compression gas engine and thus deal with a smaller compression-pressure range. The desirable characteristics of the convertible engine are: Simplicity and reliability, high economy for each fuel, first cost (little above that of the standard engine), easy convertibility, and as nearly as possible the same power developed for each fuel.

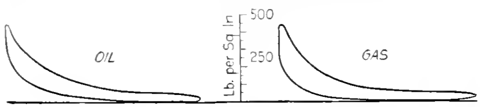


Fig. 2. Indicator Diagrams with Oil and with Gas

Consideration of the subject may be more clearly undertaken by dividing the types of engines in use into three groups, with further subdivisions, due to peculiarities of design: (1) Engines of low compression and low power; (2) engines of high compression and higher power; (3) engines of medium compression and higher power.

GROUP 1—As an example of the first group, take the ordinary motor-car engine having a compression up to 90 lb., and which, with slight modifications, will run on gasoline, good kerosene with an exhaust-heated carburetor, town gas and producer gas. It is designed for and works best on gasoline; fairly well, however, but not so economically, on town gas; requires very good kerosene and is not efficient at the low-compression with producer gas.

To extend the range to use a poorer grade of kerosene or a good grade of crude oil, means must be provided whereby more heat is available for the ignition. This can be conveniently done by the addition of an unjacketed portion to the cylinder head; then the engine becomes of the hot-bulb type. A change of parts for such an engine does not present any difficulties. The gas fittings are provided with electric ignition, which is also suitable when gasoline is used, while the kerosene and good crude oil would be self-ignited by the hot bulb. Fig. 1 illustrates the practical application of these modifications. The results obtained with this engine, are:

	Compression, Lb. per Sq.In.	Maximum Pressure, Lb.	M.E.P. Lb.	B.t.u. per B.hp.-hr.
Kerosene	55	210	58	14,500
Producer gas	90	230	65	12,000

This type of engine is suitable only for comparatively low powers, and the range of fuels does not include any heavier than good crude oil. Furthermore, its economy on oil is not high. It is described here because it contains the basic principles of a more suitable engine for large powers.

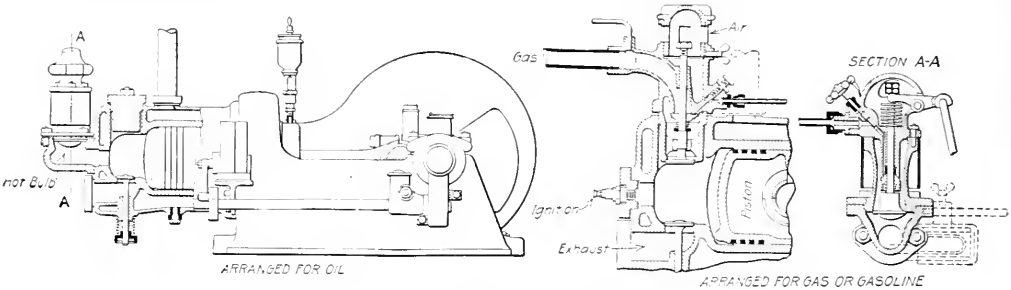

Fig. 1. Convertible Engine for Small Powers Using Gas and Liquid Fuel

GROUP 2—This group is represented by the Diesel engine, with a compression of over 500 lb. when using tar oils (unless an ignition oil is used). As the maximum compression for gas normally does not exceed 150 lb., there are mechanical difficulties in building an engine in which both of these compressions can be obtained with reasonable modification. Furthermore, the Diesel has an expensive high-pressure compressor which is unnecessary for the ordinary type of gas engine. Apart from mechanical difficulties, we may compare the commercial possibilities of this type, the oil and gas sides being as follows for engines of the same cylinder dimensions:

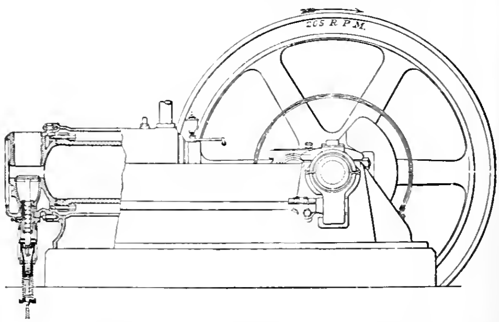

Fig. 3. Convertible Engine with Exhaust Valve Attached but without Head

	Compression, Lb. per Sq.In.	Abnormal Maximum Pressure, Lb.	M.E.P. Lb.	Approx. B.t.u. per B.hp.-hr.
Oil engine....	500	Over 1000	100-110	8000
Gas engine...	150	600	80	8500

These figures show how incompatible the two designs are, for they illustrate that the Diesel structure must be built twice as strong for the very high maximum possible pressure, owing to the fuel valve sticking, etc. The higher

*Read before the Institution of Mechanical Engineers, London, on Feb. 19, 1915.

mean effective pressure used is some compensation for this extra cost and weight. The mean cylinder pressures reveal a still further disadvantage when the gas conversion is considered; for besides this high first cost, there is a reduced power, owing to working at a lower mean effective pressure—80 as against 100-110 lb. A convertible engine on these lines does not seem a commercial possibility.

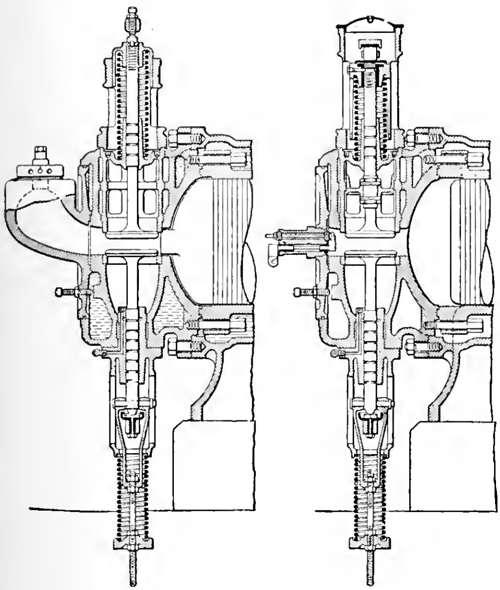

FIG. 4. SAME ENGINE AS IN FIG. 3 ARRANGED FOR OIL AND FOR GAS

GROUP 3—The range of the compression of these engines lies between that of Groups 1 and 2, and usually is from 150 to 300 lb. A compression of 150 lb. is suitable for most forms of producer gas, but because of preignition it is not usually exceeded. On the other hand, it is necessary for all compressions below self-ignition pressure to employ some auxiliary means to obtain the necessary temperature for the proper combustion of the residue oil. Normally, the additional heat is obtained by an unjacketed surface or ignition bulb at the cylinder end.

The various devices concerning temperatures, compression and convertibility of this group may be considered by subdividing it under the following heads:

a. Engines working with a compression not exceeding 150 lb. both for oil and gas, and which may employ pocket-firing with or without air injection for one and electrical ignition for the other, or some combination, the smaller compression not involving material mechanical changes of the parts.

b. Engines working with a higher compression for oil than gas, involving some modification of the combustion chamber by substitution of a part for oil as against a part for gas; otherwise maintaining the simplicity of both types.

c. Engines obtaining the necessary change from gas to oil by temperature control of the air charge, together with alteration of the valve settings.

d. Engines employing the super-compression of Dr. Dugald Clerk, to control effectively the compression required for either fuel. (Final ignition temperature by other means.)

Under subdivision a there are a large number of engines used only for oil, but which might, without much alteration, become effective in the use of gas, although the whole combination is not as efficient as the highest individual member.

In considering division b, a useful comparison of its possibilities is given in tabular form, for engines of the same cylinder dimensions:

	Compression, Lb. per Sq.In.	Abnormal Maximum Pressure, Lb.	M.E.P. Lb.	B.t.u. per B.hp.-hr.
Oil engine.........	250-280	600	80	8100
Gas engine.........	150	600	80	8500

It will be seen from this that the outputs and general figures relative to the engine bear a great similarity. Moreover, the diagrams of Fig. 2, taken when running on oil and on gas, are similar. Therefore, the possibilities of this type of convertible engine appear great, and an engine which has been made in considerable numbers to fulfill these conditions is shown in Figs. 3 and 4. (Built by Messrs. Ruston, Proctor & Co., Ltd.) These views show clearly that in both cases the engine presents the ordinary features of the four-stroke-cycle type, and the only change involved in converting from oil to gas lies around the combustion bulb of the oil engine, and in the change from an oil-type to a gas-type piston.

The arrangements in division c may be justified for mechanical and constructional convenience, but they can hardly be defended on the score of efficiency. In one method the jacket of the cylinder cover is formed to withstand a pressure, and is worked in the manner of a boiler. The increased heat is impressed in the charge of air during the compression stroke to raise the temperature sufficiently for ignition. This arrangement thus replaces the hot-bulb or unjacketed end of the cylinder. It has some advantages, in that it is perhaps more controllable and the steam generated may be used for some useful purpose, perhaps in conjunction with an exhaust-heated boiler for an auxiliary steam cylinder on the main engine. The water injection of some hot-bulb engines is also done away with. This type of engine is unusual in practice.

When in use as a gas engine, such a convertible machine would have to dispense with the pressure-jacket temperature when using the lower compression and temperature needed for such an engine. Actual heating of the inlet air may be a practical convenience for dealing with a particularly refractory oil not amenable to the available compression of the engine. The valve setting may be modified to give suitable compressions for oil and gas; this can be worked in conjunction with the temperature arrangement just described. The gas engine, however, suffers in loss of output.

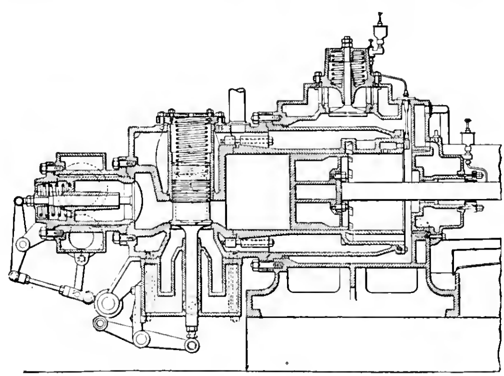

FIG. 5. SECTION THROUGH CLERK SUPER-COMPRESSION ENGINE

The Clerk super-compression engine (Fig. 5) is a much more suitable and promising type for dealing with the variable compression problem of the convertible engine. In this, an extra charge of air or inert gas is added to the working mixture at the end of the suction stroke, by which means much lower maximum flame temperatures are obtained and a higher mean cylinder pressure is rendered possible. As a convertible engine, it is particularly suitable, for by varying this amount of added air the compression can be adjusted between wide limits, the final temperature being controlled by any of the previously indicated means. For instance, with a compression of 300 lb. maximum, the full displacement of the air pump may be used; for the lower compression of the gas engine one can, by any suitable valvular means such as an ordinary bypass, reduce the amount of discharge as required.

CONCLUSION—The conclusions of the author are that, for powers up to say 1000 b.hp., a type such as the Ruston is the most suitable as a convertible engine, while for still larger powers, when tandem engines and size and weight of removable parts become a problem, the Clerk super-compression type offers very interesting and hopeful possibilities in this field.

Troubles Encountered with Carbon Brushes*

By E. H. Martindale

SYNOPSIS—The paper is divided into five sections, based on the location of the cause of the trouble: (1) field, (2) armature, (3) commutator, including brush rigging, (4) external electrical, and (5) external mechanical.

The characteristics of carbon brushes which commonly affect the operation are resistance, hardness, abrasiveness, coefficient of friction, contact voltage drop and heat conductivity. None of these terms needs explanation, but the writer wishes to emphasize the importance of not confusing hardness with abrasiveness. By abrasiveness is meant the scouring or cutting action of the brush. Relative hardness may be judged by cutting the brush with a pocket knife or by marking with it on paper, or if more accuracy is desired, a set of pencils from 2B to 8H will be an aid, as a pencil softer than the brush will mark it and one harder will scratch it. The hardest brush with which the writer is familiar has no abrasive action, while one of the softest has a decidedly abrasive action.

FIELD TROUBLES

As the field coils are connected in series or series parallel, a partial short-circuit may occur in one coil without materially affecting the heating of the coil. This is usually attended with severe sparking at one or two studs, although in a wave-wound machine the commutation may be little affected. This trouble can best be located by noting the voltage drop across each coil with a constant current through the coils. Similar trouble may be caused by an error in rewinding a field coil. On some machines the shunt fields are connected with two or three fields in series and two or more of these groups in parallel. A partial short-circuit in one coil will then affect the entire group, electrically unbalance the machine, and cause heavy short-circuit currents.

In a cumulative compound machine one series field may be reversed accidentally and, as the load increases, sparking will occur usually at two adjacent studs; or the entire series field by mistake may be connected to oppose the shunt field, which will result in blackening of the commutator, with severe sparking at heavy loads. The best way to detect this is to excite separately the shunt and the series fields, being sure that the current flows in the same direction as when the machine is in operation. The polarity of each pole should be tested with a compass and should reverse as the compass is passed from one pole to the next. Furthermore, the polarity of each should be the same when either field is excited. In a generator the voltage will decrease and in a motor the speed will increase as the load increases.

Unequal air gaps are responsible for much commutation trouble. If one pole face is nearer the armature the flux across the gap is greater and a higher voltage will be developed in the coils under that pole. This may result in heavy short-circuit currents between the studs adjacent to that pole and other studs of the same polarity.

ARMATURE

An open circuit in an armature coil causes the most vicious form of sparking, accompanied by pitting of the mica between the commutator bars connected to this coil and the adjacent ones. The usual method is to connect an incandescent lamp in a testing circuit, and with two pointed terminals make a bar to bar test on the commutator; the open circuit is shown when the lamp does not light. Similar sparking in a lesser degree may be caused by a high-resistance connection between the end of a coil and the commutator riser. This can be detected by passing a current through the armature and noting the voltage drop between adjacent bars, as the voltage will be higher than normal when the poor connection is in the circuit measured. This method may also be used to detect an open circuit, but a voltmeter reading as high as the voltage impressed on the armature must be used.

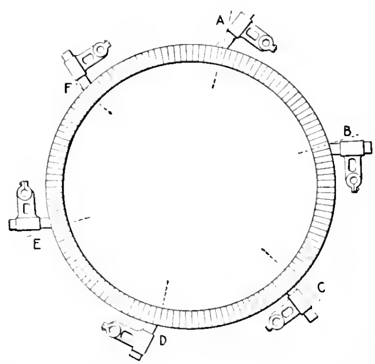
A short-circuit between two sections of a coil, two coils in the same slot, the end connections of two coils, or between the commutator bars, will be evidenced by excessive heating of the coils affected, and unless repaired will sooner or later result in a burned-out coil. The same method may be used as in the preceding case, and the voltage between adjacent bars when the coil is in the circuit will be below normal.

The demagnetizing and cross-magnetizing actions of an armature have serious effects on the commutation of many machines. To get good commutation in a non-interpole machine, the brushes usually must be set ahead of the mechanical neutral on a generator and back of the mechanical neutral on a motor.

If the brushes are shifted far to obtain good commutation, and if the magnetization of the polepieces is not well above the knee of the saturation curve, the demagnetizing effect of the armature may seriously reduce the voltage of a generator or increase the speed of a motor. On the other hand, the cross-magnetizing effect may be sufficient, if the brushes are not shifted to the electrical neutral, to place the coils undergoing commutation in a heavy field, with resultant heavy short-circuit currents, severe sparking at the brushes and all the attendant evils. The remedy is to widen the neutral field by filing away the edges of the polepieces.

COMMUTATOR

Commutator-brush troubles are numerous, and often difficult to identify. One of the most troublesome problems with non-interpole generators or motors which do not operate at constant load is the difficulty of finding a point at which the brushes will operate at all loads without injurious sparking. This is due to the cross-magnetizing action described.



Unequal Spacing Due to Brush-Holders Being Rotated Too Far

Spring tension, or the pressure with which the brushes bear on the commutator, seldom receives proper attention. The most economical pressure is the lowest consistent with a low contact loss, a clean commutator and freedom from sparking, glowing or pitting of the brushes. It is seldom advisable to use a pressure less than 1½ lb. per sq.in. of cross-section. The writer recommends on stationary machines a pressure of from 2 to 4 lb., depending on local conditions and the grade of brush; and from 4 to 8 for crane motors, haulage motors, railway motors and similar machines.

Brush spacing is important, but is usually neglected. In the sketch the studs are equally spaced and the dotted lines show the correct brush position, but owing to the brush holders on arm A being rotated too far in one direction and on arm C too far in the opposite direction, the voltage generated in section ABC is different from that in AFE or CDE, and this will result in short-circuit currents between A, E and C, high enough to neutralize the unequal voltage.

The magnitude of this short-circuit current may be illustrated by a test conducted a few years ago by the writer on a 400-amp., 250-volt, six-pole shunt generator. On one positive stud the brush holders were rotated to place the brush ¾ in. ahead of the correct position; the other positive studs were left unchanged. With the brushes incorrectly

*Excerpts from paper read before the Cleveland Section, A. I. E. E., March 18, 1915.

spaced but operating at the best point, the short-circuit current was not excessive. When the brushes were shifted two bars away from the neutral and with no external load on the machine the short-circuit current rose to 800 amp., or twice the normal full-load current. As the voltage back of this current was low the actual power loss was small, but the heating of the windings and the effect on the commutator and brushes were serious. This is an extreme case, but a smaller difference in spacing may often be serious.

From the time a commutator bar touches one edge of a brush until it leaves the opposite edge, the current in the coil undergoing commutation should fall from full load to zero, and rise in the opposite direction to full load. If the current in the coil is more or less than that value, the final adjustment comes as a sudden rush of current as the bar leaves the brush. In many machines the time of commutation is less than 0.001 sec. The brushes should therefore be shifted to a point where the coils undergoing commutation are in a field strong enough to make this change. If the brushes are too thin, sufficient time is not allowed for commutation, and if too thick, the coil may over-commutate.

If there is not sufficient clearance between a brush and its holder or if foreign matter becomes lodged in the holder, the brush will not move freely and may make poor contact, resulting in blackening of the commutator, sparking, heating and other evils.

On the other hand, if there is too much clearance and the brushes are not equipped with shunts, the current may pass from the brush to the brush holder through a small arc and cause undue wear of the holders. On machines which have been in service a long time trouble frequently arises from worn holders. This is particularly true if the machine runs in both directions, as the brush face changes when the machine is reversed and thereby reduces the time of commutation and increases the current density in the brush faces. Brushes in worn holders are also more inclined to chatter and chip.

Brushes are sometimes ordered longer than standard with a view to securing a long life, but the spring usually gives a side push and causes trouble, which shortens the life of the brushes and perhaps damages the commutator.

Noise of carbon brushes is due to a mechanical vibration called chattering. If due to the friction of the brush on the commutator, the noise may have various pitches. The remedy is a change in spring tension, angle of operation or grade of brush, although relief may be obtained by lubrication of the commutator at intervals. If the noise results from high mica or wide slots in a slotted commutator, the pitch of the sound will correspond to the number of bars passing under the brush in a second. If the noise is caused by slots, it may be necessary to change the spring tension, the angle of operation, or grade of brush, as lubrication is not advisable on a slotted commutator.

Pitting or honeycombing of the brush faces is nearly always caused by short-circuit currents or a very low brush pressure, but occasionally it is due to insufficient current carrying capacity of the brushes. Many cases of pitting may be corrected by reducing the thickness of the brushes, but it is better to look for some other cause first, as already described.

A loose commutator bar may be flush with other bars when the machine is stationary, but may be thrown out slightly when running, owing to centrifugal force. This will lift the brush and will burn one or more bars just ahead of the high bar, depending on the number which the brush spans, and further, will burn some of the bars back of the high bar, depending largely on the speed of the machine and the brush pressure. Its presence can often be detected by the knocking sound of the bar hitting a brush once every revolution.

In repairing commutators and sometimes in manufacturing them, commutator bars of different hardness are used, and one bar may wear faster than another, causing a flat spot or a high bar.

Blackening of a commutator may be caused by sparking, the use of too much lubricant, or by the character of the brush. Blackening will sometimes occur on every alternate bar or every third bar, corresponding to the number of coils per slot, and may often be shifted to another group of bars by shifting the location of the brushes. This seems to be due to a magnetic kick in the coil undergoing commutation when the armature tooth next to the coil suddenly leaves the field. The remedy is to have the neutral field wide enough to permit the tooth to leave the strong field before the commutator bar comes under the brush.

The best practice in commutator slotting consists in undercutting the mica about 3/64 in. below the surface of the commutator. It is important that great care be exercised to see that all the slots are free from strips or particles of mica flush with the commutator. It is not advisable to use lubricant or artificially lubricated brushes on a slotted commutator, as the lubricant may get into the slots, collect dirt and cause short-circuits between bars. On slow-speed machines, where the peripheral speed is not sufficient to throw out particles of dirt, the commutator slots should be blown out or scraped out at regular intervals. On a slotted commutator a brush with no abrasive action may be used and will result in long life of the commutator and brushes. A non-abrasive brush or a self-lubricating brush does not necessarily mean a soft brush.

Heating of the commutator on a machine may be caused by any form of sparking, short-circuit currents, friction of brushes, high brush pressure, too low brush pressure causing high contact loss, dirty commutator, overloads, too small commutator, resistance of windings, loose connections, eddy currents and hysteresis. As the ultimate capacity of a machine depends on the allowable temperature rise, it is important to prevent heating wherever possible.

OUTSIDE ELECTRICAL CAUSES

Outside electrical causes of commutation trouble may be briefly stated as overloads, line surges, and cross currents between two or more machines running in parallel. Where the angular speed of a reciprocating engine varies greatly, surges may occur, caused by a slight reduction in speed of motors on the circuit when the voltage is low and a consequent rush of current when the voltage reaches its maximum. It may be impossible to locate surges or cross-currents without the use of an oscillograph.

OUTSIDE MECHANICAL CAUSES

If an armature is mechanically unbalanced severe vibration may occur, especially if it is run at high speed. This may produce flat spots, unbalanced electrical conditions, loosening of commutator bars and other serious troubles.

If the machine is on unstable foundations similar troubles may be experienced, owing to vibration of the entire machine. In this class may be placed crane motors and similar machines which, however, are usually designed with this factor in view. Poor belt lacing or uneven gears may produce vibration or strain, with the same results.

Condenser-Tube Corrosion

The third part of the Institute of Metals' "Contributions to the History of Corrosion" has been issued. It consists of a contribution by Arnold Philip, Admiralty chemist, attacking the conclusions of G. D. Bengough and R. M. Jones, and a supplement containing their reply. An abstract of the first two parts appeared in "Power," Dec. 2, 1913, page 781.

We do not reproduce the third part at length, as it seems largely to reinforce Bengough and Jones' original work and conclusions, namely, that entrained pieces of coke are not grave causes of condenser-tube corrosion. Some of their minor points concerning the technique of their experiments may, however, be of interest.

The point is made that the method of determining loss of weight is of little use in investigating corrosion. Of all failures, 90 per cent. "are caused by local dezincification, and when once this has been started loss-of-weight methods are useless. The action was quite local and irregular, and the white zinc salt was strongly adherent and usually could not be removed without injury to the underlying oxide layer."

The authors conclude that, consequently, a means of detecting dezincification is the only rational way of detecting the progress of corrosion. Here they leave us at sea. The only method available giving actual measurement seems to be microscopic investigation, especially of sections cut at right angles to the supposed dezincified spot. This involves destruction of the specimen. The next best is a hardness test by rubbing with a blunt steel needle, the dezincified area being softer than the unchanged brass. In fresh specimens the eye with proper training can detect the dezincified spots, even in the early stages; in old specimens the copper oxidizes, and this copper cannot be told from the ordinary oxide layer.

Another point made is that when various plates of metal are being tested for resistance to corrosion it is not fair to take pieces of tube and flatten them, or clean them, or anneal, or in any other way alter the normal skin of the metal. After attention has been called to this it seems self-evident, yet we have known cases where it has not been observed.

Another point spoken of is that sea water to which sufficient sodium carbonate has been added to make it alkaline in reaction instead of neutral, as is normal sea water, is much more active in producing dezincification than the normal sea water. Here is a practical point in condenser practice.

St. Louis Consumers Protest against Rates

The Engineers' Incitation Club, representing consumers of electricity in St. Louis, has filed a petition with the public-service commission of Missouri, protesting against the alleged discriminatory rates charged by the Union Electric Light & Power Co., of that city. The present maximum rate to small consumers is 10c. per kw.-hr., whereas it is charged that certain large consumers pay less than 1c. per kw.-hr. The petitioners would have the rate fixed at a maximum of 5c. per kw.-hr. for the first 120 hr. of installed capacity used per month, with all in excess thereof at 2½c. per kw.-hr.

It appears that the Union Electric Light & Power Co. procures a large portion of its supply from the Keokuk hydro-electric development. This power is generated by the Mississippi River Power Co., but instead of purchasing direct from this company the defendant buys through intermediary companies known as the Mississippi River Power Distributing Co. and the Electric Co. of Missouri. It is alleged that these corporations are under common control and through collusive agreements are defeating the purpose of Congress in making the water-power grant, and instead of the public being the beneficiaries of low rates, a few promoters and stockholders in the companies mentioned are reaping the benefit.

ENGINEERING AFFAIRS

American Association of Refrigeration Meeting—The fifth annual meeting of the American Association of Refrigeration will be held at the Hotel Astor, New York City, May 11 and 12. There will be important reports from officers and standing committees and commissions of the association, including a detailed financial statement of the Third International Congress of Refrigeration.

The Ohio Society of Mechanical, Electrical and Steam Engineers will hold its next meeting June 17 and 18, at Toledo. Plans are being made for an outing, together with the regular reading and discussion of papers. Among papers to be given are: "Firebricks for Boiler Settings," by W. G. Heisel; "Some Features of the Cleveland Municipal Lighting Station," by F. W. Ballard; "Low-Pressure Turbines," by a representative of the General Electric Co., and "Attainment and Maintenance of Boiler-Room Efficiency," by a representative of the Harrison Safety Boiler Works.

The American Boiler Manufacturers' Association and the National Tubular Boiler Association at a joint meeting held in Pittsburgh on Mar. 29 unanimously approved the Code of Boiler Specifications prepared by the committee appointed for that purpose by the American Society of Mechanical Engineers, and steps were taken toward securing its adoption by the various states. Several of the members and the representative of a prominent boiler-insurance company declared that they should adopt it as their standard, whether compelled to by legislation or not.

The National Gas Engine Association is to hold its annual meeting on June 23 and 24 at the La Salle Hotel, Chicago. Reports will be presented by the Standardization, Insurance, Cost Accounting, Legislative and Publicity committees. The following papers are scheduled: "The Data Work," by Prof. P. S. Rose; "Educating the Buyer to Your Type of Engine," by H. G. Diefendorf; "Possibilities of the Farm Lighting Plant," by C. H. Roth; "What of the Kerosene Engine?" by C. E. Bement; and papers by unannounced speakers on "The Future Work of the Association," "How Dealers May Be Induced to Buy for Cash" and "The Magneto of the Future." An accessory exhibition will be arranged, space in which can be secured by addressing the secretary, H. R. Brate, Lakemont, N. Y.

NEW PUBLICATIONS

COAL GAS RESIDUALS. By Frederick H. Wagner. Published by the McGraw-Hill Book Co., 239 West 39th St., New York, 1915. Cloth; 179 pages; 6x9 in. Price, $2.

Convinced that, even under normal conditions, the recovery of coal-gas residuals is an important means of conserving our natural resources, Mr. Wagner has described German theory and practice in recovering coal gas byproducts and has given estimates of initial and operating costs and of the possible income from the production of tar, naphthalene, cyanogen, ammonia and benzol. Coke is not considered, but is to be treated in a separate volume. Most of the methods outlined were devised by the German chemist Feld, and relate to installations in Germany. Unfortunately, no photographs are given, but the book is illustrated by drawings of the different apparatus required.

BOOKS RECEIVED

PRACTICAL IRRIGATION AND PUMPING. By Burton P. Fleming. John Wiley & Sons, Inc., New York. Cloth; 226 pages, 5½x8¼ in.; 27 illustrations; tables. Price, $2.

HEATING AND VENTILATING BUILDINGS. By R. C. Carpenter. John Wiley & Sons, Inc., New York. Cloth; sixth edition; 598 pages, 6x9¼ in.; 290 illustrations; tables. Price, $2.

HEAT ENGINEERING. By Arthur M. Greene, Jr. McGraw-Hill Book Co., Inc., New York. Cloth; 462 pages, 6x9½ in.; 198 illustrations. Price, $4.

CENTRIFUGAL PUMPS. By R. L. Daugherty. McGraw-Hill Book Co., Inc., New York. Cloth; 192 pages; 6x9½ in.; 111 illustrations; tables. Price, $2.

VOCATIONAL MATHEMATICS. By William H. Dooley. D. C. Heath & Co., New York. Cloth; 341 pages; 5x7½ in.; illustrated; tables. Price, $1.

TRADE CATALOGS

McNab & Harlin Mfg. Co., 55 John St., New York. Bulletin. Brass fittings. Illustrated, 5x7 in.

Trill Indicator Co., Corry, Penn. Booklet. Outside spring engine indicator. Illustrated, 16 pp., 6x9 in.

The Scranton Pump Co., Scranton, Penn. Bulletin No. 101. Duplex piston pumps. Illustrated, 16 pp., 6x9 in.

Armstrong Cork Co., Pittsburgh, Penn. Folder. Nonpareil high-pressure covering for boilers, etc. Illustrated.

"Gripwell" Pulley Covering Co., Candler Building, New York. Folder. Gripwell pulley covering. Illustrated.

The Lagonda Mfg. Co., Springfield, Ohio. Catalog W-1. Lagonda locomotive arch tube cleaners. Illustrated, 12 pp., 6x9 in.

York Mfg. Co., York, Penn. Booklet. Ice-making and refrigerating machinery, ammonia fittings and supplies. Illustrated, 20 pp., 6x9 in.

Automatic Steam Trap & Specialty Co., Detroit, Mich. Catalog No. 8. Barton expansion automatic steam trap. Illustrated, 16 pp., 3½x6 in.

Hercules Float Works, 200-10 Franklin St., Springfield, Mass. Catalog. Seamless copper floats and air chambers. Illustrated, 8 pp., 4x8½ in.

Harbison-Walker Refractories Co., Pittsburgh, Penn. Catalog. Silica, magnesia, chrome and fire clay brick, etc. Illustrated, 160 pp., 4x6½ in.

Yarnall-Waring Co., Chestnut Hill, Philadelphia, Penn. Bulletin R. A. Richards unloaders for air compressors. Illustrated, 8 pp., 6x9 in.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Bulletin No. 34-M. Class O steam and power driven compressors. Illustrated, 36 pp., 6x9 in.

BUSINESS ITEMS

Swift & Co., Chicago, Ill., have recently placed an order with the Builders' Iron Foundry, Providence, R. I., for an extra heavy 4-in. Venturi meter tube with type M register-indicator-recorder for use on their boiler feed service.

The Ingersoll-Rand Co., 11 Broadway, New York, has just issued Form 3015, "Portable Air Compressors," which is a 32-page illustrated treatise on the subject of portable air-compressing outfits. Copies are mailed free on request.

The American District Steam Co., of North Tonawanda, N. Y., has opened offices at Suite 610, West Street Building, 140 Cedar St., N. Y. This office will be in charge of G. C. St. John, formerly president of the New York Steam Company.

The Elliott Co., 6908 Susquehanna St., Pittsburgh, Penn., has published two new leaflets of interest to power-plant men, one on twin oil strainers, type "U," and the other (Bulletin J) on pump governors. Copies will be sent on application to the company.

J. G. De Remer, member of the American Society of Mechanical Engineers, American Institute of Electrical Engineers, and formerly chief mechanical and electrical engineer of the United Light & Power Co., San Francisco, has been made manager of the general engineering department of the American District Steam Co., of North Tonawanda, N. Y.

The Canadian Fairbanks-Morse Co., Ltd., has been appointed selling agent in Canada for Penflex metal hose, manufactured by the Pennsylvania Flexible Metallic Tubing Co., Broad and Arch St., Philadelphia. The Canadian Fairbanks-Morse Co. has branches in 14 of the largest cities of Canada, and will carry a complete stock of Penflex in different sizes and styles at its different warehouses, so that Canadian consumers will have the same service as purchasers on this side of the boundary.

POWER

Vol. 41 NEW YORK, APRIL 27, 1915 No. 17

The Old Standby

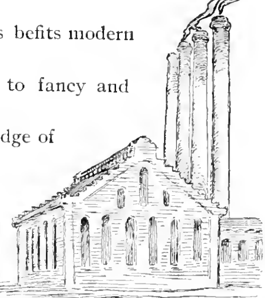
By R. T. Strohm

SUNDAY SUPPLEMENTS often attract
our attention
By printing, with scareheads two inches
in height,
An extended account of some splendid invention
Whose wonderful value has just come to light.
We are calmly assured that, for turning out
power,
This latest contraption will soon be supreme,
But its memory lives for a day or an hour,
And still we rely on the pressure of steam.

Just as likely as not, it's a new style of turbine,
Designed to be run by the ambient air,
And adapted for service in regions suburban,
In cities, in deserts, and most anywhere;
Or if not, it's a waterwheel, complex and weighty,
Intended to turn in the rush of a stream,
With a total efficiency far above eighty—
Yet still we depend on the power of steam.

Now and then it's a form of perpetual motion,
Producing its energy quite without cost,
Or perhaps it's a wave motor set in the ocean
To harness the forces that long have been lost.
And our minds are amazed at the marvels of
science
Displayed in each clever, ingenious scheme,
But we pass them all by, and we pin our reliance
On motors deriving their power from steam.

We are told that the gas engine sooner or later
Will drive out the type that we credit to Watt,
But as gas-fuel prices grow steadily greater,
Deep down in our hearts we are sure it will
not.
So we dig out our books, as befits modern
toilers,
And leave the romancer to fancy and
dream,
While we add to our knowledge of
engines and boilers,
Convinced that there's
always a future for
steam.



Diesel-Engine Central Station at Winchester, Ind.

By Thomas Wilson

SYNOPSIS—A 400-kv.a., two-unit plant generating current for light and power and the pumping of city water. Fuel costs less than 1/4c. per kw.-hr. The operating cost is 0.457c., and including overhead, the total cost is 0.96c. per kw.-hr.

In the past few years the Diesel engine has made rapid progress, and it is now generally conceded that there are certain fields in which it excels. Where oil can be bought at a reasonable figure, these engines, as now made, show remarkable results. The initial expense is high, but this is offset by an operating cost so low that the total per unit of output will fall below that of the average steam plant. There are no stand-by losses, and with proper care, maintenance is no higher than with steam. The engine may be brought into service on short notice, and the labor required to operate is less than would maintain a steam plant of equal capacity. In plants under 1000 hp., such as would be employed in small factories or for the lighting of small towns, the Diesel engine is at its best.

An interesting example of a small central station tending to prove the above assertions may be found in Winchester, Ind., which has a population of 5100. The plant, which is operated by the Citizens Heat, Light & Power Co., contains two 200-kv.a. units, furnishing commercial and street lighting for Winchester and four adjacent towns. Power service is supplied over the same circuits, and at the station, current for pumping water to the home town and to run the air compressors serving the prime movers. Three-phase current is generated at 2300 volts. During the day one unit will carry the load, which runs up to 160 kw. At the peak, which lasts from 5 to 10 p.m., the load is practically double, and in the morning hours it is comparatively light. It is thus evident that one machine must be operated continuously and the other for five hours, the two running in parallel. During the latter period there is no reserve unit. Both machines must operate every day, and for the past two years and three months, during which they have been in service, this schedule has been maintained without a shutdown.

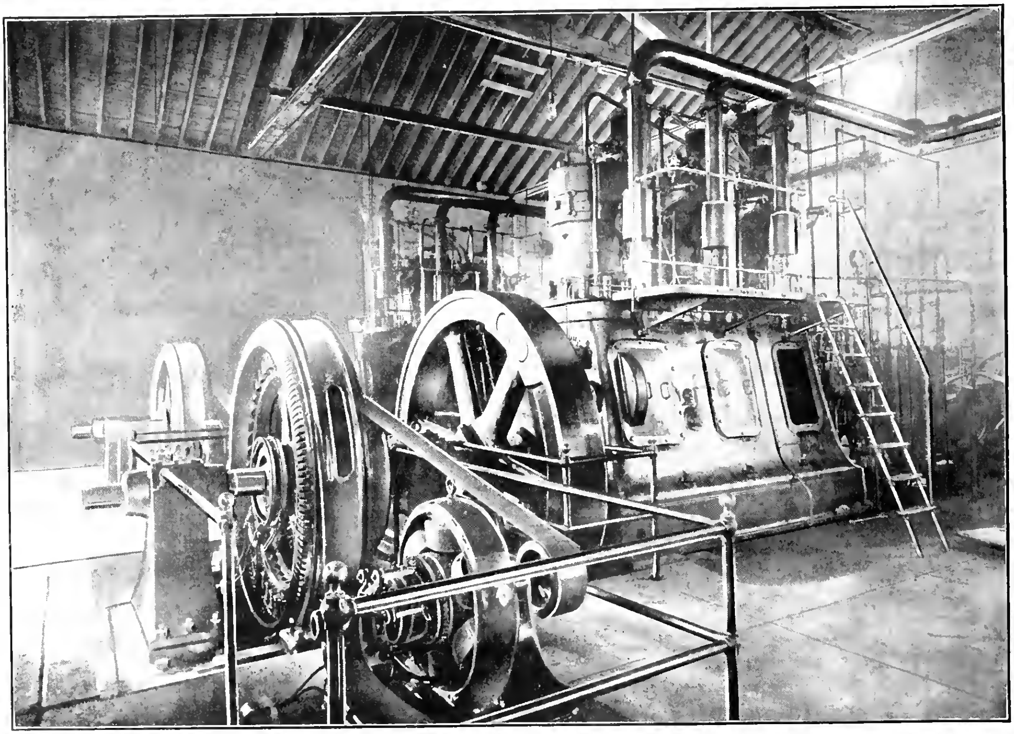


Fig. 1. Diesel-Engine Units

The engines are of the three-cylinder vertical type, 16x24 in., with a speed of 165 r.p.m. They are rated at 225 hp. and are connected directly to 200-kv.a., three-phase, 60-cycle generators, which, at 80 per cent. power factor, will deliver 160 kw. As shown in Fig. 1, the exciters are belted to the shaft. The latter machines are rated at 11 kw. and are driven at a speed of 600 r.p.m. The two units are exact duplicates.

Air for fuel injection and starting is supplied by two three-stage, motor-driven air compressors and is stored at a pressure of 60 atmospheres, in 10 steel bottles. This is equivalent to 882 lb. per sq.in., and on heavy loads the pressure is run up to 955 lb. When only one engine is running, the smaller compressor, which has cylinders 8, 5 and 2⅜ by 8 in., is operated. This machine is belt-driven by a 25-hp. induction motor. The other compressor, which has cylinders 10, 6½ and 3 by 12 in., is large enough to serve the two engines, and is operated during the peak load. It is belt-driven by a 50-hp. induction motor.

Jacket water is drawn directly from the mains and is returned to the reservoir, located near the plant. As a large quantity is used for this purpose, the rise in temperature is small, so that no lime is deposited in the jackets.

Fuel is stored in an underground oil house located between the plant and the railway. It has two 8000-gal. tanks, which are filled by gravity from railway tank cars. An interesting method was used when installing these tanks. Everything, including the foundation, was made ready for their support. The pit was then filled with water and the tanks rolled into the opening. As the water was pumped out, they gradually settled and were guided into place with little difficulty.

From the underground storage two elevator tanks in the engine room are filled with oil by a motor-driven pump, or by a hand pump which has been provided to guard against emergencies. From this elevated location on the engine-room wall, the oil flows by gravity through a strainer to the fuel pumps, which force it up to the

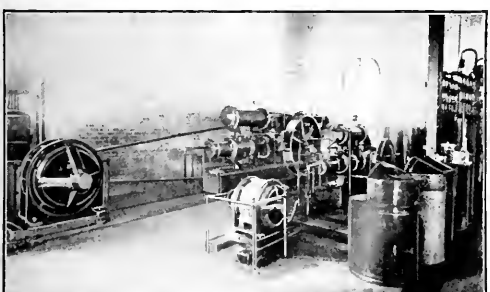

FIG. 2. MOTOR-DRIVEN, THREE-STAGE COMPRESSOR

fuel valves. A meter attached to each engine measures the quantity of oil in gallons, and a gage shows the pressure in the air line.

The plant is equipped with an uptodate switchboard consisting of nine gray-slate panels, carrying horizontal edgewise ammeters and voltmeters, polyphase integrating wattmeters, induction watt-hour meters on the different circuits, a synchronizing indicator, a power-factor indicator and a Tirrill voltage regulator. The switches and copperwork are standard throughout.

Water for the City of Winchester is obtained from a reservoir on the premises, which is supplied from seven 8-in. wells 190 ft. deep. A pressure of 45 lb. is maintained on the system, and in case of fire it may be run up to 95 lb. To supply this water, three triplex power pumps are installed in the station. Two of these have a capacity of 250,000 gal. each per 24 hr. One is driven by a synchronous motor which has double the capacity needed and is over-excited to raise the power factor on the electrical system. The other is driven by a 40-hp., 8x12-in., three-cylinder gas engine. A large fire pump of the same general design, driven by an induction motor, is also installed. Its capacity is 450,000 gal. per 24 hr. Ordinarily, one of the smaller units will supply the demand for water. In case of fire the second small unit, or the fire pump, which is large enough to supply all requirements may be started. Natural gas from a

FIG. 3. SWITCHBOARD

commercial pipe line is used in the gas engine. An additional source of power is thus afforded that will tend to prevent a shutdown should anything happen to the electrical plant.

COST OF THE EQUIPMENT

Table 1 gives the cost of the generating equipment as entered on the company's books. The engines, air compressors and everything required for their operation cost $29,000; the generating equipment, $5000; foundations

TABLE 1. COST OF GENERATING EQUIPMENT

Engines and air compressors	$29,000
Generators	5,000
Foundations and installation	2,000
Switchboard	6,000
Building and oil tanks	10,000
Total	$52,000
Rated engine horsepower	450
Generating capacity, 80% p.f., kw	320
Cost per horsepower	$115.55
Cost per kilowatt	$162.50

TABLE 2. OIL USED AND COST PER UNIT

Months	Kw.-Hr.	Gal. Oil	Oil per 100 Kw.-Hr., Gal.	Cost of Oil at 3c.	Fuel Cost per Kw.-Hr. Cents
November, 1914	107,270	8,280	7.7	$248.40	0.2316
December, 1914	119,560	9,250	7.7	277.50	0.2321
January, 1915	94,010	8,930	9.5	267.90	0.2849
Totals	320,840	26,460	8.2	$793.80	0.2474

and installation, $2000; making a total of $36,000. Per kilowatt of generating capacity, this reduces to $112.50. Adding to the above total the cost of the switchboard, the building and the oil-storage tanks, gives a total of $52,000, or $162.50 per kilowatt of generating capacity. Compared to the cost of a steam plant per unit of generating capacity, this is high. Interest and depreciation on this figure naturally handicap the plant, but are more than offset by the low operating cost.

Data taken from the log book for the three months previous to the writer's visit show that the load averaged over 100,000 kw.-hr. per month. The quantity of oil used averaged 8.2 gal. per 100 kw.-hr., which is a trifle under

0.6 lb. per kw.-hr. The fuel oil used ranges in density from 32 to 34 deg. Baumé and its cost delivered in tank-car lots was 3c. per gal. Dividing the total cost of the oil by the total output in kilowatt-hours, the average fuel cost for the three months was 0.2474c. per kw.-hr. This is much less than in an average steam plant of the same capacity.

Table 3 gives the operating, overhead and total costs

TABLE 3. GENERATING COST AT SWITCHBOARD

		C. per Kw.-Hr.
Fuel at 3c. per gal.		$0.2474
Labor: One chief engineer, $75 per mo.; One assistant engineer, $60 per mo.; One night engineer, $60 per mo.	$195	0.1823
Maintenance per month, $926		0.0086
Supplies, lubricating oil, waste, etc., $20 per month		0.0187
Operating cost		$0.4570
Overhead: Interest, depreciation and taxes, 12½% on $52,000		0.5065
Total cost		$0.9635

of power generation. It will be noticed that only three men are required to run the plant continuously, but during the writer's visit two were carrying on the work, an accident to the chief engineer having kept him away.

PRINCIPAL EQUIPMENT OF WINCHESTER OIL ENGINE PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
2	Engines	Diesel	3-cyl., 16x24-in.	Generating units	32-34 deg. oil, air 60 atm., 165 r.p.m.	Busch-Sulzer Bros. Diesel Engine Co.
2	Generators	Three-phase, 60-cycle	200-kw.	Generating units	2300-volt, direct-driven by Diesel engines	(Fort Wayne) General Electric Co.
2	Generators	Direct-current	11-kw.	Exciter	125-volt, 600 r.p.m., belt-driven	(Fort Wayne) General Electric Co.
2	Air compressors	Three-stage	8x5x2¾x8-in. 10x6½x3x12-in.	Air for Diesel engines	60 atm., belt-driven by induction motors	Ingersoll-Rand Co.
1	Pump	Triplex	7⅞x12-in.	Pump city water	Chain-driven by Fort Wayne synchronous motor	Goulds Manufacturing Co.
1	Pump	Triplex	7⅞x12-in.	Pump city water	Driven by 40-hp. Nash gas engine	Goulds Manufacturing Co.
1	Pump	Triplex	11x12-in.	Pump city water	Driven by 50-hp. independent motor	Goulds Manufacturing Co.
1	Pump	Centrifugal	1-in.	Oil from storage to tanks in engine room	Driven by 1-hp. motor	Chas. S. Lewis & Co.
1	Hand pump		1-in.	Oil from storage to tanks in engine room		Trahern Pump Co.
2	Meters	Integrating		Measures oil to engines		National Meter Co.
2	Gages	Indicating		Pressure in air line		Schaeffer & Budenberg Mfg. Co.
4	Lubricators	Force feed	Three feeds	Lubricate cylinder of engine and air compressor		
	Switchboard and all instruments					General Electric Co.

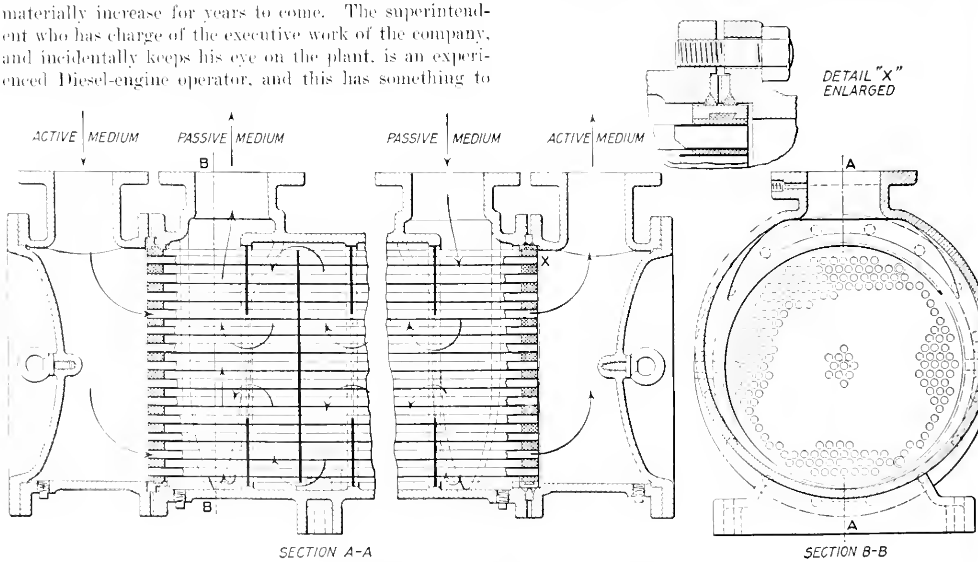
The two Diesel-engine units were started Dec. 1, 1912, and during the 27 months of operation about $250 has been expended for maintenance. The equipment is, of course, new, but indications are that this item will not materially increase for years to come. The superintendent who has charge of the executive work of the company, and incidentally keeps his eye on the plant, is an experienced Diesel-engine operator, and this has something to do with the maintenance item. Lubricating oil, waste and supplies averaged $20 per month. The sum of the various operating items is only 0.457c. per kw.-hr., and when an overhead of 12½ per cent. is added, the total is below 1c. per kw.-hr. delivered to the switchboard. This showing is exceptional for a small plant, and if the load should increase up to the capacity of the generating units, the overhead cost per unit will be reduced, which in turn will lower the total operating cost appreciably.

To O. N. Eiler, superintendent of the company, we are indebted for the information contained in this article.

The S. & K. Oil Cooler

The essential feature of the S. & K. oil cooling apparatus is its high efficiency, which is attained by the arrangement of the cooling surface and the method used to pass two mediums through the apparatus, exchanging the heat through the tube walls in counter currents. As the thickness of the tubes has considerable influence on the heat condition, comparatively thin walls are used, which also make a saving in weight and space.

The tube sheets of the apparatus are built of metal in which the tube ends are cast, and therefore the spacing and the shape of the tube may be so chosen as to give



DETAILS OF THE S. AND K. OIL COOLER

the best results in heat transfer, instead of being determined by the strength of metal required for expanding, rolling or inserting of the tube end and spacing the tubes.

This oil cooler serves the purpose of removing the heat from the lubricating oils used on bearings and can be used in any forced lubricating system. The arrangement consists of a continuous circuit in which the oil is taken by pumps from the bearings and forced through the apparatus, where it is cooled and then returned to the bearings.

In order not to block the supply of cooled lubricant coming from the machine, the hot oil is removed quickly and rapid circulation is obtained, which is a factor in cooling the bearings.

The illustrations show an important part in the construction of the cooler. The arrangement of packing prevents any mixing of the oil and water, and any leakage will come to the surface and be at once detected. The apparatus requires a small pump for water, which keeps down initial cost and operating expenses. The water passages can be cleaned by removing the cover without disconnecting any pipe, and the whole tube bundle can be withdrawn to inspect the outside of the tubes. The oil cooler can be used in any position, but it is better to use it in a vertical one, as the flow of both water and oil is more uniform, and any sediment in the oil will settle at the bottom and is easily removed.

The appliance is manufactured by the Schütte & Koerting Co., 12th and Thompson St., Philadelphia, Penn.

The Specific Heat and Heat of Fusion of Ice

By H. C. Dickinson and N. S. Osborne

Results of previous determinations of the specific heat of ice by certain observers have indicated a rapid increase in the specific heat on approaching the melting point, whereas A. W. Smith* has found the heat capacity of ice to be practically constant up to temperatures close to zero.

The present investigation has been undertaken with the object of securing further evidence as to the thermal behavior of ice at temperatures near the freezing point and of obtaining reliable data for the construction of tables of the total heat of ice and water in the range of temperature with which refrigerating engineers are concerned.

The measurements were made by means of a calorimeter of aneroid type, i.e., without stirred liquid as calorimetric medium. The samples used were from 400 to 470 grams each. Three were of redistilled water of fairly high purity, while a fourth, which was distilled directly into the container, appeared from the experimental results, to have a much higher degree of purity.

In the determinations of specific heat it is found that over the range of temperature covered by the experiments (—40 to —0.05 deg. C.), the specific heat S in 20-deg. calories at any temperature θ of the four ice samples is represented within the limit of experimental error by the equation

$$S = 0.5057 + 0.001863\,\theta - 79.75\,\frac{l}{\theta^2}$$

in which the constant l is assumed to represent the initial freezing point of the specimen and has the following value: Sample No. 1, —0.00125 l; No. 2, 0.00120 l; No. 3, 0.00095 l; No. 4, 0.00005 l.

[The large calorie, or French heat unit, is usually taken as the amount of heat required to raise one kilogram of water one degree Centigrade, or from 15 to 16 deg. C. The "20-deg. calorie" as used by the authors means the heat necessary to raise one kilogram of water one degree Centigrade at 20 deg. C. instead of at 15 deg. C.—Editor.]

From the fact that the term which represents the departure of the specific heat from a linear function of the temperature is found to depend on the purity, being less the higher the purity of the ice, it is concluded that the specific heat of pure ice in 20-deg. calories may be closely represented by the equation

$$S = 0.5057 + 0.001863\,\theta.$$

Determinations of the heat of fusion made upon three of the samples used for the specific-heat determinations gave the following values: Heat of fusion of sample No. 1, 79.68 cal.; No. 2, 79.85; No. 4, 79.75; mean, 79.76 cal.

The results of a previous investigation at the Bureau of Standards using different methods to determine the heat of fusion of ice give, when corrected for the newly found value for specific heat, a mean value of 79.74 20-deg. calories.

The mean for the two investigations is 79.75 20-deg. calories per gram.

For the use of engineers a table of total heats of ice and water is given, expressed in B.t.u. per pound at temperatures from —20 to +100 deg. F.

TABLE OF TOTAL HEAT OF ICE AND WATER

Temperature of Ice t Deg. F.	Difference in Total Heat per Pound from Ice at t to Ice at 32 Deg. $H_{32}—H_t$ B.t.u per Lb.	Difference in Total Heat per Pound from Ice at t to Water at 32 Deg. $h_{32}—H_t$ B.t.u. per Lb.	Temperature of Water t′ Deg. F.	Difference in Total Heat per Pound from Water at 32 Deg to Water at t′ $h_t—h_{32}$ B.t.u. per Lb.

*Physical Review," 17, p. 193; 1903.

A Monster Aqueduct—The aqueduct conducting the waters of the Owens River, at Los Angeles, is said to be the largest in the world. It is designed to deliver a minimum of 258,000,000 gallons of water daily into the San Fernando reservoir, 25 miles northwest of the city. No pumping plant is required, as the source of supply is several hundred feet above the city. The water will furnish a great amount of power—7000 horsepower is anticipated—for electric lighting and other purposes. The total cost of the water-works will be $25,000,000, and the installation of the power plant will cost approximately $5,000,000 more.—"Exchange."

The Ridgway Steam Turbine

The steam turbine of the Ridgway Dynamo & Engine Co. is of the Rateau type and is built under license from Professor Rateau and C. H. Smoot, of the Rateau-Battu-Smoot Co., the American representatives of the professor. As our readers know from previous descriptions, the Rateau is a pressure-stage turbine, and is shown in conventionalized section in Fig. 2. Steam is expanded through the set of nozzles at the left, impinging upon the bladed wheels *EE*, the engraving showing some of the blades in section. The pressure drop in passing through each set of nozzles is sufficient to generate only a velocity which can be practically abstracted by the single row of buckets upon which the steam impinges in each stage.

With the first few pounds of drop in pressure the velocity generated is great in comparison with the increase one-third of that which would be generated by effecting the expansion in a single stage, 9 stages will be required; if one-fourth 16 stages; etc.

Fig. 1 shows this type of turbine, as built by the Ridgway Dynamo & Engine Co., connected with a 375-kw. alternator at the power plant of the Cascade Coal & Coke Co., at Tyler, Penn. This is a mixed-pressure machine designed for high-pressure steam of 125 lb. gage and exhaust steam of 16 lb. absolute pressure and runs at 3600 r.p.m. The low-pressure steam is the exhaust from reciprocating engine units, pumps, etc. By the installation of this unit the capacity of the power plant was increased 66 per cent. without any increase in the boiler plant, and with an actual decrease in the amount of coal consumed over the previous operating condition.

Fig. 3 is a section of the regular high-pressure type.

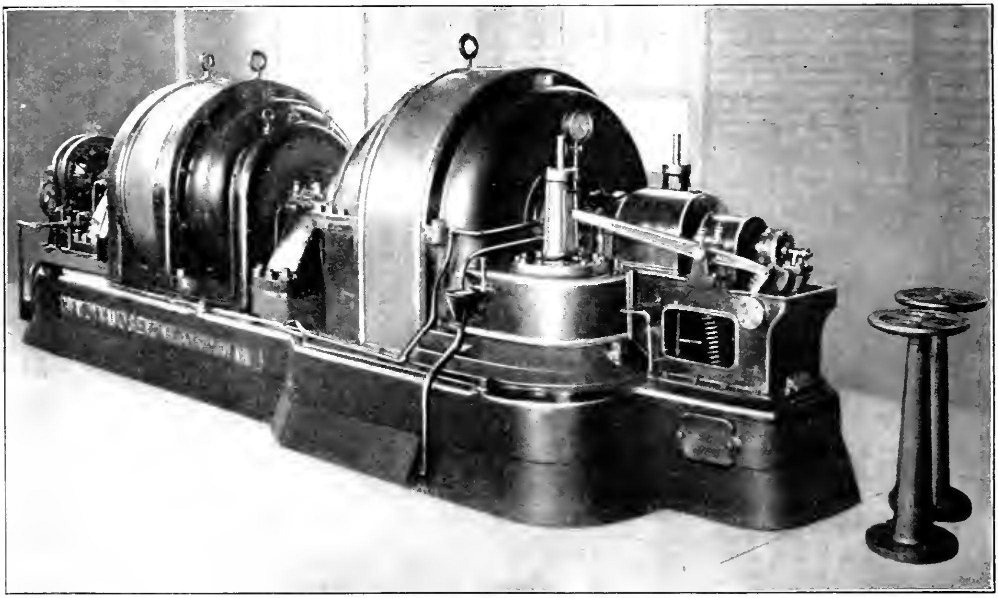

Fig. 1. 375-Kw. Ridgway Turbo-Driven Unit at Plant of Cascade Coal & Coke Co.

of volume, so that a smaller nozzle section is required to pass the same weight of steam. It is not until the lower pressure reaches about 58 per cent. of the higher that the volume begins to increase faster than the rate of flow necessary to take care of it, and the area of the nozzle necessary to pass it increases. As the pressure-drop in the Rateau turbine for the ordinary condition is well within this range, the nozzles are converging. Although the steam expands in going through them, the outlet is smaller than the inlet, as shown in Fig. 2. After having its velocity reduced by passing through the moving blades, the steam is discharging into a second series of nozzles, where it is further expanded, and so on until it is discharged to the condenser. The number of stages required for complete expansion varies inversely as the square of the velocity. If the velocity per stage is to be Steam enters at *A*, passes through seven sets of nozzles and bladed wheels having passages of ever-increasing section, and is finally discharged into the exhaust passage at the right. There are, therefore, eight different pressures existing in the machine, counting those of the steam chest and the exhaust passage, and the chambers containing these different pressures are divided by heavy partitions. But whatever the pressure in any chamber, it is the same on both sides of the wheel revolving in each chamber, so that, with the symmetrical buckets used, there is no end thrust, and all that is needed to keep the shaft in place and the nozzles and blades in their proper relations are the few thrust rings *RRR* in the bearing of the low-pressure end.

Fig. 3 shows the partitions in section, and it will be seen that they are heavier and more securely packed where the shaft passes through them, in the case of the high-pressure stages to the left, than in those at the right, where the pressure differences are less.

As the pressure is the same all around the wheel,

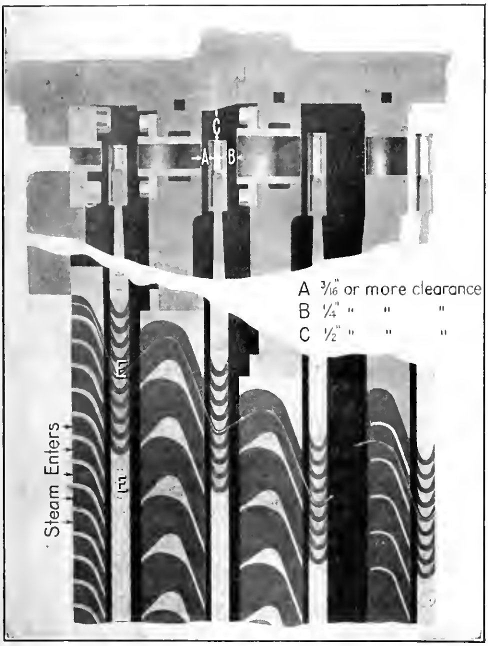

Fig. 2. Conventionalized Section of Nozzle and Blading

there is no tendency for the steam to leak by it, and the clearances, both longitudinally, as at A and B in Fig. 2, and radially, as at C in the same figure, may be comfortable and generous, the axial clearance even in small machines being $\frac{3}{16}$ and the radial ½ in. In large turbines these clearances are as much as ⅜ and 1 in., respectively.

The rotating element consists of a high-carbon steel shaft of such diameter that its normal speed is below the critical speed, and on which are turned the thrust rings referred to. The wheels are machined from disks of flange steel, and are keyed upon the shaft, being separated from each other by steel collars which run against the packing in the diaphragms which divide the stages. The buckets are machined from solid bars, the material selected, usually bronze, being adapted to the particular service for which the turbine or stage is designed. They are made in the

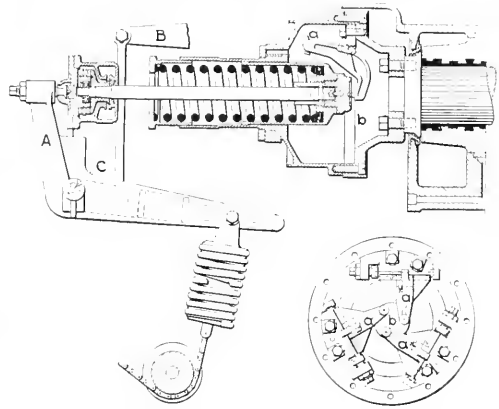

Fig. 4. Section and Details of Governor

two styles, Fig. 7, the smaller being secured by rivets through their shanks, so placed as to retain the maximum possible section, the larger with bulb ends which are driven into slots in the periphery of the wheel and peened solidly into place. Each bucket of either type carries its own shroud and, when assembled in the wheel, is in rigid contact at its outer end with the adjacent bucket, affording mutual support against vibration and damage.

The casing, the heads, and the diaphragms which separate the stages, are split horizontally, the top halves of the diaphragms being attached to the upper half of the

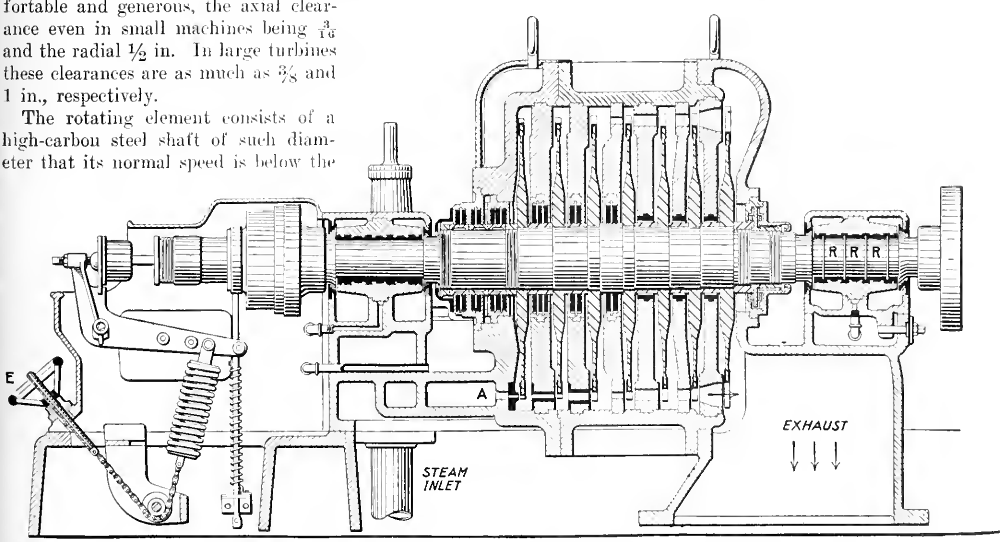

Fig. 3. Longitudinal Section Ridgway-Rateau Steam Turbine

casing and lifting with it. The steam and exhaust connections are made to the lower half, so that they need not be disturbed when the turbine is opened. The nozzles with small area for the initial stages are machined castings bolted into place, as shown in Fig. 5. In the later stages the blades forming the nozzles are cast in place in the diaphragm and extend all or part way around its periphery, as shown in Figs. 6 and 7.

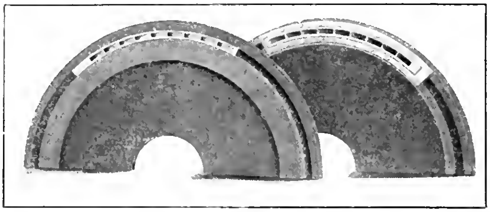

Fig. 5. Cast Nozzles

For the high-pressure boxes and the diaphragms the packing is made of carbon blocks. For the low-pressure boxes a water impeller is used, so arranged that it does not prevent the adjusting of the clearance between the stationary and revolving elements.

The governor is mounted directly upon the end of the main turbine shaft, as shown in Fig. 3. It is shown more in detail in Fig. 4. The actuating weights consist of the longer arms *a*, of three bell-crank levers fulcrumed upon tool-steel knife-edges, the relative location of which is shown in the detail drawing in the lower right-hand corner, the parts being similarly lettered. The small projections shown at the end of the lever in the section are buffers. As the weights fly outward the member *b*, upon which the other arm of the bell crank presses through tool-steel cup points, is moved to the left against the tension of the spring, turning the larger bell crank *A* around the fulcrum *C* and communicating its movement to the throttle valve through the lever *B*. Additional tension may be put upon the governor through the handwheel *E*, in Fig. 3. The thrust which is interposed between the flyball governor and the valve gear is provided with two ball bearings to take the direct thrust as well as any side thrust due to lack of perfect balance. The usual auxiliary governor, which shuts the turbine down automatically when the speed exceeds a predetermined limit, is included. The bearing lubrication is by the gravity-pressure system with circulating pump, filter and cooler, or by ring oiling with water-cooled bearings.

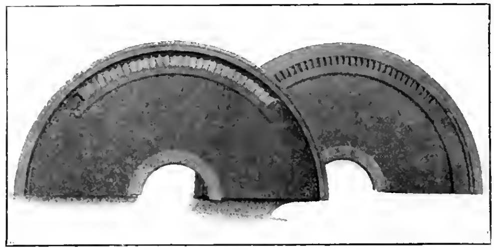

Fig. 6. Cast-In Nozzles

The turbo-alternator, also made by the Ridgway company, is of the revolving-field type, with radial slots for the field coils. In the process of stacking the core numerous air ducts are provided, insuring a more thorough ventilation than is possible with a solid core. Generous ventilating ducts are also provided in the stator, and an outside lagging directs the heated air to an outlet at the bottom. Direct-current turbo-generators are carried directly upon the turbine shaft without the interposition of gearing, the strength necessary to resist the high centrifugal force being secured by holding the winding which is made of bar copper wedged into the slot by heavy bronze rings.

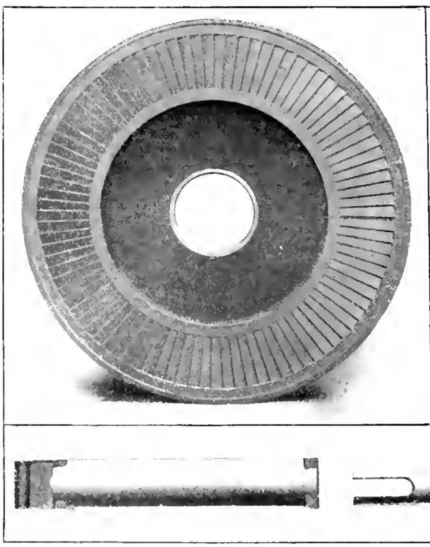

Fig. 7. Full Peripheral Nozzle

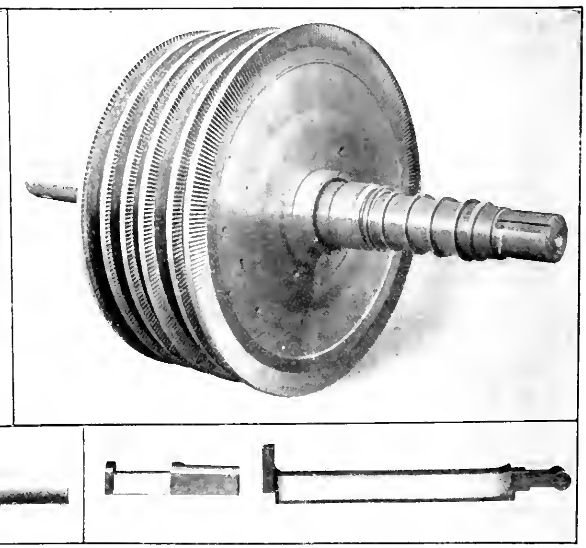

Fig. 8. Full Set of Moving Blades

Simplex Condensation Meter

This meter, Fig. 1, is designed for the measurement of steam used in buildings heated from an outside source, by weighing the water of condensation. It can also be used for measuring various liquids where a gravity discharge permits, but it will not operate under pressure.

The meter consists essentially of a tilting copper bucket which measures the condensation. When sufficient water

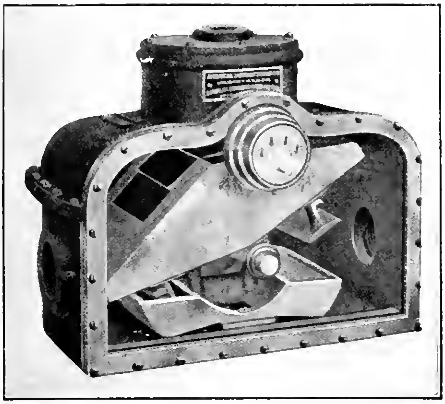

FIG. 1. INTERIOR OF THE SIMPLEX CONDENSATION METER

has run into one side to overbalance it, the bucket tilts, discharging the contents into the meter case, and then through the outlet pipe to the return system or to the sewer. In tilting, the empty side is brought to the filling position. The tilting action is repeated until water ceases to flow to the meter.

The bucket is mounted on a shaft that is supported on roller or ball bearings on the outside of the meter case. In the bottom of the case are dashpots which remain

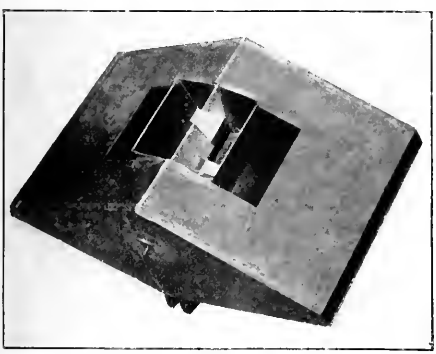

FIG. 2. AUXILIARY BUCKET IN TILTING BUCKET

filled with water and serve as cushions to prevent objectionable noises in the operation. A recording dial indicates the number of pounds of water that have passed through the meter.

To prevent waste of condensation when the tilting occurs, an auxiliary bucket has been arranged to catch the water discharging from the inlet nozzle. This is shown in Figs. 2 and 3. Referring to Fig. 2, the open spaces in the main bucket are for the inlet nozzle to discharge into the empty half. The auxiliary is made with two sections, each discharging to opposite sides of the main tilting bucket, which, when one side contains a certain height of water, starts to tilt to the discharge position.

Fig. 3 shows the operation of the auxiliary in catching the water which would otherwise be wasted between the point of beginning of the bucket dump and the time when the center partition of the main bucket passes under the nozzle. During this period the water is diverted to the empty side.

The auxiliary bucket cannot cut off the total amount of water which would be discharged during the complete tilting movement. It does, however, intercept a large percentage of this waste. Referring to Fig. 3, the heavy arrows marked *A* indicate the bulk of water entering the main bucket. As soon as this has received its full quota of water, it tilts and discharges, and at that instant the edge of the auxiliary bucket passes under the nozzle opening and the water passes into it, as shown by the arrows *B*, thence through a hole in the middle partition to the other side of the bucket, where it is received and weighed on the next discharge. The operation when getting under way for discharging is necessarily slow, and while gather-

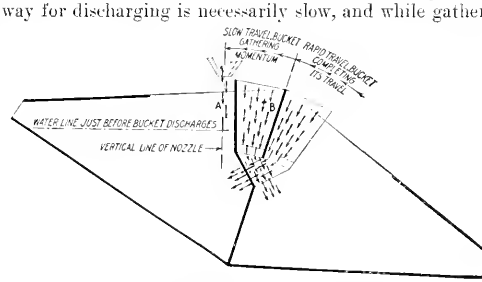

FIG. 3. DIAGRAM OF THE TILTING BUCKET

ing momentum the auxiliary bucket cuts off the water. After the bucket has acquired momentum and is traveling at a rapid velocity, only a small amount is wasted, owing to the fact that it passes over to the other half of the auxiliary and back into the side which has already discharged.

Tests of these meters show that this very simple device, which requires no actuating mechanism, takes up and records the bulk of the waste water which would otherwise have entered the bucket after it had started to dump, and for which, previously, corrections had to be made in the testing.

This meter is manufactured by the American District Steam Co., North Tonawanda, N. Y.

⁂

Steam Separators with receivers of liberal proportions should be used near engines, to provide a reservoir of steam near-by and to minimize pulsations in the lines.

⁂

An Experience in Seeking Help, cited by Charles T. Porter in his "Engineering Reminiscences," is more typical of former times than the present.

"I called upon a friend who was a great mathematician and the editor of a series of mathematical books then largely used, and stated my trouble in calculating the centrifugal force and momentum as applied to my governor. He illuminated the subject to me as follows: 'You seem to be a persevering young man; keep hard at it and you will solve the difficulty by and by.'"

The Uniflow Steam Engine

The fact is established, not only by numerous and repeated tests, but by everyday practice, that the uniflow engine requires only about the same amount of steam as a compound engine. There are others besides our correspondent who cannot see how this can be. Here is one way of accounting for it.

An incredulous correspondent writes:

I studied with interest the article under this heading in Power *of Nov. 17, and as I have written before in regard to this engine, I do not see how it can show good economy.*

Regardless of the test data given (which are undoubtedly correct figures), there remains much that should be explained. Take the figures on page 702 in regard to compression; it is found that with 26-in. vacuum there will be about 38 lb. compression with a clearance of 5 per cent. This does not seem so bad at first thought, but it is bad, for figuring along the same line, I find that at half stroke there is a back pressure of 18 lb.—3.3 lb. above atmosphere. Imagine producing a 26-in. vacuum for an engine that is in direct connection with it for only $\frac{1}{10}$ stroke, and at half stroke is exhausting or, what is of the same effect, has a back pressure over 3 lb. higher than it would have running noncondensing! In the several articles I have seen regarding this engine, the claim is made that the exhaust steam not returning through the cylinder keeps a more even and hotter temperature. So far, in my experience it never has been explained to me why steam is hotter at a given pressure traveling in one direction than in some other. If the engine exhausts down to 2 lb. the temperature will be around 126 degrees, regardless of whether it departs by the back or front entrance. If not, why not? Then again, there is some condensation in any steam cylinder and, as is well known, this portion of the impulse charge sticks more or less to cylinder walls and, in general, lags behind the portion that remains steam. Then it would seem that a large percentage of this near water will not get out of the exhaust, but will remain to be compressed, for that $\frac{9}{10}$ of stroke in the uniflow cylinder. Perhaps this tends to high economy. If so, why?

I note this particular engine has steam jackets. This, of course, will increase the economy of any type of cylinder, but down home it is the custom to take the cost of maintaining this steam jacket. This takes us sort of back to the coal heap, which, after all, is the item that most interests us of the monkey-wrench and overalls. We do not write for argument, we wish to learn. That is why we take Power. *So, if the editor and the higher professors will bear with us and show us just how some nice things are done and why, we will be truly thankful.*

A 100-per cent. engine, i.e., an engine that could turn into work all the heat set free by working steam between 150 lb gage, 100 deg. superheat, and atmospheric pressure, would run on about 13½ lb. of steam per hour per i.hp. The best actual engines require 17 or 18 lb.

If an engine used 18 lb. per hp.-hr., it would develop $^1/_{18}$ of a hp.-hr. per pound of steam. A horsepower-hour is equivalent to 2544.65 B.t.u. Hence, the engine converts

$$2544.65 \div 18 = 141.4$$

of the 1252 B.t.u. which is brought into it with each pound of steam into work.

If the engine had no losses it could run on 13.5 lb. per i.hp.-hr., and convert

$$2544.65 \div 13.5 = 188.5 \text{ B.t.u.}$$

What becomes of the difference between this and the 141.4 B.t.u. converted by the best actual engines and the much less converted by the less efficient types?

The heat which is carried into the engine cylinder by the steam can get out in only three ways:

Radiation;

Conversion to work;

In the exhaust.

And it has got to get out as fast as it goes in, or it will accumulate in the cylinder and melt it down.

The radiation loss from a well lagged cylinder is trifling. It is evident that most of the unutilized heat escapes in the exhaust.

How does it get there?

It is absorbed by the containing surfaces, the cylinder walls, port surfaces, cylinder, and piston heads when the steam is hotter than they are, i.e., through a large part of the forward stroke, and given out to the exhausting steam throughout the entire return stroke, or until, by compression, the temperature of the inclosed steam equals that of the walls.

Whatever goes to nullify or to discourage this transfer of heat between the working medium and the containing surfaces, tends to reduce this bypassing of the heat from the hot to the cold side, from the steam chest to the exhaust, without doing work, and hence tends to increase the efficiency of the engine.

Suppose a cylinder could be so thoroughly jacketed on heads and on barrel with steam so hot that the inside skin of the containing surfaces would be as hot as the entering steam. When the steam came in it would remain in a vaporous or gaseous condition, instead of some 20 per cent. condensing upon the cooler iron, as in the usual case, and it would retain its initial condition until cutoff occurred and expansion commenced. Then it would commence to cool and to absorb heat from the containing surfaces. Perhaps it has some superheat in its initial condition, so that it will not commence to condense immediately, or until the temperature has been reduced by expansion enough to use the superheat all up.

Superheated steam, dry steam, is a very poor absorber of heat. The heat from the cylinder head can radiate or "shine" through it, as the heat from the sun can radiate through the air without warming it up much. It is only when the sun shines on the rocks, and other substances which will readily absorb its heat, and then the air passes over them and picks the heat up by convection, that we get an energetic heating effect. The mere shining of the sun through the air heats it but little, as witness the temperature at elevations where there is little solid material, as compared with the exposure, to absorb and radiate the heat.

Under these conditions it can readily be conceived that even after the expansion has proceeded until the steam is below the saturation point, or even if there is initial condensation, the film in immediate contact with the hot surfaces gets dried out and superheated. Then the absorption of heat from the surfaces stops or becomes very slow.

The effect is analogous to that produced when a stratum of air gets around the cooling surface in a condenser, or when, in a boiler with poor circulation, the steam does not get readily away from the heating surface, or when, in a high vertical radiator, an inside pipe is so smothered that the already heated air hugs it instead of getting away and allowing other and cooler air to come up and be heated. So long, in the case of the engine, as this blanket of highly heated steam can be kept against the hot surfaces, there will be little transfer of heat to the contents of the cylinder, to be carried off in the exhaust.

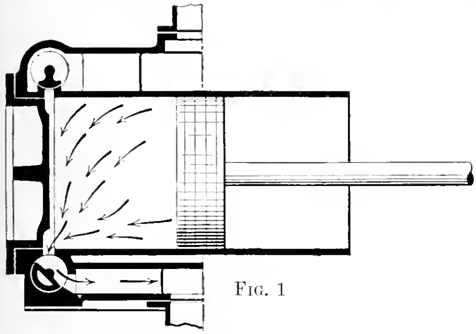

Fig. 1

Now, in the case of the counter-flow, or usual, type of engine, where the exhaust and the steam valves are both at the same end of the stroke, there comes, when the release occurs, an immediate rush of the steam backward toward the hot head, in a struggle to get out at the open exhaust port, as shown in Fig. 1. This steam, even if it were superheated to start with, has become cool and moist by expansion and the conversion, with consequent condensation, of more of its heat into work than it could spare and remain dry. The protecting blanket of superheated steam is swept away from the hot surfaces of the entering end, and the cold wet steam impinging upon these surfaces absorbs heat from them by evaporation and convection to be carried uselessly into the exhaust or to make more work for the condenser. In a single-valve engine, where the same port is used for inlet and exhaust, even the surfaces of the port through which the hot entering steam must come are washed and cooled by this heat-absorbing mixture of low-pressure steam and water.

With the uniflow, or central-exhaust, engine, Fig. 2, there occurs no such reversal of flow. When the piston passes over the central port the steam is released from that end of the cylinder, the hotter steam at the head or jacketed end simply expanding and pushing the cooler wetter steam before it. The protective blanket on the cylinder head and the hot end of the cylinder is not swept off, but remains intact, and all the heat which is carried to the exhaust is that which the steam in the exhaust end of the cylinder can pick up in sweeping over the cooler piston head and the walls near the exhaust port, as it is pushed out of that port by the expansion of the rest of the steam from the pressure at release to that of the exhaust or condenser, and by the backward movement of the piston up to the point where it again covers the central port—usually about one-tenth of the stroke. When the exhaust port is covered there is the volume of the return stroke yet to be completed, plus the clearance volume, full of steam of the exhaust pressure; that near the piston probably at a temperature corresponding to its pressure, that in contact with the hot head superheated considerably above that temperature. As the compression proceeds the temperature rises with the pressure, and there will be some condensation against the piston head, which is now absorbing heat that will be carried off in the next outrush of exhaust, but when the compression stroke is completed the clearance will be full of steam of practically the initial pressure, the cylinder head and clearance surfaces will be good and hot and the piston head as hot as it could get by taking heat from the compressing steam, so that the entering steam is received upon surfaces of about its own temperature and initial condensation much reduced.

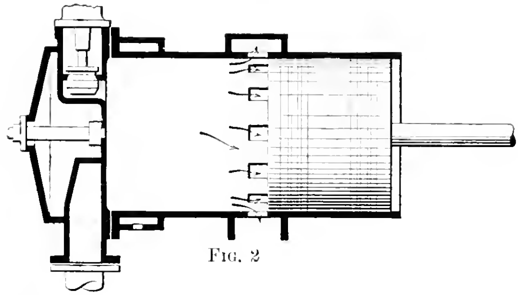

Fig. 2

Our correspondent, in saying that he would not care

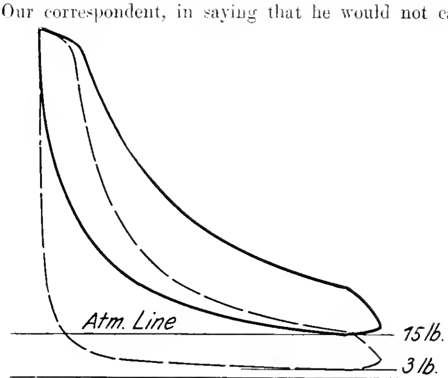

Fig. 3

to maintain a condenser which was in communication with the cylinder for only one-tenth of the stroke, loses sight of the fact that the diminution in the back pressure endures throughout the stroke by reason of the lower initial compression pressure. Fig. 3 will make this plain. The full line represents the counter-pressure running noncondensing, the dotted line condensing, the exhaust port closing when the return stroke is one-tenth completed in both cases. The diagram ought also to make plain to our correspondent that the method by which he computed the absolute back pressure at half stroke to be 18 lb. absolute has something the matter with it. The steam used in the jackets is included in the steam rates reported.

Electric-Motor Noises

By Francis H. Davies

SYNOPSIS—Motor noises classified as to the nature of their causes—namely, magnetic, ventilating, and mechanical. How to detect the cause and the remedy to be applied.

Primarily, the noises arising from the operation of any machine may be divided into two classes—those directly transmitted by the air and those transmitted through the ground and walls. Air-transmitted noises may arise from several causes, but in the case of electric motors they are usually magnetic, being due to vibration of armature teeth and laminated pole shoes under a high-frequency alternating field. Such noises are characterized by a penetrating hum or shriek and are difficult to cure. Their intensity depends upon the field strength, the frequency of reversal, the form of the core and pole stampings, and the manner in which these are put together. Designers appreciate the importance of reducing magnetically generated noises to a minimum, and the following points out what experience has proved necessary to this end.

Magnetic Noises

It is inadvisable that the pitch of the armature slots at the circumference exceed $\frac{5}{8}$ in., as it is found that wide and open slots produce oscillations of the field flux which, acting on the laminations, cause vibration and consequent noise. Where the slots are wide, iron wedges may be inserted, the action of which is to spread out the flux and allow the teeth to enter and leave the field more gradually. The same effect is secured in many armatures by slanting the slots instead of arranging them parallel with the shaft axis; and, with a similar object, pole shoes are sometimes constructed with their horns on the slant as shown in Fig. 1, which allows the core teeth to enter and leave the field gradually. A noisy machine may sometimes be cured by this alteration to the poles, which is comparatively simple provided the poles are of the solid and not the laminated class. It is generally understood that for noiseless running the polar horns should be well rounded and tangential to the armature (Fig. 2) instead of embracing it closely at the tips, the object being to reduce the intensity of the field at the extremities.

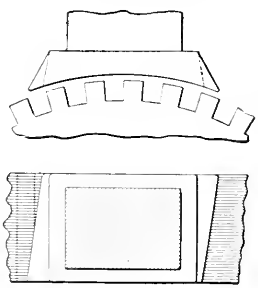

Fig. 1.

Weakening the field by increasing the air gap is another method of minimizing magnetic noise, but this results in a higher speed for an equal output.

Laminated poles are certain to give rise to noise unless the laminæ are so tightly built up that vibration is impossible. Furthermore, the rivets securing the laminations must be as close as possible to the outer edges, particularly those passing through the horns, as this will render them less liable to vibration arising from the rapidly changing density of the magnetic flux as the teeth of the armature core pass the horns. This effect is at a maximum when the number of slots in the armature core is small, because then the magnetic disturbance will be greatest. Therefore, the designer allows for as many slots as possible, taking care also that they are so pitched that one does not leave the pole at the same time as another arrives under it; such spacing will cause maximum swinging of the flux and consequent noise. In other words, the length of the pole face measured on the arc should not be a multiple of the slot pitch.

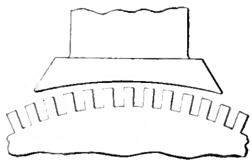

Fig. 2.

Ventilating Noises

Second to magnetically generated noises are those arising from the ventilating arrangements. The churning of the air by revolving parts and its flow at high velocity through the end-shield openings set up a deep noise comparable to that of a fan. It is not very objectionable, but may be lessened by partially closing the vents in the end shields, although this interferes to some extent with the ventilation. It is important that there be as few projecting parts as possible in both the field and armature as these act as vanes and propellers.

A more objectionable noise is that caused by air passing at high speed through ventilating ducts. It is often difficult to distinguish this from magnetic noises. This point may be settled, however, by running the machine up to speed and then switching off the current. It is always possible to modify ventilation noises by reducing the speed, and in some cases a small reduction will be effective.

Mechanical Noises

Noises arising from mechanical causes are usually attributable to faulty design, poor workmanship, or wear. An armature that is out of balance will set up heavy vibrations and an annoying sound that will travel some distance through the framework or walls of the building, unless special steps are taken to isolate the machine. Bearing wear, also, will result in an armature losing its true concentric position with regard to the poles, and this sometimes causes a heavy knock. The remedy for an unbalanced armature is, obviously, to balance it carefully, noting whether it is a case of a sprung shaft and not an original fault, or if the bearings are worn and require replacement. When the bearings are in good condition and it is found that the armature is not truly concentric with the fields owing to bad assembling, this can often be rectified by the insertion of liners or their withdrawal from between the poles and the yoke ring, unless the field be one solid casting. In the latter case liners can sometimes be placed under the bearing pedestals.

Another likely cause of knocking is a loose part, and it is often necessary to overhaul the machine thoroughly in order to locate it. Motors working under arduous conditions of frequent reversal are apt to develop a loose armature core owing to wear of the keyway.

It is well known that sound is carried by solid bodies better than by air; consequently, a noisy motor may cause annoyance at a considerable distance, particularly in the case of buildings of steel structure. In such cases the only remedy is to isolate the machine from the floor, wall or ceiling upon which it is fixed. There are numerous ways of doing this, one particularly good one being the placing of felt under the bedplate, with washers of a similar material inserted under the heads of the holding-down bolts. It is also well to bush the holes in the bedplate with similar felt, for if the bolts touch anywhere they will act as conductors. It should be borne in mind that felt of the ordinary type, such as that used for roofing, is quite useless and cannot long retain any sound- or vibration-absorbing properties that it may originally possess. Special felts are made for this purpose, sometimes with cork and rubber inserts.

Minor Noises

Among the minor noises are those arising from the commutator and brushes. A high bar in the commutator is a not infrequent cause, but the hissing common with many motors is due to the brushes being either too hard, improperly bedded, tight in the boxes, or adjusted at the wrong tension. These faults are easily located and call for only obvious remedies. The motor itself is not always the greatest sinner, and a noisy installation may often be quieted by proper attention to the belting or other form of transmission used. The flapping of a slack belt is easily remedied, though the noise set up by a slipping belt may require more drastic treatment. Should the slip be due to overload a larger belt and, perhaps, larger pulleys must be provided; or if it arises from too small an arc of contact the centers must be increased or an idler pulley employed.

There are also, of course, the usual remedies of wooden or paper pulleys and various dressings having for their object better adhesion of the belt to the pulley. For quiet operation belts should not be run against the joints and metallic fasteners should not be broader than the belt nor project through to the running side. Where chain drives of the "noiseless" type are installed proper attention is all that is required to enable them to justify their name. If, however, they are not properly erected and are allowed to become too worn, dirty and dry, a certain amount of noise is inevitable. Spur gearing is a type of transmission which frequently gives rise to much noise, and for the best results the wheels must be truly cut, well lubricated and correctly distanced. The last is especially important, for if the wheels engage too closely or are too far apart they will cause objectionable noise. Fiber, paper and rawhide pinions are to be recommended and provide the best solution of the problem of quiet spur gearing.

Loop, Ring and Duplicate Steam-Pipe Systems should be indulged in sparingly, especially if much extra length of pipe is involved, or should be so arranged that unused sections can be shut off. This applies, of course, to exaggerated and complicated systems designed to meet every possible contingency. There can be no objection to a complete loop where the boilers and engines are set practically parallel to each other, so that the headers may easily be connected at each end.

JUST FOR FUN

New Commutator Lubricant

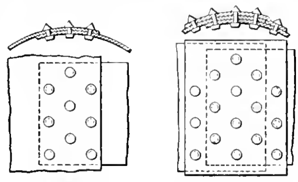
To a young man was assigned the duty of caring for the motor in a small manufacturing concern. It had been the custom to rub the commutator with a cloth dampened with thin oil after the power had been shut off, while the armature was still rotating. One evening the swab cloth was missing, but a bottle of shellac and a cloth were handy, so he used that on the commutator. In the morning the motor refused to start at all, and an inspector was sent for. He found a finely polished commutator, but the brushes were all stuck tight and had to be pried loose.—*R. A. Cultra, Cambridge, Mass.*

A Parallelism Indicator

A glass company in western Pennsylvania had five vertical gas engines of about 600 hp. installed, but brought suit against the builders, claiming that the engines were not as guaranteed. We have one of the same kind, running with the generator in parallel on a 23,000-volt high-tension line. The engine builders and the glass-company officials visited our plant to see the engine and get our reports. After we had explained that the generator was operated in parallel with the main plant about 100 miles away, one of the glass-company officials watched the make-and-break igniters working, and then asked the engineer if the engine was in parallel every time the thing clicked.—*R. G. Curren, Jr., Kittanning, Penn.*

An Improved (?) Boiler Joint

Fig. 1 shows the original longitudinal triple-riveted joint on the shell of a boiler, with an efficiency of 76.5 per cent. The Chief Engineer (?) wanted to have a higher working steam pressure in the plant than he was carrying. He had heard of boiler joints being made stronger by having a cover strap and two additional rows of rivets put in, so he got busy and ordered the change made on his boilers.



Attempt at Strengthening Joint

He cut out all rivets from the original joint and had a cover strap fitted. He had one row of rivets added on each side, as shown, Fig. 2. After all the inconvenience and cost of labor due to this change, he was informed the joint had exactly the same efficiency as before.

The weak point of the original joint was the net section of plate between the outer rows of rivets. In his change he added one row of rivets on each side of the original, but spaced them the same distance apart as the first three rows were. The three center rows were changed from single to double shear, but there still remained the two outer rows in single shear, and the net section between the outer rows had the same value as in the original joint. Therefore the joint efficiency was the same.

If this fellow had asked for proper advice he could have been put right and saved dollars for his company and trouble for himself. The boilers are still in use, but at no higher pressure.—*J. A. Sawyer, Phila., Penn.*

CO_2 and the Character of Fuel

By T. H. Reardon

A high percentage of CO_2 in uptake gases indicates in a general way a high degree of efficiency in the process of combustion, but it may not be so generally known that an increase or decrease in this gas indicates the character of the coal or fuel.

Theoretically perfect combustion is impossible whether conducted with laboratory refinement or with boiler-room methods. By perfect combustion it is understood that the agents that enter into the reaction are present in quantities necessary to yield the final products of combustion with no excess of any reacting element. It is clear that if a sample of pure carbon could be burned to completeness with the theoretically necessary quantity of oxygen, the sole product of combustion would be CO_2 and the percentage of this compound in the combustion products would be 100. Further, if a sample of fuel consisting of both carbon and hydrogen were burned under the same conditions the products of combustion would be CO_2 and water, and if a sample of these products were drawn into an aspirator for subsequent titration with caustic potash it would be found that the water present as aqueous vapor in the condition of superheated steam, would condense, its volume becoming practically nil. This removes it from the sample, leaving only CO_2 as the gas that later will be drawn into the burrette for measurement.

When combustion is supported with the theoretically necessary quantity of air, certain differences will be apparent. Air consists of a mechanical mixture of oxygen and nitrogen, the proportions by volume being usually taken as, oxygen, 21 per cent.; nitrogen, 79 per cent. If the complete combustion of carbon could be carried out with the theoretically necessary quantity of air, the percentage of CO_2 in the stack gases would be the same as that of oxygen in the air, viz., 21 per cent. This is a limiting high mark obtainable only with ideal conditions and with a combustible consisting entirely of carbon.

As soon as experiments are made with a fuel consisting of a mixture of carbon and hydrogen, the percentage of CO_2 in the products of combustion will diminish, even with perfection in the processes.

Carbon unites with oxygen according to the equation

$$C + O_2 = CO_2;\ 12 + 32 = 44.$$

Hydrogen unites in a similar way with oxygen as follows:

$$2\ H_2 + O_2 = 2\ H_2O;\ 4 + 32 = 36.$$

An inspection of the equations shows that 12 parts by weight of carbon require 32 parts by weight of oxygen for perfect combustion, or 1 part by weight of carbon requires $2\frac{2}{3}$ parts of oxygen. For hydrogen we find that 2 parts by weight require 16 parts by weight of oxygen, or 1 part hydrogen requires 8 parts of oxygen. The weights and volumes of air required for carbon consumption and for hydrogen, respectively, are in the same proportion, i.e., weights being equal, hydrogen requires three times as much oxygen or air for its combustion as carbon does.

Each per cent. of hydrogen content in the fuel, therefore, reduces the percentage of CO_2 0.21 per cent., because in combustion hydrogen yields no CO_2 and dilutes the stack gases by introducing three times as much inert nitrogen as would accompany the oxygen used in case the hydrogen content of the fuel had been carbon.

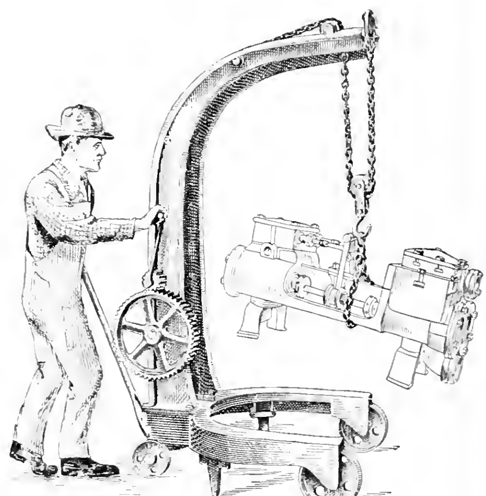
It is obvious that as hydrogen increases in amount in the fuel the percentage of CO_2 must diminish, and that if the hydrogen became equal to 100 per cent., the percentage of CO_2 would be 0.

A study of this subject is interesting, and will materially aid in making clear the significance of CO_2 in the stack gases and the extent to which its presence is influenced by various factors.

Canton Portable Floor Crane and Hoist

Engineers will find the Canton portable floor crane and hoist a convenient, and in some plants a necessary appliance for handling heavy work which would require several men and much time to perform by hand.

The crane bed is fitted with two rear-bearing and two



Portable Floor Crane and Hoist

guide wheels. The latter are provided with a tongue so that the tool can be pulled from one part of the plant to another, the same as if the load were on an ordinary truck. The crane arm and its windlass are bolted to the body.

In the engine room the contrivance will be found convenient for handling cylinder heads, heavy pillar-block caps, steam pumps or any other apparatus which would require jacking, especially where an overhead crane is not available.

This hoist is manufactured by the Canton Foundry & Machine Co., Canton, Ohio.

A Fine Engine-Room Performance—The sinking of the German cruiser "Nürnberg" by the British cruiser "Kent," in the action off the Falkland Islands, was due, primarily, to the remarkable work done by the engine-room and stokehole staffs of the "Kent." The trial speed of the "Kent," which was an eleven-year-old ship, was 22½ knots, and it looked as though her attempt to overtake the 23½-knot "Nürnberg" would be fruitless. But in response to the captain's appeal, the engineering force managed to push the speed up to 24 knots per hour, or one knot more than the ship had ever steamed since she first went into commission, and gradually she overhauled and got within range of the enemy.—"Scientific American."

A Brief History of the Thermometer

By W. S. Atchison

In looking at a thermometer—apparently a glass tube containing either quicksilver or a colored liquid and having some sort of a scale—one is not apt to realize the thought, skill and research it has taken to bring this simple, yet universally necessary article to its present state. For many centuries scientists have worked in an endeavor to perfect it, but only during the past forty years have they found out all the details necessary to the manufacture of a more or less perfect article.

Many people are credited with the invention of the thermometer, Drebble, a Hollander, being referred to more than any other; but to Galileo Galilei the laurels should probably be handed. According to history it seems that about 1592 he invented at Padua an instrument described as "a glass containing air and water, to indicate changes and differences in temperature."

With the idea started, the Grand Duke of Tuscany investigated this invention and improved it more or less between 1630 and 1640. The original thermometer consisted of a glass tube about 16 inches long with a hollow ball, or bulb, at the end. The whole was heated until the air inside became rarefied, when the open end was placed in water, the tube being kept upright. As the air in the tube cooled or contracted, the fluid (water was originally used) rose to a certain point and any subsequent changes caused the level of the fluid to be either elevated or depressed.

This was used by Sanctorius as a "heat measure," or fever thermometer. It is on record that he had his patients hold the top of the thermometer so the level of the fluid would be arrested at a point equal to the temperature of the person holding it. A point was undoubtedly determined by a normal, healthy person beforehand, and it is reasonable to assume that Sanctorius drew his deductions by noting the distance above or below this "normally healthy" person.

Before ten years had passed the Grand Duke of Tuscany had carried out his idea of first partly filling the tube with alcohol and closing the open end, thus sealing it and excluding the air. Realizing that the level of the liquids in these various instruments meant nothing, pupils of Galileo sought to make a scale of temperature and melted onto the tube of their thermometers small glass balls about the size of a pin's head, the zero of the scale being the point to which the liquid fell in a freezing mixture of salt and water.

At one time the bright minds of Europe decided that the freezing point of liquids varied to such an extent that it could not be used as a test point, and suggested taking the temperature in a cave cut straight into the bottom of a cliff fronting the sea to the depth of 130 ft., with 80 ft. of earth about it.

About 1662 Hooke, placing his instrument in freezing distilled water, marked "zero" at the top of the column of spirit after immersion of the bulb. Soon after this he suggested that the second point should be the boiling point of water, but this was not adopted at the time. Delance suggested that the freezing point of water should be marked "cold" (—10 deg.) the melting point of butter "hot" (+10 deg.) and the space midway between "temperate" (0 deg.), with ten divisions between each.

In 1714 Fahrenheit arranged a scale for thermometers that showed the freezing of water at 32 deg. and the boiling of water at 212 deg. Many suggestions have been made as to why he graduated the freezing and boiling of water into 180 divisions, one being that as he was an astronomical-instrument maker and as his machines divided to full circles (360 divisions), he used a half-circle for his scale. Seventeen years later Réaumur, a French physicist, brought out a scale on which the freezing point of water appeared as 0 deg., the distance between this and the boiling point of water being divided into eighty equal parts. Anders Celsius, professor of astronomy at the University of Upsala, proposed a scale in 1742 and called the freezing point of water 100 deg. and the boiling point of water zero degrees.

These points were afterward reversed by Christin of Lyons (France) in 1843, and the result is the well-known Centigrade scale. Athanasius Kircher was the first to use quicksilver in thermometers. Quicksilver and alcohol have been accepted by the scientific world as convenient and accurate means to indicate the temperature of anything with which the tube containing them may come in contact.

For high temperatures quicksilver is used, as it freezes at about —38 deg. F. (—39 deg. C.) and boils at 662 deg. F. (+357 deg. C.). As the freezing point of mercury is fairly high, alcohol thermometers are invariably used in very cold climates. This liquid freezes at —203 deg. F. (—130.5 deg. C.) and boils at 173.5 deg. F. (+78.5 deg. C.).

From the foregoing it will be seen that quicksilver is unsuitable for any very low temperature and alcohol is unsuitable for any very high temperature.

Conversion of Thermometer Scales

To convert Centigrade degrees to Fahrenheit degrees, multiply by 9, divide the product by 5 and add 32, if the temperature is above 0 deg C. When the temperature is below 0 deg. deduct 32 instead of adding.

In converting Fahrenheit degrees to Centigrade degrees subtract 32, multiply by 5, and divide by 9, if the temperature is above 0 deg. F. When the temperature is below 0 deg. F. add 32 instead of subtracting.

To convert Réaumur degrees to Fahrenheit degrees multiply by 9, divide by 4 and add 32, if the temperature is above 0 deg. R. When the temperature is below 0 deg. deduct 32 instead of adding.

In converting Réaumur degrees to Centigrade degrees, multiply by 5 and divide by 4.

To convert Centigrade degrees to Réaumur degrees, multiply by 4 and divide by 5.

Centigrade, water freezes at 0 deg. and boils at 100 deg.

Fahrenheit, water freezes at 32 deg. and boils at 212 deg.

Réaumur, water freezes at 0 deg. and boils at 80 deg.

Uses of Tungsten—Tungsten is used principally as an alloy of high-speed steel—that is, steel used in making tools used in metal-turning lathes running at high speed—to which it imparts the property of holding temper at higher temperature than carbon steels will, according to the U. S. Geological Survey. The now well known ductile tungsten is used for incandescent lamps, which are fast displacing carbon lamps. This alloy is practically insoluble in all the common acids, its melting point is higher than that of any other metal, its tensile strength exceeds that of iron and nickel, it is paramagnetic, it can be drawn to smaller sizes than any other metal (0.0002 in. in diameter), and its specific gravity is 70 per cent. higher than that of lead.

Power Plant of the Government Printing Office

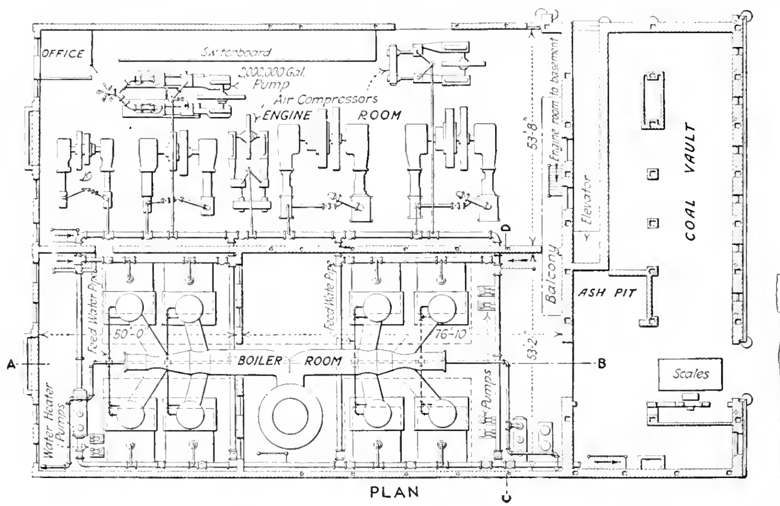
By Davis H. Tuck

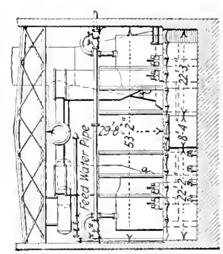
SYNOPSIS—Wherein one plant supplies light, heat and power for the Government printing office and for the new Washington post office. The old plant was remodeled and the electrical circuits changed from a two-wire, 120-volt to a three-wire, 240-120-volt system. Test figures of the redesigned plant are given.

Due to the proximity of the new Washington, D. C., post office to the Government printing office it was deemed advisable to obtain energy for heat, light and power from the power plant of the printing office. The electrical energy required by the printing office had increased until the distributing lines were likely to become overtaxed with a subsequent increase of load. The generating equipment had been added to from time to time until there were four units in the plant. The power-receiving circuits of the new post office were designed for 240, and the lighting system for 120 volts. The power-receiving circuits of the printing office were for 120 volts.

After an analysis of these conditions it was decided to change the two-wire, 120-volt system, to a three-wire, 240-120-volt system to meet the requirements of the new post office and at the same time increase the capacity of the distributing circuits of the printing office. It was also decided to replace one of the small reciprocating generating units by a turbo-generator of sufficient capacity to carry the load of both the printing office and the new post office. By such a change a gain in efficiency could be realized by the substitution of a more efficient prime mover and by the utilization of one unit of relatively large capacity in place of several small units.

The boilers in the plant were overtaxed during the winter months by the requirements of the printing office and were not adequate for the increased load imposed by the new post office. Therefore, it was necessary to add to the boiler equipment and, as the stack was not large enough to produce the additional draft required by the additional boilers, it was necessary to build a suitable stack.





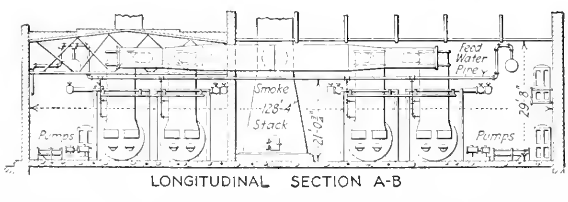


Fig. 1. Plan and Elevation of the Plant before the Change Was Made

Fig. 1 is a plan and elevation of the plant before the changes were made. The boiler equipment consisted of eight 300-hp. hand-fired Scotch-marine boilers with auxiliary apparatus including two feed-water heaters. The generating equipment consisted of two cross-compound Allis engines directly connected to two 500-kw. Crocker-Wheeler direct-current generators, one similar unit of 300-kw. capacity, and another of 125-kw. capacity. Two air compressors of 1500 cu.ft. of free air per minute capacity supply air at 50 lb. pressure to various industrial processes in the printing office. One pump of 2,000,000 gal. per 24 hr. capacity maintains a high-pressure system for industrial processes and for fire protection in both buildings.

The original plans of the changes to be made include the installing of four 500-hp. water-tube boilers with superheaters, stokers, feed pumps and piping; an alternative plan called for putting in two boilers with auxiliaries, similar to those already in place, should the appropriation not permit of water-tube boilers.

The new feed-water heater was to have a capacity for heating the water for not less than 1600 hp. of boilers to a temperature within 2 deg. of that of the exhaust steam. All piping in that part of the boiler house which was to contain the new boilers, except the main steam header, was to be removed, and all steam, exhaust, water and waste piping necessary for the new equipment put in. Changes in the heating feed pipes in the printing office and for the post office were also to be made, and coal- and ash-handling machinery was to be put in for both the new and the old boilers. The erection of a 200-ft. chimney to be 10 ft. 6 in. inside diameter at the top to serve the new boiler was also contemplated.

The new turbine and three-wire generator were to be of 1000-kw. capacity. In the proposal for this unit it was stated that in case the guarantees of the builders

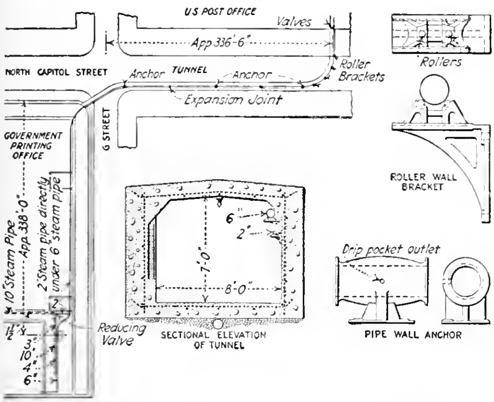

Fig. 2. Details of Tunnel Construction and Wall Brackets

differed, they would be evaluated for the purpose of comparison as follows: The cost to generate steam to be taken at 16c. per 1000 lb., the unit being assumed to operate 16 hr. per day, 365 days in the year, and the algebraic sum of the savings at one-half, three-quarter, full and one and one-half load, with load factors of 20, 50, 15 and 5 respectively, would represent the gross savings per year effected by the units with the lower steam consumption over the unit with higher.

The generator was to have a capacity for two hours of 150 per cent. of its normal load of 1000 kw. The maximum temperature rise of the generator, after being run at full normal load continuously for 24 hr., was not to exceed by more than 45 deg. C. the temperature of the surrounding air corrected to a standard room temperature of 25 deg. C., in accordance with the standards adopted by the American Institute of Electrical Engineers.

Changing of the 300-kw., 120-volt generator to a three-wire 120-240-volt generator and all necessary connections and wiring to the switchboard were also included in the original plans, also the changing of the switchboard and instruments from the two-wire to a three-wire system. The two 600-kw. generators were to be connected in series to form a three-wire system. There would then be installed one unit of 300-kw., one of 1000-kw. and one of 1200-kw. capacity. The switchboard was to consist of 16 panels and two sets of busbars, one for lighting and one for power, with switches so arranged that either set of busbars could be used for either lighting or power.

A tunnel from the printing office to the post office for the steam piping for heating and for the electric wiring was required, the construction of which was to conform with the plan and elevation in Fig. 2. A wall bracket, anchor and roll supports such as used are also shown. The tunnel is of course larger than necessary for this particular purpose, but was made large enough to accommodate a future mail-conveying equipment.

As the appropriation made by Congress for the additions to the power plant was not sufficient to carry out all of the improvements planned, it was decided to distribute the appropriation and purchase two 500-hp. water-tube boilers, without superheaters, one feed-water heater, all necessary piping, ash-handling machinery, chimney, turbine and generator to carry out the changes on the 300-kw. generator and switchboard and to construct the tunnel.

It was also decided to change the two 600-kw. 120-volt generators to 240-volt generators and install balancer sets for the new three-wire system instead of cross-connecting them as originally intended. The new plant therefore consists of one 300-kw. generator, two 600-kw. generators and one 1000-kw. generator all arranged for the three-wire system.

Referring to Fig. 1, the two 300-hp. Scotch marine boilers at the right of the new chimney were replaced by two 500-hp. Babcock & Wilcox, cross-drum, water-tube boilers. The old stack, which was of steel construction lined with firebrick, 6 ft. 4 in. inside diameter and 150 ft. high, was removed and the new 200-ft. brick stack was constructed as indicated. The 125-kw. unit next to the office was replaced by the 1000-kw. turbo-generator, which upon acceptance tests conformed to the guarantees of the makers. The results of the tests of the boilers and turbo-generators are given in detail in the accompanying reports.

On account of the amount of steam used for other purposes, including steam heat, live steam for industrial uses, for pumping water and for use in air compressors, a test was made on the steam-generating engines and it was found that they used about 20.5 lb. of water per kilowatt-hour. Then the total coal consumed multiplied by 20.5 and divided by the total water evaporated gives the coal consumed per kilowatt-hour. From this point the following formula is used to determine the cost of energy per kilowatt-hour.

$$\text{Cost per kw.-hr.} = \frac{\dfrac{w \times kw.\text{-}hr. \times c}{W} \times (Be\ Ew)\left(Ee\ De\ Ew\dfrac{o}{2}\right)}{kw.\text{-}hr.}$$

where

W = Total pounds of water evaporated;
w = Water evaporated per pound of coal;
Be = Boiler-room expense;
De = Dynamo expense;
c = Coal per kilowatt-hour;
Ew = Engineer's wages;
Ee = Engine-room expense (engines and generators only);
o = Office expense.

The load factor, defined as the ratio of the average load

Test No. 1—Report of Steaming Test of Fuel

Results of boiler trial made by the U. S. Bureau of Mines at the Government printing office, Washington, D. C., to determine the ability to make the guarantee at 150 per cent. rating.

Principal conditions governing trial: **Draft kept about constant**; coal wet in hopper.

Dimensions, Proportions, Etc.

Boiler, Babcock & Wilcox Cross Drum	
Grate surface, sq.ft	102
Water-heating surface, sq ft	5200
Date of trial	Sept. 22-23, 1914
Duration of trial, hr. (9:00 p m. to 3:00 p.m.)	18 00
Method of starting and stopping test	Alternate
Kind of coal	New River

Average Pressures, Temperatures Fahrenheit, Etc.

Steam pressure by gage, lb. per sq in.	129 3
Force of draft between damper and boiler, in. of water	0 72
Force of draft in furnace, in. of water	0 59
Temperature of air entering ashpit, deg.	94
Temperature of feed water entering boiler, deg.	72
Temperature of escaping gases from boiler, deg.	540

Quality of Steam

Per cent. of moisture in steam	0 0
Quality factor of steam (dry steam = unity)	1 000

Total Quantities

Weight of coal as fired, lb.	47,595
Per cent. of moisture in coal	3 09
Total weight of dry coal consumed, lb.	46,032
Total dry ash and refuse, lb	4,415
Total combustible consumed, lb.	41,617
Total combustible consumed, determined from analysis of coal and refuse, lb.	41,440
Ratio of dry ash and refuse to dry coal, per cent	9 6
Total weight of water fed to boiler, lb.	426,438
Equivalent water fed to boiler from and at 212 deg., lb	506,608
Total water evaporated, corrected for quality of steam, lb	426,438
Factor of evaporation based on temperature of water entering boiler	1 188
Total equivalent evaporation from and at 212 deg F., lb.	506,608

Hourly Quantities and Rates

Dry coal charged per hr., lb	2,557
Coal as fired, charged per hr, lb.	2,639
Combustible consumed per hr., lb	2,312

*For all purposes.

for the twenty-four hours to the maximum load for that time, is about 71.7 per cent.

The cost per kilowatt-hour for electrical energy is low as compared with the figures prevalent for plants of this size. It will be noted, however, that there are no overhead charges such as interest, depreciation and insurance. The Government carries no insurance, and because of the method of securing money for new apparatus by appropriation from Congress it is not necessary to make interest and depreciation charges.

The plant is now operating under the new conditions and all changes were made without any interruption to the service.

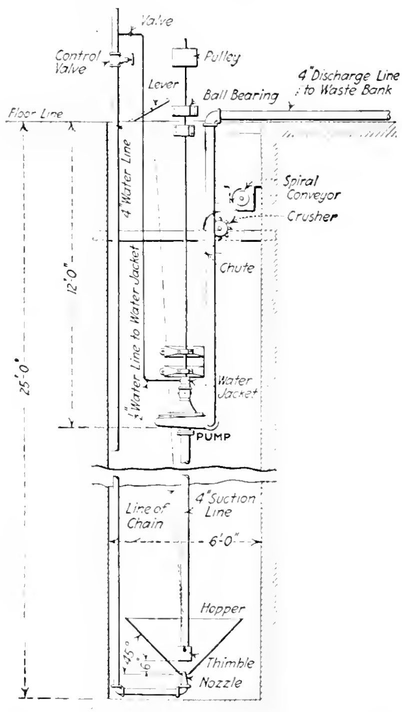
The work enumerated herein was designed by and the equipment installed under the direction of W. R. Metz, M. E., Superintendent of Buildings.

The old equipment was removed and the new equipment installed by the W. G. Cornell Co., acting as general contractors.

Dredge Pump Handles Ashes

By O. D. Havard

The Giant Portland Cement Company, Egypt, Penn., has developed a method of handling its boiler-room ashes which is believed to be new. It is an application of the centrifugal dredging pump which confines its use to plants having plenty of cheap water and those which waste the ashes within a few hundred feet of the building. The apparatus described was adopted, not because it was believed to be in all respects the best for the purpose, but because it was at hand.



Elevation of Apparatus for Handling Ashes

The plant consists of four 250-hp. and one 400-hp. water-tube boilers, hand-fired with anthracite barley coal. The grates are stationary and the ashes are drawn through the front doors. In front of the boilers and just under the floor is a 12-in. spiral conveyor; a small opening under each boiler door is provided for the ashes to enter. During cleaning, a stream of water is turned into the conveyor at its head, which serves to quench the heat and assist the conveyor by partially floating the ashes. The ashes are discharged into a crusher which reduces the clinkers to pieces of about two inches diameter. This crusher is home-made and consists of a cast-iron cylinder $8\frac{1}{4}$ in. in diameter by 12 in. long, with 1-in. spikes driven into tight-fitting holes and projecting 2 in. These rows straddle stationary spikes 2 in. apart. The cylinder is driven by a gear from the conveyor shaft. From the crusher the ashes drop into the well where a 4-in. horizontal-type dredging pump is mounted on the side wall, the weight of the shaft and runner being carried by a ball bearing at the floor level. The suction pipe is bent to come in the center of the well and terminates about a foot above the bottom. A 4-in. water pipe is led down and turned up, with a $2\frac{1}{2}$-in. nozzle directly under the suction and 6 in. away. The pump gland is water-sealed by a $\frac{1}{2}$-in. pipe tapped in above the 4-in. control valve. The water pressure at the valve is about 25 lb. The discharge, consisting of a 4-in. pipe, is led up and out to the waste bank. A thimble of 5-in. pipe is put over the suction and connected by a chain to the lever at the floor.

The process of operation is as follows: Drop the thimble before turning the ashes into the well to keep from obstructing the water pipe; run in all the ashes the well will hold. When ready to pump out, open the 4-in. valve four turns and open the gland water valve. Allow water to rise over the pump runner before starting. When the pump has run a short time on water only to insure the discharge pipe being clean, raise the thimble and allow the ashes to mix with the water. As high as fifteen cleanings have been put into the well before pumping out and have then been ejected in 30 min. The speed of the pump is 658 r.p.m. The variation of speed with head, as given by the manufacturer, is:

Head in Feet	Speed, R.p.m.	Head in Feet	Speed, R.p.m.
5	230	40	727
10	364	50	812
15	447	60	890
20	515	70	960
25	574	80	1000
30	630	90	1085
35	680	100	1145

Four horsepower is required for each ten-foot elevation.

The Colorado River Basin—A recent publication by the United States Geological Survey contains much information of value to all water users. All people interested in the water flowing in the streams of the great Colorado River basin should become familiar with the reports on the subject published by the United States Geological Survey. Such reports, covering the entire country, appear each year in twelve parts, as water-supply papers. Part 9 of this series is devoted exclusively to the Colorado River basin. This paper gives the results of measurements of flow made at about 140 regular river observation stations in the states of Colorado, Wyoming, Utah, New Mexico, and Arizona, and at about 60 miscellaneous points in those states. This information is necessary for the proper and economical installation and operation of water-power plants, irrigation projects, systems of municipal water-supply, works for the prevention of damage caused by devastating floods—in fact, all works that involve the use or control of water.

Editorials

Choosing a Profession

A correspondent recently asked us if we would advise him to continue studying electricity when he prefers steam engineering. We replied to this, as we would to any similiar question, that on general principles it is wise to study the subject which most appeals to one, and that anyone is most apt to succeed at the calling he likes best. It is better to be a successful steam engineer than a failure at anything else, no matter how much more attractive the other position might seem to be.

The young man's doubt arose from his feeling that steam was getting out of date. This, of course, is ridiculous, for the present at least. There is no denying that water power is gaining in use, and fortunately so, for the coal supply is certainly diminishing, but there will be plenty of fields for good steam operating engineers until long after this generation has finished thinking about it. There is a lot of truth in the verse foreword in this issue.

Cultivating an Engineering Hobby

The temptation to scatter one's energies over too great an area is particularly strong in engineering. The various branches of the profession are so inclusive, and the limitations of the individual are so marked, that the desire to make use of every possible opportunity to broaden one's knowledge of applied science often carries a man off his feet, so to speak, and results in a good deal of intellectual lost motion. Experienced men know how to guard against the dissipation of their resources, and one of the best methods is the cultivation of a hobby within the field of one's work.

By this is meant settling one's thoughts largely upon one special line of practice for a stated period, such as the rest of the winter and the early spring, and concentrating all one's extra efforts in the endeavor to acquire a real mastery of the selected subject. Thus, one man will decide to make a study of mechanical stokers, getting every catalog and reading every printed thing he can lay hands upon in this connection during the next two months or so, talking with men who operate, buy, sell and repair stokers, besieging the local public library for books containing matter on this theme, and absorbing data and information with might and main at every opportunity. Another man may prefer to take up the study of coal, following so far as he may the latest advances in its laboratory testing by the government, getting the new points of view regarding the volatile products of combustion, and perhaps reading about the methods of mining and preparing fuel for market. The next man may prefer to start a system of interchanging and comparing operating data among engineers of his acquaintance; another may want to master standard wiring methods or study the limitations of the gas engine and the producer.

All such work has real value. It should not blind a man to what is going on in the field as a whole, but giving direction to his special interests, it enables progress in mental acquisition to be cumulative and thus tends to lead one further into the mastery of a special subject than is possible by mere desultory reading and observation.

One engineer began a collection of station-operating costs in this way, and became so interested in the subject that he filled many pages of a notebook with comparative figures of the same and of different plants for three or four years. Much of the data were obtained from returns on file with the Public Service Commission of his state, and ultimately he was able to sell some of the material to outside interests who heard that he was assembling these costs, figured upon both unit and total bases. The material sold was all public property, being reported to the state annually, although few people knew of its existence, and in its study the engineer observed many interesting tendencies of practice, noting particularly the effect of larger generating units upon the cost of labor per kilowatt-hour, the influence of the day-load upon station efficiency, and other valuable data.

The best thing about thus cultivating what might be called a transient specialty is the enduring grasp of the subject which, if once acquired, never entirely leaves one high and dry in dealing with it later, but broadens the interest of the busy engineer in many inter-related branches of his profession.

Safe Piping

We have laws or ordinances regulating the use of boilers, the installation of electric wiring, plumbing and for safe building construction, yet for some unknown reason nothing in this direction has been accomplished with regard to the safety of steam piping. There is not even a rule making imperative the use of nonreturn valves at the boiler, and at both boiler and header when more than one boiler is used on pressure, possibly because these valves cost more than the ordinary globe or gate valves. The deciding consideration of all work seems to be the price; the safety of plant and humanity are usually secondary considerations.

Engineers seem to be averse to specifying exactly whose apparatus they require; such and such a make "or equal" is the usual way of putting it, possibly to avoid misinterpretation as to motive. However, more than one manufacturer's material is good, and why not mention more than one name, being particular in each case to specify each maker's classification? The pecuniary motive will at least be absent, the specification will be clearer to all interested, and such a practice will go far toward discouraging the sale of competing material now on the market, which is invariably sold as the "equal." It is also well to remember that ability of this "equal" material to fulfill its name is often left to the judgment of others, who may not be as conscientious as the engineers. The usual clause relating to a guarantee for defective material and workmanship is akin to locking the stable after the horse is gone. What good can the guarantee and actual replacing of defective material do to those physically injured?

It should be the aim of engineers to secure laws looking to the safety of piping work—in fact, the safety of all engineering work. Particularly where pecuniary interest can work against the safety of human life, the use of safety devices must be imperative. Rules as to layout and material, based upon past experience, must be enforced. This will also give the engineer a freer hand in designing for the penurious owner, whose sole aim is to get out as cheaply as possible.

Making the Most of Efficiency Instruments

In the report of the Committee on Prime Movers, presented at the Philadelphia convention of the National Electric Light Association, the point was made that a feeling exists among power-plant owners that the use of so-called "efficiency instruments" has been in a measure instructive, but that on the whole the results have been disappointing. The apparent reason set forth is that it was supposed that an operator with such an instrument before him would interpret the record and apply the obvious remedy for any poor results, whereas in reality, the plant does not realize from automatic station records the benefits which these might be made to yield. This is an important matter for consideration, in fairness to the busy operating engineer and in justice to his employer.

It is possible to load down a plant with automatic instruments whose records and indications give very little help to those in charge of the installation, but many plants suffer from the lack of instruments in important locations where moment-to-moment records would be of immediate help in operation. Without desiring to condemn any particular apparatus, unless equipment of this sort makes extremely direct measurements of a simple kind, its immediate usefulness to the operator is problematical except where such records have been interpreted by exhaustive comparisons with other periods, and this is a species of research work for which many engineers have no time. The interpretation of highly analytical records, in connection with some of the larger power stations, is therefore assigned to specially designated efficiency engineers having a technical knowledge of thermodynamics and chemistry, who are not burdened with routine operating duties and who report direct to the chief engineer all conclusions and recommendations, based upon a continuous analysis and study of the significant records of plant performance and personal knowledge of station apparatus and operating conditions. The distinction between operation and the analysis of plant data is a real one, and in companies where the output is large enough to warrant the expense, such a division of labor may be very useful.

In most plants, however, the control of production economy must rest in the hands of those who run the station from shift to shift, supplemented by occasional or, preferably, regular studies of performance by the engineering staff. Day after day, as the load varies, it is important to keep various pressures and temperatures, volumes and weights close to predetermined figures. For such work reliance upon steam gages, steam meters, coal scales, watt-hour meters, draft gages, and, almost above all else, upon thermometers located at strategic points, must take the place of so called continuous graphic test records whose significance cannot be taken without considering their relation to other and complex phenomena. To take the case of the carbon-dioxide recorder, for example, it should be clear that unless such data as this apparatus gives apply to the plant as a whole and not to a single boiler uptake, little immediate use can be made of the observations yielded.

In a nutshell, it is better to determine by tests what temperatures, pressures and volumes spell maximum plant efficiency for a given load and operating conditions and to try to approximate those readings, than to attempt to rapidly interpret highly complex indications drawn from portions of the station only, without having time to weigh and balance a wide range of such data. That is, efforts should be concentrated upon maintaining instrument readings known to be favorable to economy of operation, leaving the comparison of complex indications for the time when analyses can be studied at will.

There is room for establishing in many plants certain limits of operating efficiency expressed in maximum and minimum instrument readings, to stay between which should be the main object of the engineer's routine work. Prompt adjustment of fuel supply, water supply and air is more necessary in meeting the momentary conditions of service than drawing academic parallels between the percentage of ash in the pit of boiler No. 6 today and the same date of last year. For efficient handling of a plant one must have, first, a staff responsive to changes in its service conditions and competent to recognize the limits of efficient manipulation of individual apparatus, and second, the ability within the reach of the plant to draw from station history conclusions of value in meeting the demands of daily routine and emergency service.

Popularity among his fellows is a big asset to an engineer, but unless he has a commensurate amount of professional competency behind it, he's some day going to be a disappointment to himself and his friends.

The report of the commission which began about three years ago to investigate the use of electricity in the Netherlands states that the managements of a number of industrial concerns are of the opinion that it is most advantageous to furnish their own power. Many an American manufacturer found that out long ago.

On January 16, 1909, President Roosevelt sent to Congress a special message which seized the occasion of his veto of an apparently innocent bill granting water-power rights in Missouri to proclaim the discovery of a brand new trust—the Water-Power Trust—and to denounce it as a menace to the people which in a short time would be worse than even the Standard Oil Company.

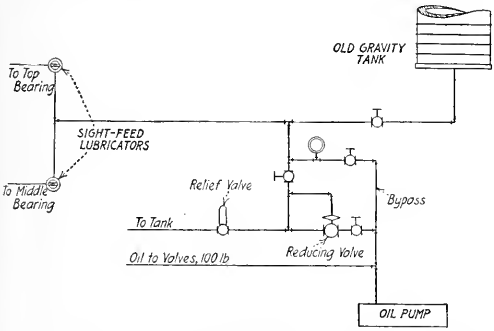
"The movement is still in its infancy," declared the President, "and unless it is controlled, the history of the oil industry will be repeated in the hydro-electric-power industry with results far more oppressive and disastrous for the people."

Subsequent developments have shown that it was no mare's-nest that the President unearthed. The "new trust" has proven itself powerful enough to hold up any legislation insuring the perpetuation of the people's rights in the water power of the country.

Correspondence

Changes Turbine Oiling System

The top and middle bearings of our 2000-kw. Curtis vertical turbine formerly received lubricating oil fed by gravity from an overhead tank. We were dissatisfied with this method of feeding and decided to take oil from the valve-oil line and run it through a reducing valve to the



PIPING FOR OILING SYSTEM OF VERTICAL CURTIS TURBINE

bearings. The hydraulically operated valves receive oil at 100-lb. pressure; the bearing-oil pressure is now maintained at 18 lb.

The changes made in the piping are shown in the sketch. The amount of lubricant fed to the bearing is controlled by manipulating sight-feed valves. We are well pleased with the change.

Newton Square, Penn.

Gas-Engine Cooling Water

The article on "Gas-Engine Cooling Water," by G. A. Field, in the Mar. 30 issue, contains some statements which do not seem to be in accord with good practice.

Discussing thermo-siphon cooling systems in small engines, he states that the bottom of the water tank should not be below the level of the water outlet of the cylinder jacket. He evidently means the jacket inlet opening, but even in this case the statement is not correct. It is usual in small engines to place the water tank so that the bottom is on a level with the engine base, with the tank outlet opening some three or four inches from the bottom, this being connected to the engine by the necessary pipes and elbows. It is safe to say that 90 per cent. of tank-cooled engines are arranged in this way and are giving perfect satisfaction.

In constructing an overhead tank special emphasis should be placed on the fact that, if the tank is placed at too great a height, there is danger of cracking the cylinder jacket. Many engines do not have a thick jacket wall and, stressed as it is by expansion, the jacket does not require many pounds of water pressure to fracture it.

I recall one installation where the cooling tank was placed on the roof of a three-story building, and the jacket fractured the first day the engine ran. When a new cylinder was received it also developed a crack after a few hours' run. It was decided that the hydrostatic head due to the height of the tank caused the trouble. This was partially demonstrated when the tank was placed at the rear of the engine room, and no further trouble was experienced.

Changing Speed of Three-Phase Induction Motor

A two-speed, three-phase, 50- to 125-hp. induction motor, used to drive a rotary pump for pumping salt water into the fire mains for fire protection and for flushing purposes, was found to be too slow on the low speed to be of any use for flushing, as it gave only 30 lb. pressure on the mains and would not raise the water to the highest point in the flushing system. Therefore, the pump had to be run at the high speed all the time, using nearly 100 kw. and leaving the low-speed winding useless.

For the two different speeds, the motor has two windings on the stator, which are entirely independent of each other. The high-speed winding has 6 poles, with the coils connected on the inner end of the motor, and the low-speed winding had 10 poles, with the coils connected on the outer end. There are 90 slots in the stator, making

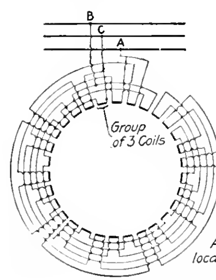

FIG. 1. ORIGINAL CONNECTIONS

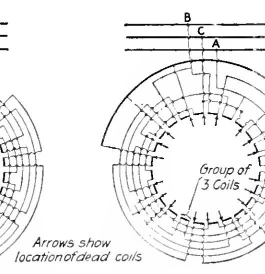

FIG. 2. CHANGED CONNECTIONS

it suitable for both a 6-pole and a 10-pole, three-phase winding, but not for an 8-pole winding, if all the coils were to be used.

After careful consideration it was decided to change the low-speed winding from 10 poles to 8, leaving 18 of the coils idle. A change was also made from delta to star connection and from series to parallel to increase the conductivity for the greater current necessary.

Fig. 1 shows the connections as they were for 10 poles, and Fig. 2 for 8 poles. The actual work of making the change was simple and cost only a few dollars, being paid for by the saving effected in less than a week's time.

The motor, when tested out at no load and at full load, was found to run just as well as when connected as a 10-pole motor with all the coils in use. It has been running almost constantly for over two years on the low-speed as an 8-pole motor, giving 45 lb. pressure on the mains, which is all that is needed, and using only 40 kw., thus making a saving of over 1400 kw.-hr. per day.

Corrosion of Iron and Steel Pipe

The conclusion of C. O. Standstrom in the issue of Mar. 23, page 416, that there is no vital difference between wrought iron and the steel used in its place will doubtless be concurred in by many who have attempted to distinguish between these two materials by ordinary tests. The reason is that the recent advances in the art of steel making have produced a steel which has nearly all the ordinary characteristics of wrought iron. It is tough, soft and stronger than wrought iron and does not harden when quenched from a red heat.

Of its many uses, the one of most importance to the engineer is in tubes and pipes. When welded pipe was first made, wrought iron alone was available, and for several years after the advent of steel its use was not even considered for welded pipe, but recently a pipe steel has been developed. Following are the comparative chemical analyses and physical tests of steel and wrought pipe as reported in the 1913 "Proceedings of the American Gas Institute:"

	Steel Pipe, per Cent.	Wrought-Iron Pipe, per Cent.
Chemical Analysis—		
Silicon	0.01	...
Sulphur	0.05	0.03
Phosphorus	0.10	0.17
Manganese	0.30	trace
Carbon	0.07	trace, irregular
Oxides (slag)	0.10	1.20 to 2.00
Physical Properties—		
Tensile strength	58,000 lb. per sq.in.	46,000 lb. per sq.in.
Elastic limit	34,000 lb. per sq.in.	28,000 lb. per sq.in.
Elongation	22 per cent. in 8 in.	12 per cent. in 8 in
Reduction in area	55 per cent.	25 per cent.

It will be noted that wrought iron contains considerable cinder, or slag, a peculiarity of wrought iron as made by the old puddling process. This slag can frequently be observed in a cross-section of iron pipe, especially with the aid of a magnifying glass. The tensile strength of the iron was measured when the sample was pulled longitudinally, and would be considerably less if pulled transversely to the direction of rolling, while the steel is practically of the same strength in all directions. A wrought-iron pipe, therefore, will fail under a lower bursting pressure than one of steel. At first, considerable difficulty was experienced in threading steel pipe, and dies which would cut a fairly good thread on wrought pipe would make a ragged thread and work hard on steel, but correctly designed dies with more rake and relief have been made.

As to their relative durability and resistance to corrosion there is much contradictory evidence, and it is difficult to separate fact from prejudice. One of the most generally accepted theories is that corrosion is due to electrolytic action, and such conditions seem to affect both iron and steel alike. It is true that structures made from puddled wrought iron have remained in good condition after exposure to the elements for more than a century. On the other hand, under certain conditions, iron and steel pipes installed together have been destroyed by corrosion within a few months, both being about equally affected.

With its passing it seems likely that wrought iron is esteemed more on account of its past reputation than because of any distinct superiority over the modern product. It is also quite probable that much of the so-called wrought iron supplied to the trade at the present time is in reality steel, and the satisfaction it gives depends upon its quality and whether it is adapted to the purpose for which it is used.

WILLIAM A. DUNKLEY.

Atlantic City, N. J.

C. O. Sandstrom states that there are no reliable data regarding the relative ability of iron and steel pipe to resist corrosion. The following is taken from the *National Bulletin:*

Prof. T. N. Thompson in March, 1906, installed alternate pipes of the two metals in a hot-water line, and at the end of a year discovered that steel pipe had approximately 7½ per cent. longer life than wrought iron under such conditions. In a similar test carried out by a committee appointed by the American Society of Heating and Ventilating Engineers with iron and steel pipe made by various companies, Professor Thompson reported: "We believe this test demonstrates that modern steel pipe of good quality is at least as durable as modern strictly wrought iron and is very much superior to a poor quality wrought iron in this class of work." (A. S. H. and V. Engineers, 1909.)

Tests carried on by the Pittsburgh Coal Co., H. C. Frick Coal Co. and others indicate that steel is at least equal to wrought iron in resisting corrosion (*Iron Age,* July 12, 1906).

In his textbook, "The Metallurgy of Iron and Steel," Stoughton, one of those who carried out exhaustive investigations, says: "The evidence goes to show that properly made steel corrodes no more than wrought iron."

J. Newton Fried, in his recent book, "The Corrosion of Iron and Steel," states that "it would appear, therefore, that when everything is taken into consideration there is practically nothing to choose between wrought iron and steel as at present manufactured" (page 286), and finally concludes with these words: "These and many other instances might be cited as illustrating the fact that good steel corrodes at much the same rate as good wrought iron" (page 288).

A. Sang, in a thorough résumé of the question, entitled "The Corrosion of Iron and Steel," says that "properly protected steel and iron rust to about the same extent, the steel doing so more uniformly," and adds, "The best quality of charcoal iron is practically as resistant as the best quality of steel used for similar purposes" (page 49), and in regard to pipe, says: "The carefully acquired experience of the largest manufacturers of tubes in the world, which induced them recently to abandon the manufacture of wrought-iron pipe, teaches that the use of steel in place of iron, at least in the United States, for the special purpose of tubing is to be preferred: the tendency of steel to pit is somewhat less than that of iron and it welds at the joint fully as well" (page 73).

Prof. Ira H. Woolson (*Engineering News,* Dec. 8, 1910) secured 89 samples of corroded pipe from seven bath houses in New York City. Of these samples 17 proved to be wrought iron and the remainder steel. He concluded: "In my judgment, from the evidence collected there was absolutely no difference in the corrosion of the two classes of pipe; they appear to be equally susceptible to the attack."

Dr. W. H. Walker (New England Water-Works Association, March, 1912), of the Massachusetts Institute of Technology, secured 64 samples of wrought-iron and steel pipe in adjacent service. These had been in use from 2 to 17 years. He reported that of the 64 samples 20 favor steel, 18 iron, 8 show no difference in corrosion and 17 no corrosion at all. These results again demonstrate that, taken on the average, there is no difference in the corrosion of iron and steel pipe. Conversations held with engineers in charge of plants during this investigation confirm the statement already made that a pipe is frequently called steel when corrosion is found to be excessive, while it is set down as iron if it rusts but little.

P. DeC. Ball (*Cold Storage and Ice Trade Journal*), in a paper read before the American Society of Refrigerating Engineers, made the following statements:

From 33 years of personal experience and observation constructing, erecting and operating ice-making and refrigerating machines, absorption and compression types, and using iron pipes for the first 14 years, and iron and steel pipes for the next 19 years, we are convinced that local conditions only govern the corrosion of pipes in refrigerating and ice-making machines, and that, chemically and mechanically, mild-steel pipe meets the requirements of the refrigerating engineers in all respects, and better than any other pipe for the reason that it is superior in point of finish, strength, strength of seam and uniformity of material.

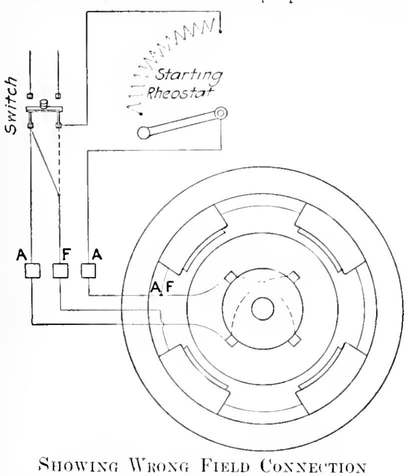
Burned-Out Starter

On account of the liability of an operator to try to start a motor with the field switch open, it is not customary to install switches in the field circuits of motors. Where standard starting boxes are used, proper connections to



Showing Wrong Field Connection

the box insure that the line voltage will not be applied to the armature with the field unexcited, unless through some fault an open circuit exists. Where a starting box that does not handle the field current is used, it is safe to connect the field circuit across the service side of the line switch so that closing this switch will energize the field before the voltage can be applied to the armature, through the starting box.

Opening of the line switch then opens the field circuit, but also opens the armature circuit. Irrespective of the details of the field connection, however, if the motor fails to start when the starting handle is thrown, and flashing of the starter indicates the armature to be taking current, a piece of magnetic metal should be held to the polepieces to see if they are energized.

A manufacturer replaced a motor with a larger one which had been bought second-hand. Both motors had three leads. The shop had been rewired with larger wire for the new motor and the operator thought he had connected the second machine the same as the first. It developed, however, that he had connected the free field wire, as indicated by the dotted line, so that both ends of the field were connected to the same side of the circuit. The result was a burned starting box before he found out the trouble.

Efficiency Engineers

The article in the Mar. 30 issue of Power on "Efficiency Engineers" sounds good. Why not get up a National Society of Efficiency Engineers based upon "deeds performed" as a degree of eligibility. Let applicants state the efficiency they are able to produce, as well as twelve sales or installations of merit on each account they may handle. There is a crying need for factory efficiency, particularly in this Southland, where negro labor is so prevalent. Thousands of plant managers are innocently losing a lot of money every twelve months, because they have never been "put wise" to a better way to run their plant.

J. S. Hoffecker.

Richmond, Va.

Strenuosity and Flywheel Risks

Referring to your editorial on "Effect of High Steam Pressure on Flywheel Risks," there is another phase of the current effort to get the greatest amount of energy out of a dollar's worth of engine which you might have mentioned. The amount of energy produced *per unit of time* depends upon the piston speed as well as upon the mean effective pressure, and the raising of the piston speed from the 600 ft. per min. usual 25 years ago to the 900 or more now not uncommon makes possible an increase in energy produced per second of 50 per cent. or more from this cause alone; and this energy, in addition to that due, as your editorial pointed out, to the increased boiler pressure, is available to accelerate the flywheel.

The fact that a flywheel running with a rim speed of 90 ft. per sec. has a smaller factor of safety than one running at 60 is too obvious to mention, yet it may be well to point out again that the stress from centrifugal forces increases as the square of the velocity, is $2\frac{1}{4}$ times as great at 90 as at 60 ft. per sec., and that if the engine runs away the wheel will burst in less time starting from a rim speed of 90 than of 60 ft. per sec.

P. H. Williams.

New York City

[In the case of a runaway engine the comparison is between the piston speed *attained* and not that at which the engine is rated. At the end of a number of seconds the piston speed of a runaway engine might be greater if the piston speed to start with were 900 ft. per min. than if it were 600, but it is not at all likely that it would be $1\frac{1}{2}$ times as much—EDITOR.]

Retubing Tubular and Water-Tube Boilers

With reference to J. C. Hawkins' article under this heading in the Mar. 9 issue, I wish to call attention to the statement, "The roller expander, which gives the best results and is generally used, consists . . ."

There was a time when the roller expander gave best results, because the prosser was undeveloped, but nowadays the sectional expander is more generally used. Both types have their good and their bad points. The roller expander does not bind the tube as firmly to the sheet as does the sectional tool, and there is always danger of rolling the tube too thin, although there is less danger of this with the sectional expander. The principal danger connected with the use of the sectional tool, according to the findings of the engineers of a large Eastern railroad, is that the tube sheet is liable to be cracked or unduly stressed. So far as I know, there are no other defects of this type A few years ago the roller expander was regarded as faster than the sectional, but the latter seems now to be well received.

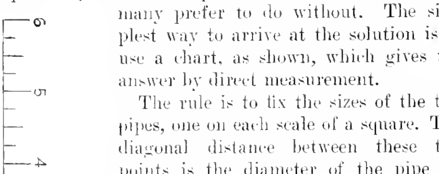
New York City.

Pipe Proportions

Every engineer at some time has to solve the little problem of the size of pipe required to equal two or more other pipes, and although this is not a difficult mathematical problem, it involves square root, and that is a thing many prefer to do without. The simplest way to arrive at the solution is to use a chart, as shown, which gives the answer by direct measurement.

The rule is to fix the sizes of the two pipes, one on each scale of a square. The diagonal distance between these two points is the diameter of the pipe required.

For example, for a pipe to equal two 2-in. pipes, measure the diagonal from 2 in. on one side of a square to 2 in. on the other; the result is $2\frac{13}{16}$ in., the size pipe which would be sufficient; but 3-in. is the nearest commercial size.



GRAPHIC METHOD OF PROPORTIONING PIPE SIZES

The line from 3 to 4 marked 5 is just a reminder of the method of constructing a square. With 3 on one side and 4 on the other and the diagonal distance 5, the first two lines will be at right angles to each other, and a square is produced. The result will be the same whether the pipes are measured in any linear unit or simply pieces of wood cut or marked to length, so long as they are equal to the pipe diameters.

Mathematically, the operation is to multiply the diameter of each of the smaller pipes by itself (as $3 \times 3 = 9$ and $4 \times 4 = 16$) and add them together ($9 + 16 = 25$); then any larger pipe the diameter of which similiarly multiplied by itself equals or comes nearest the other amount (as $5 \times 5 = 25$) will have approximately the same carrying capacity as the other two.

With piping of more than 6-in. diameter it is better to use the square root of the fifth power proportion, but this brings us up against a root again and so is outside the present scheme. Still, it gives 8 in. for a combination of two 6-in. pipes instead of $8\frac{1}{2}$ in. as given by the chart, so the chart is on the safe side.

R. HAMPTON.

Concepcion, Argentine.

Blowoff Piping Failures

Reference is frequently made to blowoff pipe failures and fatalities. Some of the fool things done are almost beyond belief. In a plant in which I operated the night shift the blowoff pipe was made up by screwing a nipple into the cracked outer end of the valve as far as it would go, then backing it out an indefinite number of turns on entering the other end into the next fitting. The piping was frequently disconnected and connected up again by the foregoing process. I chanced to step on the pipe in passing and it fell apart, after which I refused to blow down the boiler on account of this connection, so the owner gave it a "gingerly" little blow night and morning.

One day a new man, who was not familiar with the situation, nearly lost his life by opening the valve wide, which caused the pipe to give way. Such negligence seems to me to be criminal.

J. N. WOODRUFF.

West Liberty, Ohio.

Lubricating Commutators

I have been reading with interest the articles on the care and management of direct-current generators and motors and will mention a method of commutator lubrication that I have found entirely satisfactory. Since employing it I have had no trouble, whereas previously I had to give the commutators my attention every few hours. I take some $\frac{1}{2}$-in. square flax packing that has been treated with beeswax and tallow, cut a piece the length of the commutator bars and lay it on in front of the brushes, the friction holding it in place. A piece that will just fit between the end of the brush-holder and the commutator with a little pressure is better, for the friction holds it up against the brushes and there is enough lubricant from the packing to keep the brushes well lubricated. The wiping effect on the commutator keeps it clean and in a few days a nice polish will be observed.

After running the machine for a week or so, note if there is any copper wiping over the mica; if there is, simply take a sharp file and undercut the latter a little.

C. E. CUMMINGS.

Boulder, Colo.

Inquiries of General Interest

End Play of Crankshaft—What may be the causes of end play of the shaft of a vertical engine?

F. J. I.

Endplay may be caused by the crankpin brasses being out of line and bearing alternately on opposite ends of the crankpin, or to the shaft being out of line causing a wobbling motion of the flywheel, or in a single-crank engine, to lost motion in the crankshaft bearings.

Breakage of Firebox Stay-Bolts—What is the cause of breakage of the ordinary form of firebox stay-bolts?

J. M. B.

The chief cause is unequal expansion of the two sheets which are connected, one being usually in full contact with the fire and the other being heated only to the temperature of the confined water. This difference in temperature of the sheets gives rise to considerable relative motion between the two sheets resulting in formation of cracks in the stay-bolts near the inner surface of the sheets.

Use of Boiler-Tube Ferrules—What is the purpose of using ferrules on the ends of boiler tubes?

G. B.

Ferrules are used where the effects of expansion are severe upon the tube ends, as in locomotives and boilers having firebox tube sheets. Soft-copper ferrules are also used for filling tube-sheet holes that are too large for properly receiving the expansion of the tube ends. In cases where the tube material is especially weak or thin and is therefore likely to spring back when expanded, strong ferrules of hard brass or steel are driven inside of the tubes at the ends.

Position of Crankpin at Half-Stroke—In a horizontal engine does the crankpin stand vertically over or under the shaft when the piston is in the middle of its stroke?

W. L.

It cannot, for when the crosshead is in the middle of its stroke the distance from the center of the crosshead pin to the center line of the shaft is equal to the length of the connecting-rod, and as this is less than the distance from the center of the crosshead pin to the center of the crankpin when vertically over or under the center of the shaft, the crosshead must be at some distance from half-stroke toward the shaft for the connecting-rod to place the crankpin vertically over or under the shaft.

Maximum Capacity of a Boiler—What is meant by the maximum capacity of a boiler?

H. G.

The term refers to the boiler's highest rate of evaporation, or the largest number of pounds of water the boiler can evaporate per hour under stated conditions of temperature of feed water and pressure of steam generated. For purposes of comparison the evaporation under actual conditions is usually expressed in the equivalent evaporation from feed water having a temperature of 212 deg. F. into steam at atmospheric pressure, and as steam at that pressure would have the same temperature, the standard is generally referred to as "evaporation from and at 212 deg. F."

Degrees Baumé and Specific Gravities—In stating the densities of liquids, what are the relative values of degrees Baumé and specific gravities?

J. R. C.

For liquids heavier than water the relative values are given by the formulas,

Specific gravity = 145 ÷ (145 — deg. Bé.)

or

Degrees Baumé = 145 — (145 ÷ sp.gr.)

and for liquids lighter than water the relative values are given by the formulas,

Specific gravity = 140 ÷ (130 + deg. Bé.)

or

Degrees Baumé = (140 ÷ sp.gr.) — 130.

Case-Hardening Steel Governor Pins—How can steel governor pins be case-hardened?

M. G.

Case-hardening can be performed by heating the pin to a dull-red color, and after covering with pulverized cyanide of potassium or prussiate of potash the surfaces which are to be case-hardened, the operations of heating and coating are to be repeated. After the pin has cooled down almost to a black it is to be plunged in water and left until perfectly cold. In heating the pin the temperature should be raised gradually and so as not to burn or scale any wearing surfaces. The chemicals employed are violent poisons and care should be taken in handling them. A good way to coat the heated pin is to roll it over the pulverized chemical when spread out on a flat plate.

Resulting Temperature of Mixtures—What is the method of determining the resulting temperature of a mixture of two substances having different temperatures?

J. F.

The final temperature of a mixture of two substances of different initial temperatures is given by the formula:

$$T = \frac{(W \times S \times t_2) + (w \times s \times t_1)}{(W \times S) + (w \times s)}$$

in which

T = Final temperature of the mixture;
W = Weight of the hotter substance;
w = Weight of the cooler substance;
S = Specific heat of the hotter substance;
s = Specific heat of the cooler substance;
t_2 = Initial temperature of the hotter substance;
t_1 = Initial temperature of the cooler substance.

To Find Radius of Bumped Head—Knowing the diameter and height of bumping of a steam drum head what is the formula for determining the radius to which the head is bumped?

L. E. R.

In the figure if

R = The radius to which the head is bumped,
d = The diameter of the head, and
H = The height to which the head is bumped,

then

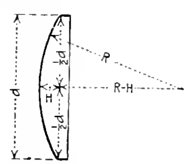
$$R^2 = \left(\frac{d}{2}\right)^2 + (R - H)^2$$

from which

$$2\,RH = \left(\frac{d}{2}\right)^2 + H^2,$$

or

$$R = \frac{d^2}{8H} + \frac{H}{2}$$



that is, the radius of bumping is equal to the square of the diameter divided by eight times the height of the bump, plus one-half of the height.

Boiler Efficiency—What was the efficiency of the boiler and grate using 14,278 lb. of coal having a calorific value of 13,000 B.t.u. per lb. for evaporation of 11,315 gal. of water from a feed temperature of 170 deg. F. into steam at 110 lb. gage pressure?

V. K. S.

Allowing 8⅓ lb. per gal., the water evaporated amounted to

11,315 × 8⅓ = 94,291.6 lb.

and the pressure of the steam was approximately

110 + 15 = 125 lb. per sq.in. absolute.

Referring to Marks and Davis' steam table it is seen that at 125 lb. absolute, each pound of steam contains 1190.3 B.t.u. above 32 deg. F., and as the temperature of the feed water was 170 deg. F., or 170 — 32 = 138 deg. F. above 32 deg. F., each pound of feed water must have received

1190.3 — 138 = 1052.3 B.t.u.

so that the total heat received from the boiler was

94,291.6 × 1052.3 B.t.u. = 99,223,050.68 B.t.u.

and as the coal contained

14,278 × 13,000 = 185,614,000 B.t.u.

the efficiency was

(99,223,050.68 × 100) ÷ 185,614,000 = 53.4 per cent.

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Cookson Return Steam Trap

The illustration, Fig. 1, is a semisectional view of the new Cookson return steam trap. The device is compact, simple and positive, and it has a powerful valve mechanism. It is easily accessible, is regrindable, and the disk and reversible seats are made of monel metal.

The operation of the trap is simple. Fig. 1 shows it in a filling position with the boiler pressure on the outlet check valve. When the returning condensation is to go to the boiler, the trap is located three or four feet above the water line, so that the water will drain to the boiler by gravity. If any returns are below the water line the pressure on them must be sufficient to elevate the water into the trap.

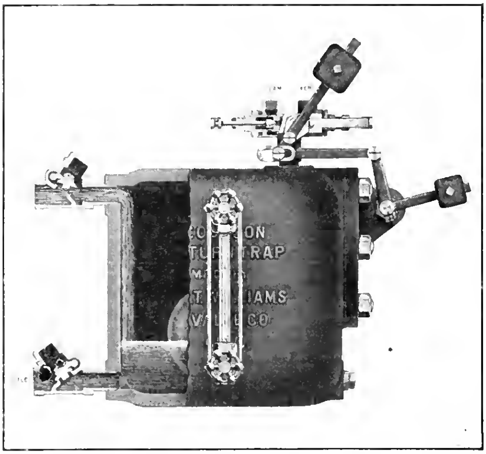


Fig. 1. Semi-Sectional View of the Trap

The accumulation of a given amount of water in the trap causes an upward movement of the float, Fig. 2, which communicates with the valve mechanism to the counterbalanced quadrant and connecting-rod. This action tilts the weighted valve lever, which opens the steam valve and lets the boiler pressure into the trap, closing the check valve on the inlet end. With the pressure in the boiler and in the trap equalized, the water flows to the boiler by gravity. After discharging, the floats drop and the weighted valve lever is tilted to its former position, automatically venting the trap of boiler pressure, and allowing condensation to flow into it until a sufficient amount has again accumulated to cause it to repeat the operation of discharging into the boiler.

To provide against any loss of steam a water seal of several inches remains in the trap after each discharge. Fig. 2 shows a detailed drawing of the trap and the valve-operating mechanism. The only thing in the body of the trap is the high-pressure float that actuates the valve mechanism. The design of the valve and seat makes it possible to regrind them while the trap is in operation. As the valve mechanism is on the outside of the trap it is easily accessible, and its movement indicates whether the trap is in operation or not. This trap is manufactured by the D. T. Williams Valve Co., Cincinnati, Ohio.

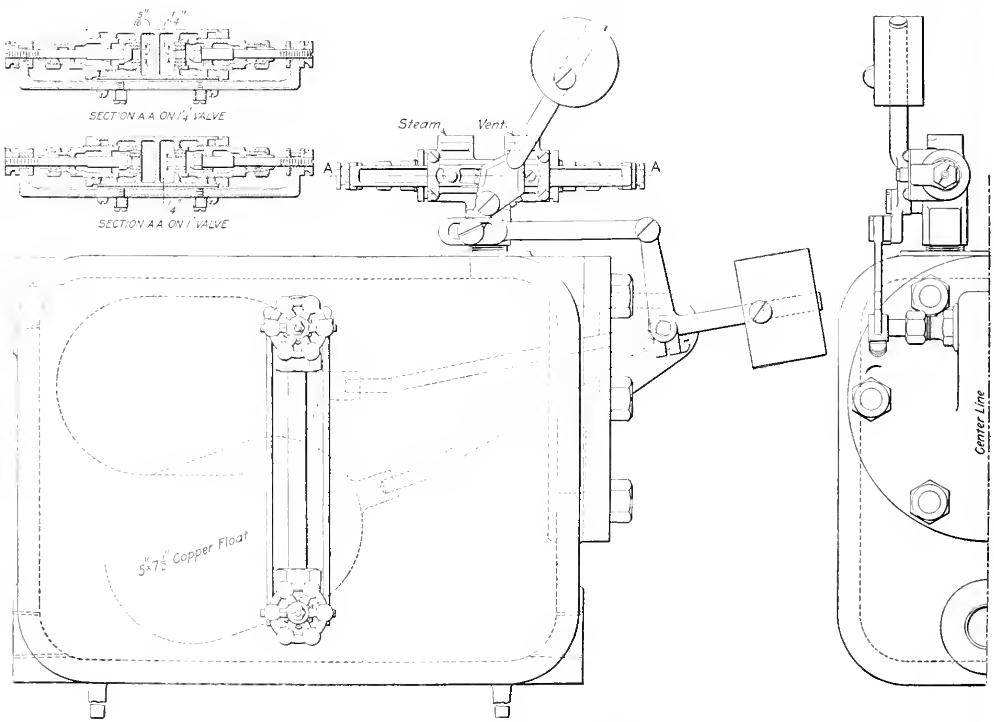

Fig. 2. Details of the Trap Construction

Fractional Horsepower Motors*

By Bernard Lester

SYNOPSIS—The development in the design and construction of the single-phase motor is traced from its origin to the present time, and the operating characteristics of the commoner types of single-phase motors are described and illustrated by the use of speed-torque curves.

During the last ten years the field for the use of fractional horsepower motors has increased enormously and many new devices have become available commercially. There have been three principal causes for this development in the small-motor field:

1. Efficiency engineering in every field of endeavor has brought to the mind of the public the realization of the saving that can be accomplished in time, labor and money by operating small appliances electrically.

2. Wide distribution of central-station circuits, primarily for the purpose of lighting, has greatly increased the possible field for the use of small motors.

3. The performance of the small motor as a reliable source of power and its proper application have established the confidence necessary to encourage the investment of time and money in the development of the industry.

Since single-phase, alternating-current distribution is so largely employed for lighting and, consequently, is available as a supply for small motor-driven machines, the development of a simple, reliable and efficient small single-phase motor has had a large share in the growth of this industry. Single-phase motors of the series, repulsion or induction type, or some modifications or combinations of these principal types, have been largely used.

Series Motor

The series single-phase motor, owing principally to its varying speed with change in torque, has a limited application. It can be safely used only where the load is rigidly connected to the driving shaft and where large variations in speed are permissible with variations in load. This type of motor is successfully used with fans attached to the motor shaft, and for exhausting or supplying air, as in the case of fan-type vacuum cleaners or forge blowers; also for portable electric tools, in which case the power is turned off when the tool is not in actual service. Its use, however, is limited to these or similar applications. A great advantage in the series motor, when especially constructed, is that it can be operated upon direct current or alternating current of most commercial frequencies and the same voltage, with speed-torque characteristics sufficiently similar to produce results generally satisfactory in motors of small capacity.

Repulsion Motor

The single-phase repulsion motor, which is a modification of the series motor, possesses in general the same limitations in regard to its speed-torque characteristics as the series motor. However, without load it does not attain the same dangerously high speed. Since the brushes are short-circuited, the interchangeability from alternating- to direct-current circuits does not exist.

Induction Motor

The single-phase induction motor possesses a speed-torque characteristic in which the speed holds practically constant under a varying torque. This is well suited to the large majority of small motor-driven machines, provided a means is supplied to bring the rotor up to a speed at which the inherent torque produced is sufficient to accelerate the load.

The split-phase induction motor is by far the most common type in fractional horsepower sizes. The most difficult problem has been in overcoming the absence of starting torque in the simple single-phase motor, and the principal steps in this development will be mentioned.

The first split-phase, self-starting motor was developed by Tesla and used for driving small desk fans, but was not employed generally for power service. Several years later, about 1893, single-phase induction motors of larger capacities were developed and used, but as there was no device for starting the motor, it had to be started by hand. Like any polyphase induction motor, when connected to a single-phase circuit and operated on one phase only, it would run in either direction, if started by some external force and accelerated to a point at which the torque developed by the primary of the motor upon the rotating element was sufficient to carry the rotor up to speed. The speed-torque curve of such a motor is shown in Fig. 1, curve AD. From 1893 to 1895 self-starting split-phase motors were designed with two windings in the primary—one for running and the other for starting. A phase splitter, consisting of a manually operated external switch and resistance, connected the primary windings to the supply circuit and inserted resistance in the starting winding. A phase displacement in this way existed between the currents in the two windings, which exerted a torque upon the rotor in starting, the starting winding and resistance being cut out as soon as the motor came up to speed. Later, motors were designed with starting devices supplied with a condenser in place of a resistance. This produced a greater angular advance in the phase displacement than was the case with the resistance starter. In this particular, therefore, a somewhat improved operating characteristic was obtained, due to higher power factor, the condenser remaining in the circuit while starting and running.

About 1898 single-phase induction motors were designed, which started as series motors. The secondary winding was similar to that of a series motor, the commutator bars being short-circuited as the armature accelerated, after which the motor ran as an induction motor. Shortly after this an advantage was found in starting as a repulsion instead of a series motor, since the motor so constructed could be connected externally for use either upon 110- or 220-volt circuits. Motors designed in accordance with this principle are now widely used, especially in sizes above ½ hp. An automatically operated centrifugal governor within the rotating element short-circuits the commutator bars. Curve B, Fig. 1, shows the speed-torque characteristics of such a motor while starting compared with that of the induction motor (curve AD). The line ab represents the speed at which the motor automatically switches from a repulsion to an induction motor.

Another development in the split-phase motor was in the use of an external clutch or clutch pulley. Owing to difficulty in obtaining sufficient starting torque to enable the motor to be used for other than accelerating very light loads, centrifugal clutches were used, allowing the rotor and shaft to accelerate to a point at which a liberal torque was exerted

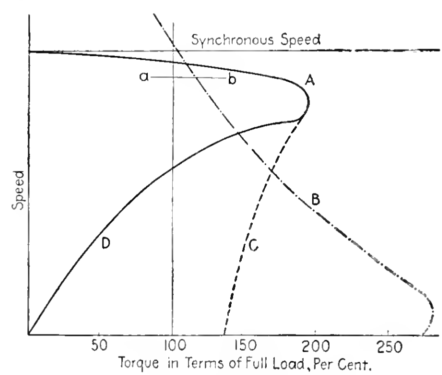

Fig. 1. Speed-Torque Curves

by the rotor; at this point the clutch took hold and applied the load to the motor. Within the past few years marked improvements have been made and sufficient starting torque can now be obtained without the use of a centrifugal clutch, for many classes of service. A light, high-resistance starting winding, in addition to the running winding, is used. Curve AC, Fig. 1, shows a typical speed-torque of such a motor. This starting winding is cut out by means of a centrifugally operated switch placed within the motor and at a speed slightly below that corresponding to full load.

*Excerpts from paper presented at Cleveland Section, A. I. E. E., Mar. 19, 1915.

It is interesting to note that small-motor engineers encounter almost identically the same problems as those which apply to larger industrial motors, in so far as cycles of operation and speed-torque requirements are concerned. For instance, in the application of small motors to washing machines with wringers, the wringer is the limiting feature, taxing the motor with sudden peak loads. This application may well be compared with a motor-driven rolling mill. The motor-driven meat grinder compares closely with the motor-driven pulp-mill beater, and the coffee grinder with the rock or stone crusher. In the design of high-speed motors for fan-type vacuum cleaners, the problems closely parallel those of the high-speed turbo-blower.

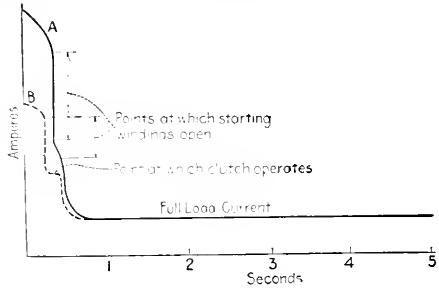

FIG. 2. CURVES SHOWING STARTING CURRENT

In applying split-phase motors, aside from the general characteristics outlined elsewhere, special attention must be given to those characteristics of starting torque, pull-out or maximum torque and temperature rating. The starting torque varies approximately as the square of the impressed voltage; consequently, any reduction in the voltage of the circuit produces more than a proportional reduction in torque. Furthermore, the starting current of split-phase motors materially exceeds the full-load running current. This factor, in addition to light wiring or insufficient transformer capacity, often results in a reduction in starting torque. Good practice in small-motor application provides that the motor should be able to start the driven machine when the impressed voltage is as low as 20 per cent. below the rated voltage. A centrifugal clutch is often incorporated in the design of the motor, not only to insure an ample starting torque and reduce the effect of the current taken during starting, principally by cutting down the time during which it is taken, but also to provide an element of flexibility in the case of a machine rigidly connected to the motor. The clutch will slip in the event of sudden or extreme overload, thus protecting the combined unit.

New Federal Employment Offices

The Department of Labor, through the Division of Information of the Bureau of Immigration, has recently established distribution branches throughout the country for the purpose on the one hand of developing the welfare of the wage earners of the United States and improving their opportunities for profitable employment, and on the other hand of affording to employers a method whereby they may make application for such help as they need, either male or female, citizens or alien residents, and have their wants supplied through the distribution branches. No fee is charged employer or employee for this service.

The following is a list of the headquarters, together with the states comprising the zone or jurisdiction over which they, respectively, have control:

Zone No	Location of Branch	Local Address	States or Territory Controlled
1	Boston, Mass	Long Wharf.	Maine, Massachusetts, Rhode Island.
2	New York, N. Y	United States Barge Office	New York, New Jersey, Connecticut, New Hampshire, Vermont.
3	Philadelphia Pa	Gloucester City, N J....	Pennsylvania, Delaware, West Virginia.
4	Baltimore, Md	Stewart Building	Maryland.
5	Norfolk, Va...	119 West Main Street....	Virginia, North Carolina.
6	Jacksonville, Fla.	Federal Building..........	Florida, Georgia, Alabama, South Carolina.
7	New Orleans, La	Immigration station......	Louisiana, Mississippi, Arkansas, Tennessee
8	Galveston, Tex...	Immigration station.....	Texas, New Mexico.
9	Cleveland, Ohio	Post Office Building. . .	Ohio, Kentucky.
10	Chicago, Ill	845 South Wabash Ave	Illinois, Indiana, Michigan, Wisconsin.
11	Minneapolis, Minn	Federal Building......	Minnesota, North Dakota, South Dakato.
12	St Louis, Mo.	Chemical Building....	Missouri, Kansas, Oklahoma, Iowa.
13	Denver, Colo.	Central Savings Bank Building	Colorado, Wyoming, Nebraska, Utah.
14	Helena, Mont..	Power Building.....	Montana, Idaho.
15	Seattle, Wash	Fifteenth Avenue, West and Blaine Streets..	Washington.
16	Portland, Ore	Railway Exchange Building.	Oregon.
17	San Francisco, Cal	Angel Island..............	California, north of the northern boundary of San Luis Obispo, Kern, and San Bernardino Counties; also State of Nevada.
18	Los Angeles, Cal	Post Office Building	California, south of the northern boundary of San Luis Obispo, Kern, and San Bernardino Counties; also State of Arizona.

All of the postmasters throughout the United States are coöperating in this work by distributing application blanks both to employers and employees. The appropriate blanks may therefore be had on request to any postmaster. However, in those cities designated as zone headquarters application for blanks or information should be made direct to the Inspector in Charge of the Distribution Branch at the office of the Immigration Service at the address indicated in the foregoing table.

Western Hydro-Electric Development

The Montana Power Co., which is attempting to enter the Cœur d'Alenes, Idaho, in competition with the Washington Water Power Co., has 101,000 hp. of hydro-electric plants in operation, 120,000 hp. under construction, 127,000 hp. of undeveloped water-power sites and 8000 hp. of steam reserve. A second unit of Prickly Pear Valley irrigation project will be completed this spring and an additional 3500 acres served with water in 1915.

During the last three months of 1915, according to the report for the year ending Dec. 31, 1914, the company expects to receive a large additional revenue from railway electrification now under way on the Chicago, Milwaukee & St. Paul Ry. The Great Falls hydro-electric plant, which will have an ultimate capacity of 80,000 hp., will be in operation in July, and four of the six units of installation will be completed in the present year. Current is expected to be furnished from the Thompson Falls plant by June. Two units will be installed this year and two added as demanded. About 75 per cent. of the work at these two developments has been completed The Hauser Lake plant has been increased to 34,400 hp. and the Black Eagle plant to 5100 hp. Sixty-seven miles of additional transmission lines were placed in operation in 1914.

Convention Dates for 1915

National Association of Stationary Engineers, Columbus, Ohio, Sept. 13-18.

American Order of Steam Engineers, Atlantic City, N. J., June 21-25.

Universal Craftsmen Council of Engineers, Rochester, N. Y., Aug. 3-7.

Canadian Association of Stationary Engineers, Hamilton, Ont., July 27-29.

N. A. S. E. STATE CONVENTIONS

California	San Francisco	May 27-28
Colorado	Denver	Aug. 6
Connecticut	Hartford	June 25-26
Illinois	Decatur	May 26-28
Indiana	Richmond	June 9-12
Iowa	Clinton	June 2-4
Kansas	Wichita	May 5-7
Kentucky	Lexington	June 10-12
Michigan	Jackson	June 23-25
Minnesota	Mankato	July 7-9
Missouri	St. Louis	May 19-21
New England	Holyoke, Mass.	July 7-10
New Jersey	Trenton	June 3-6
New York	Auburn	June 11-12
Ohio	Columbus	Sept. 12-13
Pennsylvania	Pittsburgh	June 18-19
Texas	Dallas	....
West Virginia	Clarksburg	....
Wisconsin	Sheboygan	July 22-24

The Temperature at Which Water Boils depends on the pressure upon its surface. At 1 lb. absolute its highest temperature is 102 deg. F.; at 14.7 lb., 212; and at 300 lb., 417.5 deg. (see steam tables).

Recent Court Decisions

Digested by A. L. H. STREET

Duty to Safeguard Children Against Wires—An electric-power company which knew that boys were accustomed to play on a wall near an electric wire carrying a dangerous voltage was bound to maintain the wires in safe condition, and, therefore, is liable for the death of a boy who came in contact with a wire where it was uninsulated, according to the decision of the New York Supreme Court announced in the case of Meehan vs. Adirondack Electric Power Co., 150 "New York Supplement," 714.

Care in Handling Electricity Standardized—The degree of care required in the maintenance of electric wires is declared by the Washington Supreme Court, in the recent case of Card vs. Wenatchee Valley Gas & Electric Co., 137 "Pacific Reporter," 1047, to depend upon the character of the current carried, slight care being sufficient where the current would not injure persons coming in contact with it and the highest care being required where the current would cause death or serious injury. The court finds that the jury were warranted in finding that an electric-power company was negligent in failing to insulate a high-power wire which was strung only 17 ft. above the land of one who was killed through inadvertently bringing a pipe in connection with the wire while repairing an irrigation ditch.

Proving Negligence in Explosion—In suits for injuries from boiler explosions, it often becomes difficult to establish the cause as a basis for holding the owner responsible if it appears that the accident was due to negligence attributable to him. This question arose in the recent case of Gill vs. Brown (169 "Southwestern Reporter," 752), which was passed upon by the Tennessee Supreme Court, and it was sought to hold an employer liable for injuries sustained by plaintiffs while at work in the former's sawmill, caused by the explosion of a steam boiler, on the theory that the mere occurrence of the explosion raised a presumption of negligence, in the absence of affirmative proof to the contrary on the employer's part. But the court held that the mere fact of an explosion does not change the rule of law which places the burden on the plaintiff in every personal-injury action to clearly establish the fact that the injury complained of was produced by some negligence attributable to the defendant. The court, however, held that proof in this case that the boiler was very old (the evidence tended to show that it had been used for 40 years) and the finding of several rusted rivets in the wreckage warranted a finding that the boiler had been negligently permitted to remain in a dangerously defective condition.

PERSONALS

Alfred Kauffmann is now vice-president of the Link-Belt Co. in charge of operations at Indianapolis. Mr. Kauffmann served in the engineering department at Philadelphia for a number of years, from which he was promoted to take charge of the erection work of the company. He was later transferred to the sales department, looking after the coal-mining business in the East and particularly in the West Virginia field. His many friends will be glad to learn that in recognition of his competent and able work he has been elected vice-president of the Link-Belt Co.

ENGINEERING AFFAIRS

The American Iron and Steel Institute will hold its eighth general meeting at the Waldorf-Astoria, New York, on May 28 and 29. The program, which will be announced in the near future, will contain only a few formal papers in order to encourage informal discussion.

The Detroit Engineering Society announces the following meetings: May 7 Mr. John O'Connor, Jr., of the Mellon Institute of Industrial Research, will speak on "Some Points in the Indictment of the Smoke Nuisance;" May 21 Mr. H. M. Brinckerhoff is expected to give his deferred talk on the "Detroit Traffic Situation."

Boston Association No. 12, of the National Association of Stationary Engineers, will celebrate its twenty-first anniversary with a ladies' night at 995 Washington St., on the evening of May 3. All members of the N. A. S. E. and their families are invited to be present.

Pratt Institute, Brooklyn, N. Y., exhibits the work of day students on Apr. 29, 2 to 10 p.m.; Apr. 30, 10 a.m. to 10 p.m., and May 1, 10 a.m. to 5 p.m. The students will be engaged at their regular work, and the engineering public is invited to inspect especially the methods and equipment of the School of Science and Technology.

International Engineering Congress—Volume II of the Transactions of the International Engineering Congress to be held in San Francisco, Sept. 20 to 25, will comprise two series of papers, one on the subject of waterways and one on irrigation. The former subject will be treated under four general topics with possibly two additional. These topics cover the general field of the province of waterways in internal commerce, economic aspects, physical features, natural waterways, towage and propulsion. Irrigation will be treated under 11 topics covering: Methods of handling irrigation enterprises; duty of water; relation between demand and supply; underground sources; stream sources; tail water from hydro-electric plants; regulations for use; methods of charge; metering; drainage; dams in general; and also recent developments in India and in the Argentine Republic. This volume will comprise from 20 to 25 original illustrated papers, together with contributed discussions. The transactions of the Congress as a whole will include from seven to nine other volumes, covering the various fields of engineering work. Membership in the Congress with the privilege of purchasing any or all of the volumes of the proceedings is open to all interested in engineering work. Full particulars may be obtained from W. A. Cattell, secretary, 417 Foxcroft Building, San Francisco, Calif.

BOOKS RECEIVED

DIRECT-ACTING STEAM PUMPS. By Frank F. Nickel. McGraw-Hill Book Co., Inc., New York. Cloth; 258 pages, 6x9¼ in.; 218 illustrations; tables. Price, $3.

ENGINEERING ECONOMICS. By J. C. L. Fish. McGraw-Hill Book Co., New York. Cloth; 217 pages, 6x9½ in.; illustrations; tables. Price, $2.

NEW PUBLICATIONS

STEAM TURBINES. By James A. Moyer. Published by John Wiley & Sons, New York, 1915. Second edition. Cloth; 376 pages; 6x9 in. Price, $3.50.

While intended as a manual for those operating, designing or manufacturing steam turbines, an outline of elementary thermodynamics and of the use of entropy and velocity diagrams is given. The part of the text relating to the design of nozzles and blades is valuable as an explanation of the theory, but the lack of detailed proportions and dimensions prevents its being of much use to designers. Since the first edition was issued, new applications of turbines have come into use, and accordingly, in the second edition Professor Moyer has either added or revised chapters on low-pressure, mixed-pressure and bleeder turbines. The essential elements of commercial types of turbines are clearly described and the methods of testing explained. With the exception of the numbering of the illustrations, the arrangement of the book is excellent. But to look at Fig. 192, which precedes Fig. 206, in turn followed by Fig. 195, gives the impression that the illustrations, in reality a most valuable part of the book, were an after-thought. The volume also contains interesting chapters on power-plant costs, an outline of plant design, and a theoretical discussion of gas turbines.

POURING OF BABBITT METALS

In a treatise on the "Pouring of Babbitt Metals," the Syracuse Smelting Works, of Brooklyn, N. Y., offers suggestions which every engineer would do well to follow: Among other things it says:

Better service may be obtained if you will learn that it is of the utmost importance to pour babbitt metals at a low temperature.

When practical, take the chill off the mandrel and shell by warming, as this will dry off the moisture which causes blow-holes, and also makes the metal flow better.

On the subject of remelting metals is the following:

Instructions are generally given to stir before pouring. Those who give these instructions intelligently do so because the tendency is to pour metals too hot and the stirring lowers the heat.

This dispels the idea which many engineers have, that the purpose of stirring the molten metal is to reunite the separated alloy.

To determine whether the melted metal needs cleaning, it advises that the surface be examined while it is at a fair pouring heat. If fine, spider-web lines appear on the surface after skimming, the metal is clean.

OXYACETYLENE WELDING AND CUTTING. By Calvin F. Swingle, M. E., author of "The Twentieth Century Handbook for Steam Engineers and Electricians," etc. Chicago: Frederick J. Drake & Co. Size, 4½x6¾ in.; 185 pages; 76 illustrations; indexed. Price, cloth, $1 net; leather, $1.50 net

This volume deals with many types of generators and portable apparatus in detail, together with the chemical properties and considerations of the gases used. There are numerous illustrations of different types of equipment, with notes on the mode of operation.

The chapters on torches, their management and characteristics are instructive, and useful information is given relating to the consumption of gas and methods of handling, with illustrations, weights and dimensions of torches in general use. Actual welding and cutting work could with advantage have been treated at greater length and illustrated with practical examples giving information on the work done by others and conclusions to be drawn therefrom. The impression that this mode of welding is applicable to everything should be avoided. While its uses are increasing, other forms still have a very large field where the oxyacetylene method is too costly and uncertain in its results. Costs of operation could also have been dealt with to advantage. The illustrations are not all that could be desired, but the book is well indexed; and no doubt will find favor among those interested in the apparatus required but who do not wish highly technical descriptions.

Though the names of some of the makers of apparatus are included, they are few. That of the Davis-Bournonville Co. is an especially conspicuous omission, in view of the great amount of pioneer work which this company did in introducing the art into this country. Some authors inject too much advertising into their books to have them wholesome, but this one seems to have gone to the other extreme. Credit should be given where credit is due, especially when it will be of actual interest to the reader.

PREVENTING LOSSES IN FACTORY POWER PLANTS. By David Moffat Myers. New York: The Engineering Magazine Co. Cloth; 5¼x7½ in.; 560 pages; 68 illustrations. Price, $3.

That the saving of coal in our industrial plants is necessary for the present generation, as well as those to come, can hardly be denied. The monetary saving effected today, while enabling us to procure certain improvements in our plants, to give better working conditions to our employees, higher wages, and increased dividends, is only one side of the question; possibly that uppermost in our minds, but the consequent conservation of our available coal fields is of greater importance to posterity.

Power-plant efficiency has made considerable progress in the past few years, but still not as great as efficiency applied to other lines of business, possibly because the efficiency engineer meets with greater obstacles in this field. It is usually easy to convince the manager of an industrial plant of the advisability of installing a machine that will enable him to cut down his labor or double his output; it is simply a matter of the cost of the machine installed and its earning power.

When the efficiency engineer seeks to impress this same man with the saving that can be effected through the employment of proper methods applied to the coal pile, he usually meets with considerable uphill work, and frequently with ill-concealed skepticism. Managers and owners, when approached on this subject, are prone to reply that they have made very good arrangements with their coal dealer, that they have good firemen, the steam they are allowing to go up in the air does not amount to much anyway, and kindred other replies only too familiar to engineers that have tried to lead them back to the path of efficiency. Some again, will realize that there is waste in exhausting to atmosphere, the use of bare steam pipes, the use of long and badly arranged shafting, the unintelligent handling of boilers and coal. These men are indeed wise and, regrettably, too few.

The work under review deals with this important subject in a clear and illuminating manner and should be of great benefit to all engaged either in the owning, operating, designing or rehabilitating of power plants, great or small. The theory and practice are ably explained. Every item of loss, with its consequent result, is traced in successive steps from its origin back to the coal pile. Methods of prevention, together with actual examples from the author's wide experience, are carefully shown.

The engineers at present exploiting this field, or those who may have this intention, would do well to read this work and apply the principles therein. Many useful tables and tabular results of actual tests are given.

The author undoubtedly intends the volume to be read in its entirety, as no index is provided. The subject, to be thoroughly appreciated, must be completely read.

BUSINESS ITEMS

Arthur G. McKee & Co., contracting engineers, of Cleveland, Ohio, have issued an attractive brochure, elaborately illustrated with examples of their work.

The Indiana Steel Co., Gary, Ind., has installed "Diamond" Soot Blowers, made by the Diamond Power Specialty Co., Detroit, Mich., on 26 boilers.

The Chicago Pneumatic Tool Co., Chicago, Ill., has removed its New York office from 50 Church St. to 52 Vanderbilt Ave., and its Boston office from 191 High St. to 185 Pleasant St.

L. R. Merritt & Co. has removed its office from 95 Liberty St. to larger quarters in the Vanderbilt Concourse Bldg., 52 Vanderbilt Ave., New York. This company represents the Brownell Co., Springfield Boiler & Mfg. Co., Craigs Ridgway & Son Co., Coppus Engineering & Equipment Co., Advance Pump & Compressor Co., James McMillan & Co.

The Harrison Safety Boiler Works, 17th and Clearfield St., Philadelphia, Penn., is sending out Cochrane "Engineering Leaflet" No. 18. This 48-page booklet contains an article by W. S. Giele entitled "Laboratory for Investigating and Testing Liquid Flow Meters of Large Capacity" and an article by James Barr, B. Sc., entitled "Experiments Upon the Flow of Water Over Triangular Notches." Copies are mailed on request.

Bird & Son, E. Walpole, Mass., has recently ordered of Builders Iron Foundry, Providence, R. I., a venturi meter with type M indicator-recorder for boiler feed service. This constitutes the fourth venturi meter installed by this company for measuring boiler feed water. The Inland Steel Co., of Indian Harbor, Ind., recently ordered an 8-in. venturi meter tube with type M register-indicator-recorder for boiler feed service.

"Retail Coal Pockets, Third Edition" is now being distributed by the Guarantee Construction Co., 142 Cedar Street, New York. Specialists in constructing buildings and apparatus for handling coal and ashes for power plants. This 32 page 6 by 9 booklet illustrates many pockets recently erected by them, describes modern coal handling methods, and explains which are most suited to various conditions. A copy will be mailed on request.

Recent installations of American standard copper coil feed water heaters, made by the Whitlock Coil Pipe Co., Hartford, Conn., include: Hainesport Mining & Transportation Co., Philadelphia, Penn., 600-hp. for its dredge "Philadelphia;" Lake Champlain Transportation Co., Whitehall, N. Y., 100-hp.; L. M. Hartson Co., No. Windham, Conn., 50-hp.; Metropolitan Water and Sewerage Board, Boston, Mass., 150-hp.; Chatham Bars Inn, Chatham Bars, Mass., 80-hp.; Brawn-Willard Co., Portland, Maine, 100-hp.; Rhode Island Mill, Spray, N. C., 500-hp.; Northwestern Electric Co., Portland, Ore.

"Push, Don't Knock"

Written by
L. R. W. Allison,
Newark, N. J.

A FAMILIAR PHRASE *that has many times stared at us from a conspicuous position upon a door; three simple words that are almost invariably passed by with entire thoughtlessness, attributing the significance directly to only the entrance thus slightly guarded.*

BUT stop to analyze, consider more fully the meaning beyond the external marking and we find that the expression strikingly pertains to each one of us and our daily endeavors, conveying a teaching of sterling worth.

"Push, Don't Knock" has its limits on the door of the office, it has *no* limits on the door of our future. It is erasible from the former, but it is stamped *indelibly* on the latter.

Push at the door of the office and it opens just so far; push at the door of personal advancement, and the more persistent and energetic the push, the wider does it extend.

In this sense, *push* is *progress*, and progress is *going forward*. The engineer cannot remain as stationary as his engines, he *must* move, either slipping *up* or *down* the ladder of bigger things.

There are two general classes of men, the *pushers* and the *pushless*, one drives forward and keeps his step, the other *is driven* forward and falls backward. One *uses* his best efforts, the other *abuses* them.

The motto of the progressive engineer commences with "Push" and includes "Don't Knock." This man doesn't cry for a chance for advancement, he tries for it, and with that real ambition and confidence in his own ability that gets there. The engineer with push in his makeup embraces every opportunity offered him, and if it *isn't* offered, he *makes* it. he shows right in his own plant what *he* can do.

Opportunity is like the live steam line under heavy load, it's never empty, it's never used up. The pressure back of it is the enthusiasm that is put into the work of every day. That is the real power on the job.

To *knock* is the easiest thing on earth; everyone can grumble, whine and complain and "knock" his associates, his boss and his plant. It doesn't require any real ability to do this—it's boy's play.

But did you ever see an engineer who is alive to every chance for advancement spend valuable time in "knocking"? He's too busy with something to waste his efforts in nothing.

The long running hit in the game of life is the real demonstration of your real superiority. Consider it from any angle, you will find that it is this alone that counts.

To "Push, Don't Knock" is the creed of energy; it's the small beginning that offers a big ending; it doesn't require deep thinking to see it. It's the handwriting on the door of opportunity for the man who will push it open wider and wider without knocking.

Federal Power House, Boise, Idaho

By A. P. Connor

SYNOPSIS—This hydro-electric power plant has been built to supply electrical energy for constructing the Arrow Rock dam about fifteen miles distant. There are three 625-kv.-a. vertical-type generators, each with its exciter coupled to the upper end of the generator shaft. The voltage of the main units is 2300, which is stepped up to 22,000 volts for transmission. When the dam is completed the plant will be used for supplying energy for local use.

The project which the United States Reclamation Service is undertaking for irrigation purposes at Boise, Idaho, has in reality three natural subdivisions, one being in the valley of the Payette, the second in the Boise Valley and the third in the valley on the north side of the Boise River. The reference in this article is to the part of the project which makes use of the Boise River for power purposes.

The dam across the Boise River, Fig. 1, which makes its waters available for irrigation and power purposes, is situated about eight miles above the City of Boise. The dam raises the water level 33 ft. and diverts water into a canal extending 23 miles to Indian Creek, the channel of which is then used for about nine miles, where the water is then directed into another canal, eight miles long, and which terminates in the Deer Flat Reservoir. The possible power development is estimated at 15,000 hp. The power possibilities from the various streams in the vicinity of the project are great, and a number of hydro-electric plants have been constructed.

The turbines of the Boise hydro-electric plant, Fig. 2, rest on the discharge tunnels, thus utilizing short draft tubes, Fig. 3. The thrust bearings are just above the wheel pits, and the alternators rest on the main floor of the generator room. There are three vertical-type, alternating-current generators, each of 625-kv.-a. capacity, with exciters mounted on the end of each shaft. The units generate 2300-volt three-phase current at 60 cycles, and this is transformed to 22,000 volts for transmission to the Arrow Rock dam. The generators are synchronized on the 22,000-volt side of the transformers, and provision is made for operating them in parallel. The generators are of the revolving-field type and have a rating of 500 kw. at 80 per cent. power factor with a speed of 180 r.p.m.

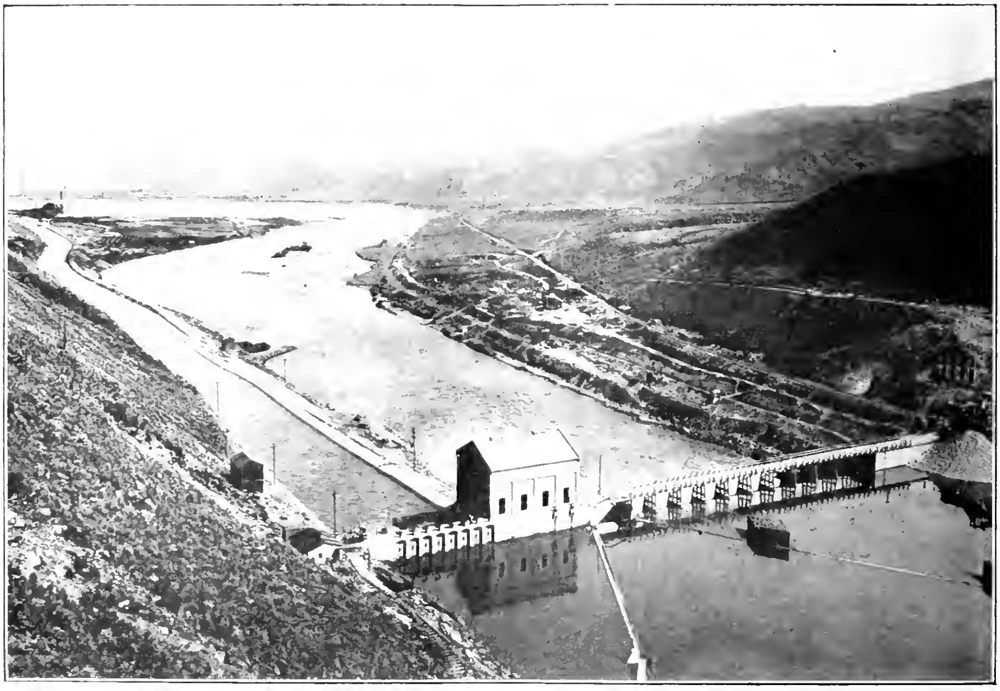

Fig. 1. Dam and Power House at Boise River

The exciters are supported by the top spiders of the respective alternators. The capacity of each is sufficient to furnish the maximum field current for two alternators, plus 10 kw. for local or other requirements. The exciters are designed to generate direct current at 125 volts. A regulator is used to control the generator voltage. Fig. 4 is a plan of the plant.

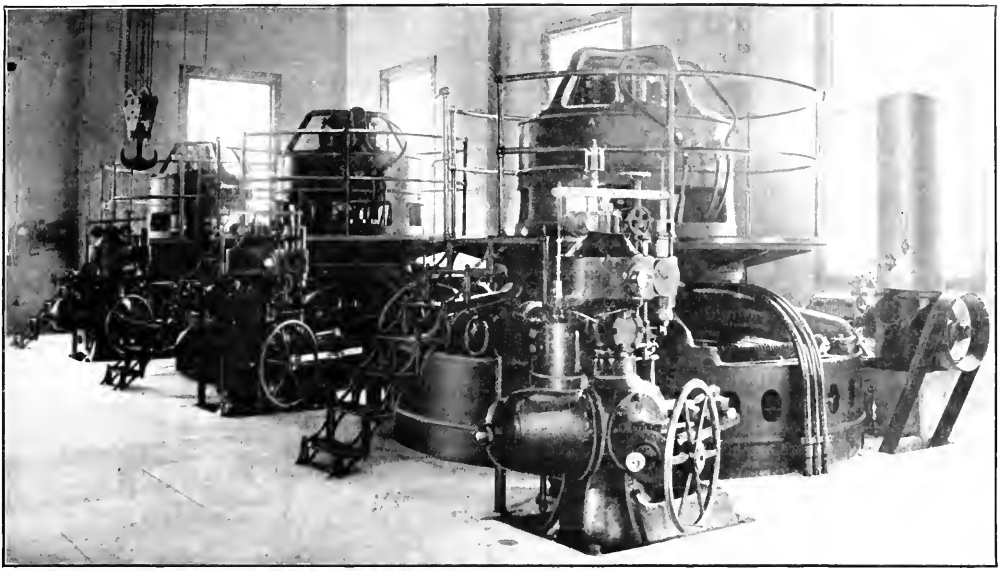

FIG. 2. GENERATING UNITS OF THE BOISE RIVER POWER PLANT

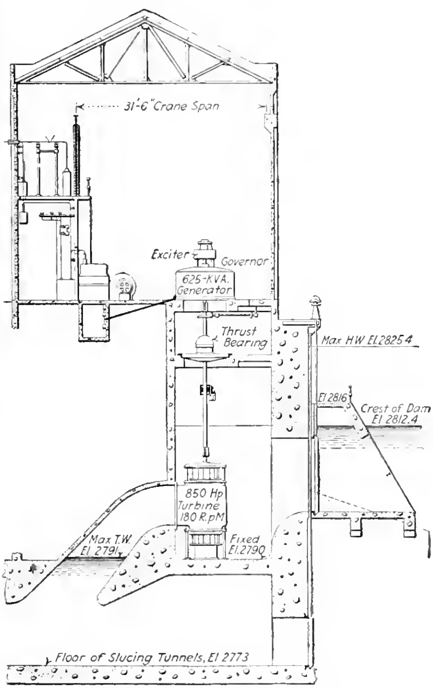

FIG. 3. ELEVATION OF ONE OF THE TURBO-GENERATOR SETS

The transformers for the alternators are air cooled by motor-driven blowers. An air compressor having a capacity of 50 cu.ft. per min. is provided for the needs of the station, and is driven by a 220-volt induction motor.

The present capacity of the plant is 1500 kw. A certain amount of electricity is used for local purposes on the dam, and some is used by the surrounding community, but the greater amount is intended and used for the building of the dam some fifteen miles distant. Nevertheless, the plant is a permanent structure and it is proposed to turn

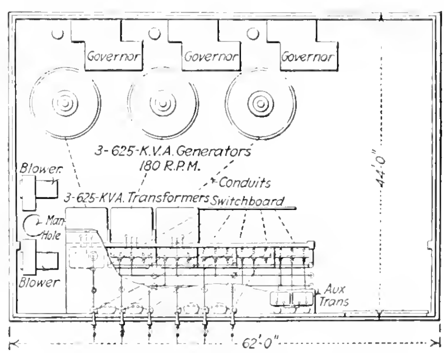

FIG. 1. PLAN OF THE BOISE POWER PLANT

the power over to local uses when the Arrow Rock dam is finished.

The plant is compact, the size of the power house being about sixty by forty feet. The irrigation canals which the dams in the project supply with water are in all about four hundred miles in aggregate length. The laterals from them are in the aggregate one thousand miles, an indication that the project is of more than ordinary consequence and magnitude.

Steam-Turbine Diagrams

By F. R. Low

SYNOPSIS—An explanation, "written so you can understand it," of the diagrams which show the working of the steam in turbine blades and how the energy of the swiftly moving jet is absorbed and converted.

To one riding in a railway car a ball traveling along parallel to the track, as in the line *mn*, Fig. 1, and with the same velocity as the car would appear to be stationary relatively to the car, just as though it were attached thereto by an invisible rod. If the car slowed up, the ball, although preserving its own velocity, would appear to shoot ahead, while if the car speeded up the ball would appear to be moving backward, with a velocity in either case equal to the difference between its own speed and that of the car.

FIG. 2

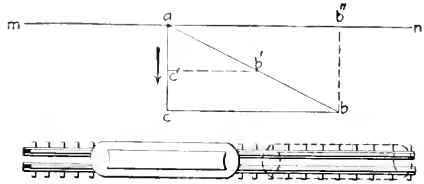

FIG. 1

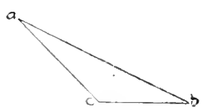

FIG. 3

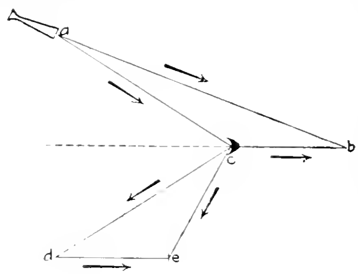

FIG. 4

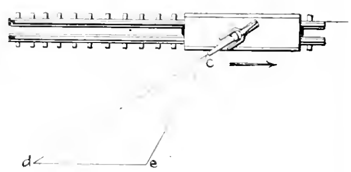

FIG. 5

Let the line *ab*, Fig. 2, represent in length and direction the velocity and direction of the ball. Set off upon it a distance *cb* representing to the same scale the velocity of the car at any instant. Then *ac*, the difference of these velocities, will be proportional to the speed of the ball relatively to the car; that is, to the velocity with which it would appear to the man in the car to be moving. Suppose the velocity of the car to be increased to that represented by the line *db*; then to the man in the car the ball would appear to be moving backward with a velocity proportional to *da*.

Returning to Fig. 1, suppose something should give the ball an impulse in the direction *ac*, with a velocity proportional to the length of that line, the velocity of the car and the previous velocity of the ball in the direction *mn* being proportional to $ab'' = cb$. To the man in the car the ball would appear to be coming straight toward him, just as though the car were standing still and the ball were batted from rest. And it would be coming straight toward him, for its motion relatively to the car would be in the line *ac*; but as the ball is going forward at the same time that it is moving sidewise toward the car, its path relatively to the ground would be *ab*, just as though it had gone to b'' first with its original velocity and direction, and then from b'' to *b*; but the car has gone ahead at the same time, so that it would hit it in the same spot and with the same velocity and at the same right angle as though both car and ball were standing still when the ball was impelled in the direction *ac*. At the end of the first half-second the ball, if moving only in the direction *ac*, would have gone from *a* to c', one-half of *a* to *c*, but in the same time, on account of its movement in the direction parallel to the track, would have gone from c' to b', so that at the end of the half-second it would be found at b'; and so for any subdivision of the time it would be found upon the line *ab*, which is the path that it would follow relatively to the ground.

If we represent, then, by the line *ab* the velocity and direction of the ball relatively to the ground, and by the line *cb* the direction and velocity of the car, the line *ac* joining their extremities will represent in length and direction the velocity and direction with and in which the ball approaches the car and with and from which it would appear to the man in the car to be coming.

With the ball still moving in the line *ab* and with a velocity proportional to the length of that line, suppose the velocity of the car to be reduced to *cb*, Fig. 3. Then the ball, although moving in the same direction and with the same speed relatively to the ground as before, will appear to the man in the car to be coming at him in the direction *ac*, Fig. 3, and with a velocity proportional to the length of that line.

Applying this to the relative motion of steam in a turbine, let *ab*, Fig. 4, represent, by its direction and length, the direction and velocity of a jet of steam issuing from a nozzle. Let *cb* represent the direction and velocity in and with which the blade moves. Then the jet would approach the blade in the direction *ac* and impinge upon it with a velocity proportional to the length of that line.

If the blade were symmetrical, so as to turn the jet back at the same angle, the jet would leave the blade in the direction *cd* and—neglecting loss from friction, impact, etc.—with the same velocity, *cd* = *ac*.

Suppose a ball to be fired from a gun placed at an angle upon a car, as in Fig. 5. If the car were standing still

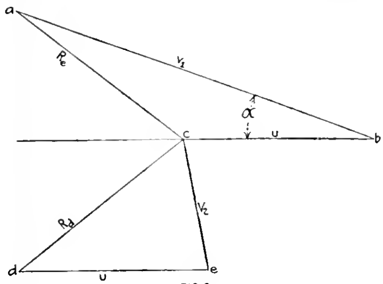

FIG.6

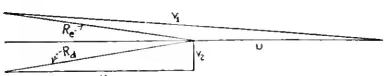

FIG.7

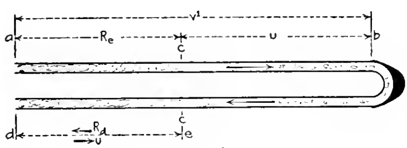

FIG.8

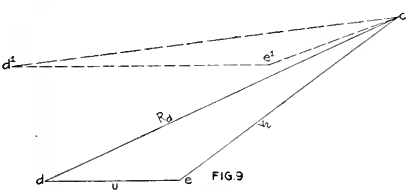

FIG.9

the ball would go off in the line *cd* relatively to the ground, but if the car were moving with a velocity which was to that with which the ball is projected as *de* is to *cd*, the ball would, by reason of the velocity acquired as a part of the car's contents, move forward a distance proportional to *de* in the same time that it moved the distance *cd* in the direction of its projection. Instead of being at *d*, therefore, it would be at *e*, and the path that it would have followed relatively to the ground would be *ce*.

In Fig. 4 we have a similar case. The steam is coming out from the blade in the direction and with the velocity *cd*, but it is traveling with the blade with the velocity and in the direction *cb* = *de*. Set off *de*, equal in length and parallel to *cb*, and the line *ce* will represent the direction and velocity of the steam when it leaves the blade with respect to the ground or to the stationary nozzle.

Fig. 4 or 6 is the typical diagram for a single-stage impulse turbine. The initial velocity is V_1 and the final velocity, V_2. The smaller V_2 in relation to V_1, the greater the proportion of the energy of the jet which has been absorbed by the turbine.

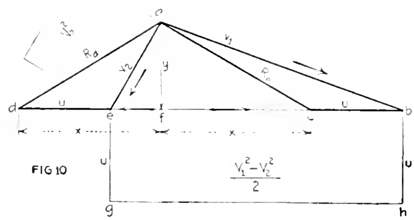

FIG 10

So long as the jet approaches the blade at an angle, as at *a*, there will be some sidewise direction to the final velocity V_2. As the angle *a* becomes less, the smaller may V_2 become, as in Fig. 7, until the jet is in line with the blade, Fig. 8, when the sidewise component disappears altogether and the diagram becomes a straight line, as shown in that figure. Its full length, $ab = V_1$, represents

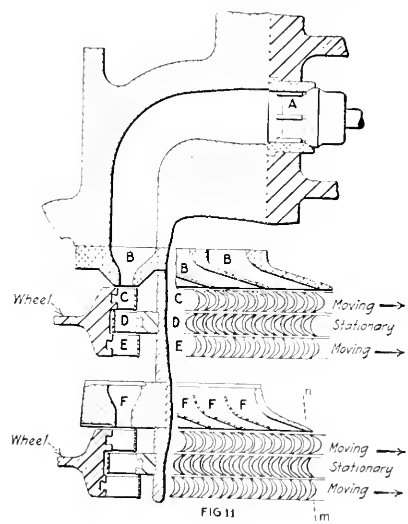

FIG 11

the initial velocity; *cb* = *u*, the blade velocity, and *ac* = R_e, the relative velocity and direction of entry, just as it did in the preceding figure, only that the triangle has been closed up and *c* lies upon the line *ab*.

If the jet is going at, say 1000 ft. per sec., and the blade is running away from it at 500 ft. per sec., the jet will be overtaking the blade at the rate (that is approaching it with the relative velocity) of 1000 — 500, or $R_e = V_1 - u = ab - cb = 500$ ft. per sec. This is R_e, the relative velocity with which the jet enters the blade. Neglecting friction, the jet is reversed in the blade and thrown backward to the same velocity R_d relatively to the blade; but, like the ball that was fired backward from the car in Fig. 4, it must have its forward motion subtracted from its backward velocity to show its velocity relatively to the ground. And when, from the relative velocity of discharge R_d, Fig. 8, we subtract the blade velocity u, by setting off upon the line $dc = R_d$ the line $de = u$, we have nothing left, indicating that velocity and energy have all been abstracted, that the steam has been brought completely to rest.

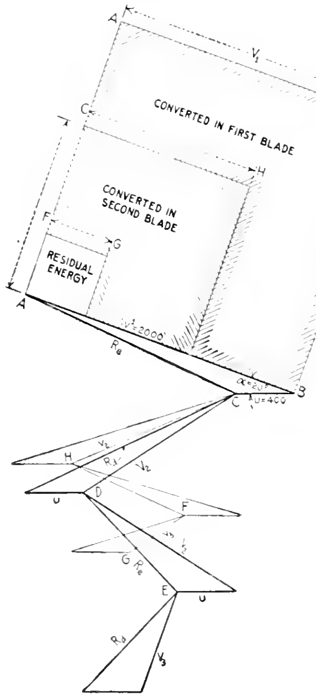

FIG 12

In order to do this for the abstract case the blade velocity u must be one-half the initial absolute velocity V_1, Fig. 7; for in order that the blade velocity $u = de$, Fig. 8, may equal and cancel the relative discharge velocity $R_d = cd$, u must also equal R_e, to which R_d is also equal; and since ab equals $R_e + u$, each of these quantities, if they are equal, must be one-half of ab.

Fig. 9 is the typical diagram for a single stage of a reaction turbine; $cd = R_d$ represents the direction and velocity with which the steam is discharged from the blade; u is the blade velocity, and V_2 the velocity relatively to the ground, as in the other diagram. So long as the jet is delivered at an angle there will be some residual velocity V_2 in the jet. By reducing the angle and increasing the blade speed, as shown in the dotted position, this residual velocity could be reduced from ec to $e'c$, but it is only when de becomes parallel with and equal in length to dc that the residual velocity disappears altogether. The blade of a reaction turbine must run at the same velocity as the jet, in order to reduce its velocity to zero and extract all of its energy. If a car were paying out a cable slower than the car was running, it would be dragging the cable along the ground. If it were paying the cable out faster than the car was running, it would be pushing the cable backward. If the speed of the cable through the opening in the car equaled the forward movement of the car, the cable would be laid quietly upon the ground with all the velocity and momentum which it possessed, as a part of the car's contents, taken out of it.

In Fig. 10 the triangle $cdec$ has been moved from the position which it occupies in Figs. 4 and 6 and attached to the other triangle at a instead of at c, producing the diagram which, as shown in the firmer lines, is frequently seen in turbine literature. The jet travels a distance proportional to ab in a second, in the direction in which it is discharged, but moves only a distance proportional to fb in the direction db in which the blade is moving.

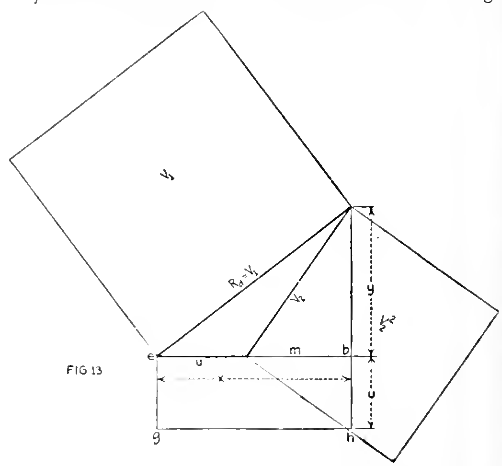

FIG 13

This line fb (the length of which is determined by dropping upon it a perpendicular as af from the other extremity of the line to one extremity of which it is connected) represents the "component" in the direction db of the velocity represented by ab. This component of the entering velocity is fb; the component of the discharge velocity ae is ef, opposite in direction from fb. The blade, therefore, has overcome, or annulled, the velocity fb and has gotten up new velocity fe. In other words, it has retarded the steam enough to destroy the velocity fb and accelerated it enough to produce the velocity fe. But retardation is only negative acceleration, and the effect is the same as though the steam had been accelerated from rest to a velocity proportional to be.

The *force* which must be exerted upon a body to produce a change in the velocity of its motion is equal to the product of its mass and the acceleration produced.

The *energy* is equal to the product of the force and the space through which it is exerted.

The energy produced by the flowing through the blades of a given mass of steam per second will be

$$\textit{Energy} = \underbrace{\textit{mass} \times \textit{acceleration}}_{(force)} \times \underbrace{\textit{blade speed}}_{(space)}$$

The acceleration is *be* and the blade speed u, equal to *bh* or *eg*, so that the area of the rectangle *ebhge* equals the product of the acceleration and blade speed, and the energy absorbed by the blade equals *mass* $\times$ area *ebhge;* that is, is directly proportional to that area.

The energy stored in a moving body is the product of the mass and one-half the square of its velocity. The energy in the entering steam is proportional to *mass* $\times \frac{V_1^2}{2}$, or to the area of the square upon the line *ab* multiplied by one-half of the mass. The residual energy in the escaping steam is *mass* $\times \frac{V_2^2}{2}$, or the area of the square erected upon the line *ae* multiplied by one-half the mass. The difference, *mass* $\times \frac{V_1^2 - V_2^2}{2}$, represents the difference in the energy of the steam as it enters and leaves the blade. But, neglecting friction, etc., there is no other place for the energy to go than to be absorbed by the blade, and the difference ought to be equal to the energy which we found to be so absorbed; hence

$$Mass \times \frac{V_1^2 - V_2^2}{2} = mass \times ebhge$$

Or, since the mass is common to both,

$$ebhge = \frac{V_1^2 - V_2^2}{2}$$

That is, the area *ebhge* equals one-half of the difference between the areas of two squares on *ab* and *ae*, or the difference between the areas of the two squares is twice the area *ebhge*.* Notice also in passing, that the work done is directly proportional to the line *eb;* that is, to the force exerted in the direction of the blade movement.

The velocity-stage turbine abstracts a portion of the residual energy V_2 by passing the steam again through the same or another set of blades. Suppose the size and speed of the turbine were such that a blade velocity u of 400 ft. per sec. could be obtained. Suppose, further, that the conditions as to initial pressure, superheat and vacuum were such that the steam would attain a velocity of 4000 ft. per sec. if allowed to complete the expansion in a single stage.

If the turbine were designed so that the steam would acquire half this velocity in the first stage, there would have to be three more such stages to complete the expansion; that is, if the work were to be equally divided between the stages, or if in no stage was the velocity to exceed 2000 ft. per sec., it would have to be a 4-stage turbine. The energy in a moving body varies as the *square* of the velocity. There is only one-quarter as much energy in steam flowing at 2000 ft. per sec. as at twice that speed, so that three similar stages with velocities of 2000 ft. would have to be used to take out the other three-quarters.

The velocity decreases inversely as the square root of the number of stages—½ the velocity for 4 stages, ⅓ the velocity for 9 stages etc.

Suppose, then, the steam is expanded in the first stage through a range that will give it a velocity of 2000 ft. per sec. The blade speed is 400 ft. per sec. and the angle a of the nozzle 20 deg., as shown in Fig. 11. It will be seen that there is considerable residual velocity V_2. The only way to reduce this would be to reduce the initial velocity V_1, which, as just shown, would require a number of stages varying as the square of the number of times the velocity is reduced, or to increase the blade speed u, which by the conditions of the case is impossible.

The somewhat common impression that reducing the blade speed and employing more stages produces better economy is not borne out by this analysis. For the abstract case the hydraulic efficiency depends upon the ratio of the steam speed to the blade speed and would be the same for one-half the blade speed if the steam speed were also halved. The turbine built with the greater number of stages would, however, be the more efficient because of the reduced surface friction, and because of the greater area of blade passage due to the lower velocity. The nozzles would occupy a greater number of degrees of the wheel surface and the gain from reheating would be slightly greater.

Fig. 11 shows diagrammatically a Curtis turbine. The high-pressure steam enters at A and expands in the nozzles BBB, impacting upon the moving blades CC, which are carried upon the crown of the running wheel, as shown at the left. Carried upon the casing is a set of stationary blades DD into which the steam is discharged with the velocity and in the direction R_d (of the diagrams), and in which the steam is turned around and discharged upon the blades E, also attached to the moving wheel. The blades E are deeper than the first ones C, not because the steam is supposed to expand in going through them, but to allow the constant volume of steam to pass at a decreased velocity. It comes off from the last row of blades E at the same pressure as that with which it left the nozzle B, but with its velocity very much reduced, and passes to the second set of nozzles FFF to have its velocity accelerated by another expansion.

If the blades were symmetrical the diagram for the abstract case would be that shown by the heavy lines in Fig. 12. The velocity V_2 with which the steam leaves the blade C is the same with which it enters the stationary blade D and with which it is discharged in the reverse direction upon the blade E, but the angle of this line is no longer 20 deg., and that of the relative entry R_e (see line DE, Fig. 12) approaches the bucket at much too broad an angle. The buckets are, therefore, so fashioned as to send the steam off at a sharper angle than that at which they receive it. Notice that a line drawn across the tips of a blade, as *mn*, Fig. 11, is not square with the line of the blade's movement. This results in a diagram more like that shown by the lighter lines in Fig. 12.

The final residual velocity V_3 is reduced to that indicated by the line FG. The initial energy is proportional to the area of the square on V_1, the energy of the steam as it enters the second rotating blade by the middle square, the difference being proportional to the energy taken out in the first blade. The residual energy is proportional to the smallest square and the energy taken out by the second blade to the difference between the areas of this and the middle square. The side of the second square is the V_2 and of the smallest square the V_3 of the lighter diagram. Unsymmetrical buckets on the moving wheel result in end thrust and must be used with discretion.

The reaction of a jet, or the force with which it pushes the nozzle backward, is *mass* $\times$ *velocity*. The absolute ve-

---

*$V_1^2 = (x + u)^2 + y_2 = x^2 + 2xu + u^2 + y^3$
$V_2^2 = (x - u)^2 + y^2 = x^2 - 2xu + u^2 + y^3$
Subtracting the two equations
$V_1^2 - V_2^2 = 4xu$
Hence $\frac{V_1^2 - V_2^2}{2} = 2xu = 2x \times u$, which is the area ebhge, for eb = dc = 2 x.

locity with which the jet leaves the blade is R_d in Fig. 13; the component of this velocity in the direction of the blade movement is $x = u + m$. The energy absorbed per second is the product of this force by the space moved through in a second, that is, by the blade velocity. It is, therefore, proportional to $mass \times u \times (u + m) = mass \times (u^2 + um)$. The energy due to the issuing velocity is $mass \times \frac{V_1^2}{2}$, that due to the residual velocity $mass \times \frac{V_2^2}{2}$, and the difference $mass \times \left(\frac{V_1^2 - V_2^2}{2}\right)$.

Leaving off the mass, which is common to both, it would seem that, as in the case of Fig. 10, the rectangle $ebhge = u^2 + um$, representing the energy absorbed, ought to be equal to one-half the difference of the two squares representing to the same scale the initial and final energies. But the difference in the two squares is easily proven to be $u^2 + 2\,um$.* Twice the rectangle would be $2\,u^2 + 2\,um$. The difference in the squares is less than twice the rectangle by just u^2; that is, by just the square of the blade velocity. This is because there was in the steam not only the energy due to the velocity with which it issued from the jet, but the energy which it took to get it into the blade and moving with the blade's velocity. If a diagram similar to Fig. 10 be drawn with the line $ac = R_e$ at right angles to the movement of the blade, it will represent the action of a pure reaction turbine, and the additional energy will be found in the motion represented in the line ab of such diagram.

Staying a Furnace Arch

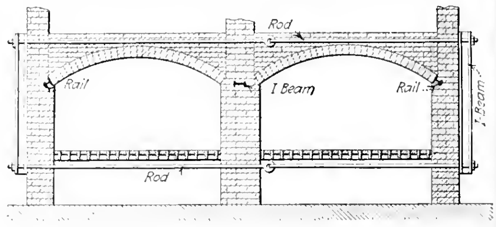
By J. C. Hawkins

Nearly every type of modern boiler furnace recommended to assist in giving complete combustion and to prevent smoke consists of firebrick piers, baffle walls, etc., placed directly in the path of the gases to cause a better mixture of the air and combustibles.

These gases are at a high temperature and impinge on the baffles and piers, often causing the firebrick to melt down quickly. The writer has seen bridge-walls in standard horizontal water-tube boiler settings, in which the top of the wall was melted and had run down on the back like huge icicles. The same trouble, only of a more serious nature, may occur in the arch of a dutch-oven furnace. If the arch is wide it exerts considerable pressure on the side walls and when the bricks become hot they tend to crush, the wall settles and exerts a greater pressure on the side walls. If the walls are not well stayed they will be pushed out and much air may leak in where it is not wanted.

The writer had considerable trouble of this kind in a battery of two vertical water-tube boilers with dutch-oven furnaces. The grate was 84 in. wide in each boiler and each furnace had a single-span arch. Each time the arch was renewed, which was about once a year, it pushed the walls farther out, and it was necessary to put in additional tie-rods. The accompanying sketch shows how this was accomplished. Four rods, 1¼ in. diameter each, were used; one was set at the end of the arch and one just inside the front wall. The lower rods were put in below the grate and close to it so as to be out of the way and not interfere with the pulling of the ashes. The top rods were covered with firebrick and ashes to protect them from the heat. The rods were made long enough to pass through the two settings, with a long thread and nut on each end. On account of close quarters the rods had to be linked in the center to get them in place. Four pieces of old railroad rail, each about 6 ft. long, were used as buckstays. In addition to these rods a 5-in. railroad rail about 8 ft. long was embedded in the center wall and also in the outside walls at the point where the arch rested, to strengthen the wall at this point.

This arch was constructed of a special grade of furnace brick and would last about a year, with hard firing. It is not usually possible to patch this arch when the center burns out, as it is generally sprung out of shape and sagged in the center. It is left as long as it will stand,



How the Furnace Arches Were Stayed

then torn out and a new one built. In the parts of the lining where the brick is not subjected to the extreme heat common firebrick will be found satisfactory and cheaper than the high-grade brick used in the furnace. After the bricks become glazed over, which protects them, they should not be disturbed until it is necessary to repair them.

Fluid Cling-Surface

To overcome the necessity of heating Cling-Surface belt dressing without impairing its efficiency has long been the aim of the Cling-Surface Co., Buffalo, N. Y.

This has been accomplished, and the dressing has been converted to a semifluid ready for use at any temperature above 60 deg. F. In other words, no heating is required during eight to ten months of the year, nor in the winter if it is kept in a warm room. Where it is kept in a cold room or exposed to winter temperature, it need not be heated above 100 deg. F., and then only for a few minutes for softening.

U. S. Coal Production in 1914—According to Edward W. Parker, statistician of the United States Geological Survey, the total coal production of the United States in 1914 was about 510,000,000 short tons, a decrease of about 60,000,000 tons compared with the record output of 1913. Practically all of this decrease was in the output of the bituminous mines. The production of Pennsylvania anthracite in 1914 was not materially different from that of the preceding year, which was 81,718,680 long tons. In 1914, however, about 1,000,000 tons (principally nut and steam sizes) went into storage, so that the quantity sent to market was about 1,000,000 tons less than in 1913. The principal decreases in the production of bituminous coal were in the coking districts. It is estimated that in Pennsylvania alone the production of bituminous coal decreased between 20,000,000 and 25,000,000 tons, and that the larger part of this decrease was in Fayette and Westmoreland counties, which constitute the Connellsville and Lower Connellsville coking districts.

$$\begin{aligned} {}^*V_1^2 &= y^2 + (u+m)^2 = y^2 + u^2 + 2\,um + m^2 \\ V_2^2 &= y^2 + m^2 \\ \text{difference} &= u^2 + 2\,um \end{aligned}$$

Interior Wiring for Lighting and Power Service—I

By A. L. Cook*

SYNOPSIS—The first of a series of articles covering the methods employed in making plans of lighting and power systems for industrial establishments and office buildings, and in calculating the sizes of wires required for such service. The treatment is such as to meet the requirements of superintendents or engineers in charge of such buildings, who may be called upon to make additions to or changes in the equipment; and no attempt has been made to cover problems which should be handled by the illuminating engineer or a power specialist. The first installment covers the voltages and systems employed, the National Electric Code Rules, the types, number and spacing of lamps and the determination of the lighting load.

The usual voltages employed for lighting are about 120 or 240 with a two-wire system and 120 for each side with a three-wire system. Either direct or alternating current may be used. Occasionally, three-phase or two-phase alternating current is employed for lighting, because of peculiarities in the conditions of supply. For alternating-current lighting 60 cycles is generally used, since 25 cycles is not as satisfactory owing to a flickering of the lights in some cases. It has been found, however, that tungsten lamps having a rating of 60 watts or more can be employed satisfactorily on 25 cycles. With ordinary inclosed arc lamps, 25 cycles is not satisfactory, although flame-carbon arc lamps can be used on this frequency. For direct-current motors, the standard voltages are 115, 230 or 550, and for alternating-current motors, 110, 220, 440 and 550 volts are commonly employed, although in some cases for very large motors, 2200 volts is used. The frequency may be either 60 or 25 cycles, and occasionally 40.

The voltages given for lighting and power service are the values at the lamps or motors. The standard generator voltages for direct current are 125, 250 and 600, and for alternating current, 120, 240, 480 and 600, which allows a reasonable drop between the generator and the load. In some cases a multivoltage system is used for motors, in order to give a ready means of varying the speed. This is not generally necessary, however, since modern direct-current motors permit wide speed variation by a change in the field strength.

The choice of a particular system for lighting or power service is affected by a number of factors, such as the character of the existing system or the central-station source of supply, and the relative sizes of the power and lighting loads. When an extension is to be made to an existing installation, the same system must be used for the extension, unless the addition is so large or the requirements differ so widely that a change in the system or the addition of a different kind of supply can be seriously considered. For a new plant more freedom of choice exists, and the relative merits of the various systems will therefore be considered.

Direct vs. Alternating Current

For lighting, either alternating or direct current would, in general, be satisfactory, and the advantage of easy change of voltage in the case of the former makes it preferable in supplying buildings covering large areas. However, the lighting load is usually small, compared with the power load; hence the choice is fixed by the power requirements. The important advantages and disadvantages of alternating and direct current for power supply may be summarized as follows:

DIRECT CURRENT	ALTERNATING CURRENT
It is not generally feasible to use more than 240 volts for lighting. Therefore this limits the voltage of the system if supplied from the same generator as the motors.	The voltage can be easily transformed, using voltages suitable for lights and motors.
2. Maintenance is higher, owing to commutators.	2. There is no commutator; hence the motor is more rugged. It will stand larger momentary overloads, there is no danger of fire from sparks at the commutator and it is more reliable.
3. Wide speed variation of motor by simple means, with high efficiency.	3. Speed variation is difficult and the motor is less efficient at reduced speeds.
4. Motors have better starting characteristics for cranes and elevators.	4. Operation is not satisfactory on high-speed elevators and large cranes. Starting current is greater.
5. Starting current is lower for usual types of constant-speed motors.	5. Starting current for ordinary type is large. Special arrangements are necessary to reduce it.
	6. A somewhat larger generator is required for a given motor load.

The relative sizes of the power and lighting loads will have an important bearing upon the selection of the system. In some cases of light manufacturing, particularly if all the work is in one building, where the feeders would be short, direct current might well be used, employing 120 volts two-wire for small systems, and 240 volts three-wire, or possibly two-wire, for larger systems. If a two-wire system be used, the feeders would be about one-fourth as large for the 240 volts as for 120 volts; but, on the other hand, the lighting would have to be supplied at 240, which would entail somewhat greater cost for lamps and maintenance. It is better to operate the motors at 240 volts and supply the lights on a 120-240-volt three-wire system. By this means, the saving in size of feeders is nearly as great as if the entire load were supplied at 240 volts and the advantage of the lower-voltage lamps is secured. The additional power-house equipment is of small cost.

For most industrial uses, the alternating-current motor is satisfactory, and in some cases almost necessary, either because of the great distances from the power house or the

*Head of Department of Applied Electricity, Pratt Institute, Brooklyn, N. Y.

severe operating conditions due to dust, moisture, etc. Its principal disadvantage is the difficulty in adjusting the speed. With a direct-current system it is possible to obtain motors which will allow a speed change of three to one. When the speed is adjusted to a given value between these limits, it will remain practically constant regardless of the load. Such motors are extensively used for driving lathes and similar machine tools. It is possible to provide means by which the speed of an alternating-current motor can be adjusted to as wide a range as the direct-current motor, but usually at a sacrifice in efficiency; whereas, the direct-current motor has nearly the same efficiency at all speeds. Moreover, the variable-speed alternating-current motor, having been adjusted to a particular speed, will not maintain this as the load changes; instead, the speed will increase as the load decreases. This wide speed variation is objectionable where constant speed with varying load is necessary, as in machine-tool driving; but for some purposes, such as ventilating fans, centrifugal pumps, paper machines, and the like, where the load does not vary suddenly, the use of an alternating-current adjustable-speed motor is satisfactory. Alternating-current motors are not as satisfactory for cranes and elevators, owing principally to the difficulty of control, particularly when making stops. For this reason direct-current motors are to be preferred for high-speed elevators and large cranes. Therefore, in an office building where the elevator load is usually greater than the other motor load and the length of the feeders is not great, the direct-current system is preferable. For large buildings the three-wire, 240-volt system should be used, the motors operating at 240 volts and the lights at 120. Only in small buildings should the 120-volt two-wire system be used.

If the building is not supplied from a power plant on the premises, but obtains its supply from a central station, the type of service will depend upon the system of the supply company. If only alternating current is available it will be best to use alternating-current elevators unless the speed is high (above 300 ft. per min.) rather than provide the necessary transforming apparatus. For industrial establishments in general, the alternating current is to be preferred unless the cranes and variable-speed tools form a large proportion of the total load. If it is absolutely necessary to use direct current for some of the motors, it is better to provide alternating-current service for general uses, with a direct-current supply for cranes and special work.

When installing any wiring it is desirable to conform in all respects to the local rules governing such installations. The rules of the National Board of Fire Underwriters, called the "National Electric Code," form the basis of most of the regulations which have been issued by various cities and other parties interested, and must be followed in order to obtain fire insurance on property. These rules may be obtained gratis from the National Board of Fire Underwriters by applying to its New York, Boston or Chicago offices. The Inspection Department of the Associated Factory Mutual Fire Insurance Companies, with an office in Boston, has issued the "National Electric Code" with explanatory notes, thus giving in many cases more specific directions for the proper installation of electrical apparatus than is contained in the "Code." In many cases there are rules issued by the city inspection departments, which are substantially the same as the "National Electric Code," but care should be taken to see that the work not only meets the code requirements but also conforms to the local rules. In the following discussion the rules of the "National Electric Code" are followed.

Choice and Distribution of Lamps

The subject of the proper illumination of industrial establishments has in the past few years been given considerable attention on the part of factory superintendents and managers, who have begun to realize that it pays to provide sufficient illumination. Investigations have shown that an efficient lighting system increases the output from 2 to 10 per cent., and it has also been found that the number of accidents is materially reduced when adequate lighting is provided.

For interior illumination of buildings, there are available the following types of lamps:

Lamp	Service
1. Carbon-filament	A.C. or D.C.
2. Gem- or metallized-filament	A.C. or D.C.
3. Tantalum	A.C. or D.C.
4. Tungsten, including "nitrogen" filled lamps	A.C. or D.C.
5. Inclosed-carbon arc	A.C. or D.C.
6. Metallic-flame or magnetite arc	D.C.
7. Flame-carbon arc	A C. or D.C.
8. Nernst	A.C. or D.C.
9. Cooper-Hewitt mercury arc	A.C. or D.C.

While all of the foregoing types have been used for interior illumination, the practice has now become so standardized as to make the tungsten lamp by far the most common for ordinary heights of ceilings. The metallic-flame arc and flame-carbon arc are used for lighting large floor areas with high ceilings, particularly where there is more or less smoke and gas. The so-called nitrogen-filled lamp, which is a special form of tungsten lamp with the bulb filled with nitrogen or a similar gas, is very useful where large lighting units can be employed, and the tendency is to use this in place of the metallic-flame or flame-carbon arc, owing to the reduced cost of maintenance. The mercury arc has also been used extensively, principally because of its small power consumption, but it produces such an objectionable color that it is unsuitable for many uses and can better be replaced by the nitrogen-filled lamp. This gives a light even whiter than the ordinary tungsten lamp with a power consumption not much greater than that of the mercury arc. Present practice, therefore, for rooms of ordinary height, has narrowed down to the use of tungsten lamps with glass or steel reflectors, mounted near the ceiling and arranged to give sufficient illumination to the entire room. In general, drop cords with individual lights have been eliminated as far as possible and are used only for special work which cannot be lighted from the overhead lamps. Where it is necessary to use individual lights, a 16-cp. carbon-filament or a 40-watt gem lamp is used. The latter is preferable as it gives the same candlepower as the carbon and requires about 20 per cent. less power. Table 1 gives data on the various sizes of tungsten lamps.

TABLE 1—DATA ON TUNGSTEN LAMPS*

Size, Rated Watts	Candle-power	Watts per Candle-power	Life, Hours	Approximate Current, Amperes 120 Volts	240 Volts
25	24	1.05	1000	0 21	0.11
40	39	1.03	1000	0.33	0.17
60	60	1.00	1000	0.50	0.25
100	105	0 95	1000	0.83	0.42
150	167	0.90	1000	1.25	0.62
250	278	0.90	1000	2.08	1.04
400	445	0.90	1000	3.33	1.67
500	555	0.90	1000	4.16	2.08
†200	222	0.90	1000	1.67	...
†300	353	0.85	1000	2.50	...
†400	534	0.75	1000	3.33	...
†500	714	0.70	1000	4.16	...
†750	1150	0.65	1000	6.25	...
†1000	1665	0.60	1000	8.33	...

*From figures supplied by the National Lamp Works of the General Electric Co. The above applies to 120-volt lamps; for 240-volt lamps the watts per candlepower are about 10 per cent. higher.

†Nitrogen-filled lamps of 120 volts only.

Sizes smaller than 25 watts are manufactured, but are not suitable for industrial lighting. For multiple inclosed-flame arcs the following values are typical:

	Direct Current	Alternating Current
Voltage	110	110
Watts	715	510
Amperes	6.5	7.5
Power factor		0.62
Candlepower	1740	1600
Watts per candlepower	0.41	0.32

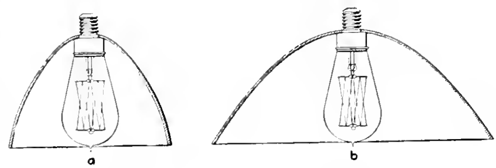
In the case of the arc lamp, the candlepower refers to the average for the lower hemisphere of the lamp. For the tungsten lamps the candlepower and efficiency values are based on average candlepower in a horizontal direction when the lamp is vertical, no reflectors or shades being used.

It is not the intention to go into the details involved in the determination of the proper number and spacing of lamps for all classes of service, as this is a task for the illuminating engineer. Careful calculations of such a problem require considerable experience and a knowledge of the effect of reflection from walls and ceilings. It is frequently necessary, however, to make a rough estimate of the amount of power required for lighting, in order to provide the necessary feeder and generator capacity. There are a few simple rules that can be applied in such cases, which will give satisfactory results under usual conditions.

It is first necessary to determine the amount of power required for a given floor area. This will depend, of course, upon the amount of light necessary, which will vary with the character of the work carried on. Table 2 gives the number of watts required per square foot of floor area for different classes of work, with various arrangements of tungsten lamps. These values are based on good practice and will give first-class illumination under average conditions. The principal item which would affect these values is the color of the ceilings and walls. For offices, stores, corridors and drafting rooms it is assumed that both the ceilings and the walls are fairly light in color, while for factories, warehouses and power houses they would be darker and less light would be reflected. The figures given for general office illumination are sufficient for usual office work, while those for special illumination should be used where bookkeeping or work of a similar nature is carried on. The amount of power allowed for a drafting room is sufficient to provide suitable illumination without the use of individual lamps. For rooms where rough manufacturing is carried on and where close application to the work is not required, the figures for general factory illumination should be sufficient; for fine machine work, toolmaking and bench work, those for special factory illumination should be used. The lamps should be provided with suitable reflectors, in order to direct as much of the light as possible on the work. There is a great variety of these reflectors, but they can all be grouped in a few general classes, each of which is best adapted for particular conditions. There are on the market several types of glass reflectors which direct most of the light in a downward direction, but allow a certain amount to pass through to the ceiling. The best example of this type is the prismatic "Holophane." In order to have a good distribution of light, it is necessary to employ the proper style of reflector; hence a different size is manufactured for each size of tungsten lamp. It is necessary also to use the right type of shade holder in order that the lamp may be correctly located in the reflector.

Since modern systems of illumination are usually laid out to give practically uniform lighting over the entire floor area, it is necessary to use different types of reflectors for different heights of ceilings and spacings between lamps. The Holophane prismatic glass reflectors are made in three styles: "Extensive," for low ceilings; "intensive," for medium ceilings; and "focusing," for high ceilings. Glass reflectors are best adapted for offices, stores, drafting rooms and similar places, where it is desirable to light the walls and ceilings, as well as the work. They have also been used quite extensively for factory lighting, but are not suitable for use where there is danger of breakage.

Steel reflectors are made in a number of styles, with white porcelain-enamel surfaces, white painted surfaces, or aluminum painted surfaces. In general, the porcelain-enameled reflector is better than the others, owing to a great reflecting power, and the ease with which it can be kept clean. There are two general types of steel reflectors—the bowl, shown in Fig. 1-*a*, and the dome, in Fig. 1-*b*. These reflectors are made in various sizes to suit particular tungsten lamps, and in various shapes for different heights of ceiling. The dome type (*b*) should be used generally; the bowl type (*a*), which incloses the lamp more than the dome, being used only when the lamps are mounted so low that they would be in the line of sight of the workmen. When steel reflectors are used, the ceilings are not illuminated, except by a small amount due to reflection from the benches or tables; but for many industrial applications this is not objectionable. In offices the steel reflectors do not give a pleasing effect. Values for either glass or steel reflectors are given in column A of Table 2, since they are both classed as direct illuminants. For the same character of walls and ceilings there would be only a slight difference in the amount of illumination produced by the two types.



a b

FIG. 1. BOWL TYPE DOME TYPE

TABLE 2—POWER REQUIRED FOR ILLUMINATION. TUNGSTEN LAMPS*

Class of Work	Watts per Square Foot Direct A	Indirect B
Office—general	1.00	1.60
Office—special	1.25	2.00
Drafting room	2.00	3.20
Corridors and halls	0.50	0.80
Factories—general	0.80	...
Factories—special	1.50	...
Warehouses	0.50	...
Stores	1.25	2.00
Power house	0.80	...
Storage	0.30	...

*If nitrogen-filled lamps are used, multiply the watts per square foot as given above by 0.75.

In some cases, particularly in drafting rooms, the indirect system of lighting is preferable. With this the light is directed upon the ceiling and is then reflected onto the work. It results in lower efficiency, but in many cases is justified, in order to eliminate troublesome shadows. A modification of this system involves the use of reflectors, which allow a small portion of the light to be directed downward, giving what is called a semi-indirect system. A satisfactory arrangement with this system is to employ glass reflectors mounted on suitable fixtures and pointed toward the ceiling, instead of downward, as is usual. The indirect system depends for its efficiency upon light-colored ceilings and walls, and therefore is better adapted for use in offices, stores and drafting rooms than in factories.

The allowable watts per square foot for a given class of work can be found from Table 2, and when multiplied by the floor area, will give the total power required. It may seem to some that the height of the lamp above the work would have a decided effect upon the amount of power required, but this is not the case provided a suitable reflector and proper spacing of the lamps are employed. There is, however, a considerable difference in lighting depending upon the number of units employed and the color of the walls and ceiling.

As an example, the figures of Table 2 will be applied to the lighting of four floors of a factory building having a width of 46 ft. and a length of 135 ft., divided into nine bays 15 ft. wide, with a line of columns down the center of the building. Table 3 gives a tabulation showing the lighting to be provided for each floor.

TABLE 3—EXAMPLE OF LIGHTING CALCULATION

Floor	Character of Work	Ceiling Height, Feet	Area, Sq.Ft.	Assumed Watts per Sq.Ft.	Size of Unit	Actual Watts per Sq.Ft.
Basement	—Storage	8	6210	0.30	60	0.35
First floor	—Machine shop	14	6210	1.50	100	1.74
Second floor	—Assembly...	12	6210	1.50	100	1.74
Third floor	—Stock room..	12	6210	0.50	100	0.58

This building would employ direct lighting by means of tungsten lamps, and steel or glass reflectors. From the

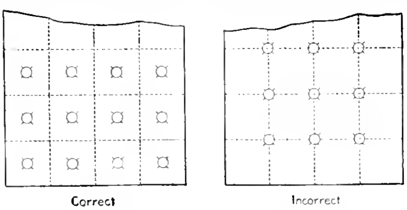


Fig. 2. Spacing of Ceiling Outlets

given floor areas and the allowable watts per square foot, the approximate amount of power can be estimated. This would be sufficient for an estimate of the total load required for the lighting, but in general it is best to choose the size of units and determine the number to be employed, since the spacing which must be used often modifies the total load.

The spacing and size of unit to be used are affected by the height of ceiling as well as by the arrangement of the beams or girders. There is a certain relation between the height of the lamps and their size, which must be adhered to as closely as possible, in order to get uniform illumination without objectionable shadows. For low ceilings the units should be small and closely spaced, while for high ceilings large units, more widely spaced, should be used. Table 4 will serve as a guide to the selection of the proper size of unit. This should be used in connection with Table 5, which gives the approximate spacing of lamps of different sizes.

The units should be mounted at least 8 ft. from the floor and more if possible; a height of 10 ft. being satisfactory for rooms with ceilings 11 to 16 ft. high. For higher ceilings, cranes and other obstructions usually fix the height of mounting. If deep girders divide the ceiling

TABLE 4—SIZES OF LIGHTING UNITS FOR VARIOUS MOUNTING HEIGHTS

Height of Unit above Floor	Size of Unit, Watts
Up to 9 ft................	40 or 60
9 to 11 ft................	60 or 100
11 to 16 ft................	100 or 150
16 to 20 ft................	150 or 250
20 ft. and above............	250, 400, 500 and nitrogen-filled lamps or flame arcs

TABLE 5—APPROXIMATE SPACING DISTANCES FOR LIGHTING UNITS

Size of Units, Watts	Watts per Sq.Ft., Direct*	Spacing Distance	Size of Units, Watts	Watts per Sq.Ft., Direct*	Spacing Distance
40	0.3	11 ft. 6 in.	150	1.5	10 ft.
40	0.5	9 ft.	150	2.0	8 ft. 8 in.
40	0.8	7 ft.			
			250	0.3	29 ft.

100	2.0	7 ft.			
			500	0.8	25 ft.
150	0.5	17 ft. 4 in.	500	1.0	22 ft. 5 in.
150	0.8	13 ft. 8 in.	500	1.25	20 ft.
150	1.0	12 ft. 3 in.	500	1.50	18 ft. 3 in.
150	1.25	11 ft.	500	2.0	15 ft. 10 in.

*The figures given apply to ordinary tungst lamps. In general the spacing of lamps should be about 50 per cent. greater than their height above the work illuminated.

into bays, the lamps should be located slightly below the bottom edge of the girders if possible. Having fixed upon a suitable mounting height, a size of unit should be chosen by reference to Table 4. The rating of this unit divided into the total watts for the given floor area will give the required number of lights. This number should then be laid out upon a plan of the room and the spacing checked with the average values given in Table 5. The lamps should be located without reference to the individual machines, so that a change in the latter would not affect the system. Each light should, if possible, be located in the center of a square, the length of the side being the spacing distance assumed. The lamps should be arranged in parallel rows, the distance between rows each way being as nearly as possible equal to the given spacing distance. The distance from the wall to the first row should be about one-half the spacing distance, except where benches are located at the side walls, when the first row of lights should be located about 12 to 18 in. nearer the wall than the edge of the bench. If the room is divided into bays by deep girders or columns, each bay should be treated as far as possible as a unit, and the lights so spaced as to avoid shadows from the columns. If the size of lamp first selected does not give a suitable number for convenient location, a different size should be chosen and another arrangement tried. It is, of course, desirable to use as large a unit as possible, to reduce the cost of the wiring; on the other hand, a smaller unit gives more uniform distribution of the light, greater freedom from shadows, and less trouble due to one light being extinguished. With a smaller unit it is also possible to arrange a more flexible method of control, allowing some of the lamps to be extinguished during a part of the time, and resulting in a saving in power.

In the example selected, the basement requires about 0.3

watt per square foot. From Table 4 either 40- or 60-watt lamps could be used. From Table 5 it will be seen that 40-watt lamps, to give 0.3 watt per square foot, must be spaced on 11-ft. 6-in. centers. This does not work in well, since the bays are 15 ft. wide. If 60-watt lamps are selected the spacing could be 14 ft. 2 in., which would allow one lamp in each row per bay. Allowing four rows—two either side of the line of columns—gives a total of 36 lamps or $36 \times 60 = 2160$ watts, which gives $\frac{2160}{6210} =$ 0.35 watt per square foot. The spacing of the rows would be $\frac{46}{4} = 11$ ft. 6 in., the two rows next the walls being 5 ft. 9 in. from the wall.

For the first floor about 1.5 watts per square foot will be required. From Table 5 it will be seen that a 100-watt unit would give a spacing of 8 ft. 2 in., and from Table 4 that this size is suitable for the height of ceiling. Therefore, two units per bay can be allowed, giving a spacing of 7 ft. 6 in. With six rows there would be a total of 108 units, requiring 10,800 watts. This is equivalent to 1.74 watts per square foot, which is somewhat more than was assumed. If the same number of 60-watt units were selected, a total of 6480 watts would be required, or 1.04 watts per square foot. Because of the columns through the center seven rows could not be used and with eight rows the spacing would be too small and the cost of installation too great. The distance between the wall and the first row would ordinarily be one-half the distance between the other rows; but in this case, as there would be benches along the walls, the rows next the walls could be located 2 ft. away and the other rows spaced evenly, giving about 8 ft. 5 in. for the distance between these rows. The other floors would be treated similarly. If there are no beams to divide the room into bays, the problem is simplified, but it must be remembered that the lamps should be located in the center of the square or rectangle and not at the corners; see Fig. 2.

Vacuum Heating Systems

By W. L. Durand

The use of vacuum heating systems has increased to such a large extent in the last few years that a general description of this method of heating may be of interest to engineers who are not familiar with it.

The advantages of a vacuum system over a gravity system may be summarized as better circulation, the use of smaller pipes and the absence of air valves. In buildings with steam power plants, when the exhaust steam is in excess of the requirements for heating, a vacuum heating system is a distinct factor for economy, since the back pressure on the engines can be reduced to atmospheric, thereby correspondingly decreasing the water rate of the engines, and for very high buildings, buildings with large floor areas, or a group of buildings, a vacuum system is practically the only type of steam heating system that will work satisfactorily.

One of the claims set forth by the manufacturers of vacuum valves is that wide variation in temperature is permissible. This is, however, more a talking point than anything else, as in the best-designed systems the pressure in the radiators is rarely lower than 2 in. of vacuum or more than two pounds above atmosphere, or a range of only about 10 deg.

There are three types of vacuum return valves on the market—the float, the thermostatic and the differential. The float type acts on the principle of a bucket trap, the condensed water raising a float which opens an outlet that allows the water to run out until just enough is left to maintain a seal, when the outlet is closed. A very small opening is left for the air to escape. This type of valve has the disadvantage that the opening for the escape of air allows steam to leak into the return lines, keeping the temperature of the returns so high that it is necessary to use an injection of cold water at the pump to maintain the desired vacuum.

In almost every case the manufacturers of the float type of valve have gone over to the thermostatic type. In this a hollow metal disk, usually made of copper, is filled with one or more liquids that vaporize at or around 200 deg. The action of this valve is extremely simple. Any air or condensed steam of a lower temperature than the valve is set for passes through the outlet, but as soon as steam reaches the disk the expansion of the liquid inside shuts the valve off. The advantage of this over the float type is that it is noiseless and does not pass steam, thus doing away with the use of jet water at the vacuum pump.

Thermostatic valves may be divided into two classes—one in which the expansion disk is on the pressure side of the valve and the other in which the disk is on the vacuum side. In most cases either kind of valve works satisfactorily, but experiments have shown that those with the disk on the pressure side can carry about 20 in. of vacuum, as against 10 in. for the other kind.

The third type of vacuum return valves is used on what is known as th differential system. In this a weighted check valve with restricted orifice is placed on the return side of each radiator. These valves are placed at different points, usually at the bottom of each return riser on the end of a horizontal run. The valve disk is weighted with a number of lead disks, the size of opening and weight of disks being so proportioned that for each lead disk a difference of pressure of 1 in. of mercury is required to lift the valve. By varying the number of disks any vacuum from 2 in. or 3 in. to 15 in. can be carried, as may be desired. This is the only type of valve by which the vacuum carried can be so varied, a feature which is advantageous for systems spread out over large areas or which have long horizontal runs.

In its installation a vacuum system is no different from a gravity system except that smaller pipes can be used, especially for the returns, and the vacuum valves are placed on the radiators and no air valves are used. The main return line is carried through a strainer to the vacuum pump, which can be either steam or electric driven, and from there it is pumped to a small tank with a vent open to the atmosphere. This relieves the tank of entrained air, and the return water is either fed direct to the boiler or through a feed-water heater.

It is not advisable to cover the returns in a vacuum system, as the exposed pipe surfaces allow the water to become sufficiently cooled for operation of the vacuum pump without the use of jet water. Where vacuum return valves are used dirt pockets should be provided, and in starting a new system the interiors of the valves should be removed and the system should be operated for four or five weeks as a gravity system.

The Peterson Power Plant Oil Filter

This filter, which is manufactured by the Richardson-Phenix Co., Milwaukee, Wis., embodies new principles of oil purification. Its operation is as follows:

The dirty oil enters through the strainer box at the top and passes down through the removable strainer, where large particles of foreign matter, such as waste and the like, are strained out; the oil then goes to the heating tray where its viscosity is reduced. It then flows to the compartment below the heating coils and down through the funnel. The further operation of the precipitation compartment is more clearly shown in Fig. 2.

Passing down through the tube conductor, the oil is spread out by a baffle under the lower tray. Under the action of the greater head which builds up in the tube conductor, the oil is forced to take a zigzag path upward, passing under and over several trays, as shown by the lines of flow. It then passes out through the opening below the heating tray to the filtering compartment. The separated water collects in the bottoms of the different trays and is bypassed to the bottom of the precipitation compartment by means of funnels that surround the tube conductor, and does not again come in contact with the traveling oil.

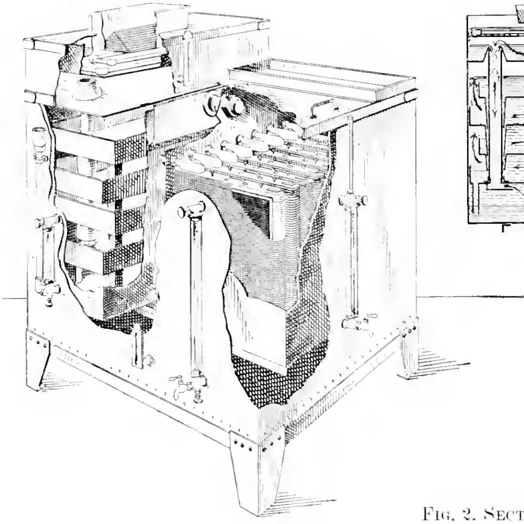

Fig. 1. Showing Interior Construction of the Filter

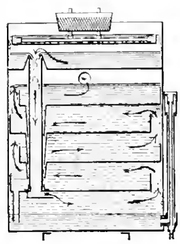

Fig. 2. Section through Water-Separating Chamber

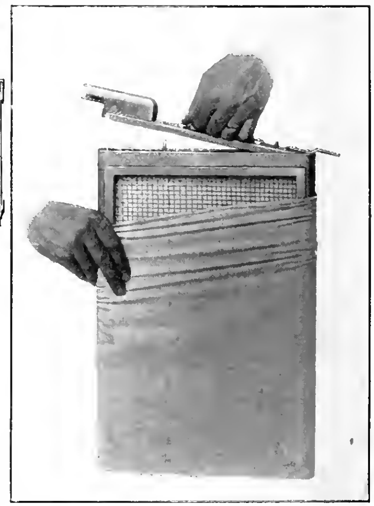

Fig. 3. Noncollapsible Filtering Unit

The water which is removed by the precipitation process is automatically ejected by an overflow tube at the right, which consists of two concentric pipes. The water flows upward through the outer tube and spills over the top of the funnel. The lower end of the tube can be connected to a sump or sewer. The funnel is threaded and can be raised or lowered, providing for proper adjustment for oils of different specific gravities. This water overflow simply operates on the U-tube principle; that is, the column of water in the outer pipe balances a column in the filter made up partly of oil and partly of water. As oil is lighter than water, the top of the overflow is a little lower than the level of oil in the precipitation compartment. As more water is precipitated out of the oil, the water level in the precipitation compartment tends to rise and the leg of the U-tube, which is inside the filter, becomes heavier because it is made up of a greater proportion of water and less of oil, thus water flows over the top of the funnel until the two legs of the U-tube again balance. In this way a low-water level is automatically maintained in the precipitation compartment.

Referring to Fig. 1, the level of the oil in the top tray is maintained constant by the skimmer, and the oil then flows through a pipe into the filtering compartment, which contains nine noncollapsible filtering units, such as is shown in Fig. 3. The oil passes from the outside to the inside of the filtering units, then out through the nozzles which project through the wall of the filtering compartment, to the clean-oil compartment. The nozzles on each unit fit into a spring-actuated valve so that any individual unit can be withdrawn and cleaned without interfering with the continuous operation of the filter. When the unit is withdrawn, this valve closes and prevents unfiltered oil from flowing into the clean-oil compartment. The filtering cloth is so arranged that it is free from folds or plaits, thus rendering every square inch active in filtering.

No oil can pass to the clean-oil compartment until the level in the filtering compartment reaches the outlets. Thus no filtering takes place until every square inch of cloth is submerged in oil; then as soon as a slight head builds up over the outlet, the process of filtration begins and is distributed over all of the surface, which is subjected to equal pressure.

The head of oil over the filtering disks is shown by an indicator at the top of the gage. When the filter is being operated at normal rating this gage should show a level of about three inches. If a greater height is indicated it shows that the oil is not passing through the cloth as fast as it should and that the cloths need cleaning. The filters are rated at 3-in. head over the filtering disks, but space is provided for carrying a 6-in. head. Thus the apparatus is capable of handling short overloads of 100 per cent., so that in case a large batch of oil should be run in, the filter will be able to take care of it.

The advantage in arranging the filtering cloth in a vertical position and having the oil pass from the outside to the inside of the units is that the slime and sediment which collect on the cloth continually work toward the bottom and drop off, thus automatically tending to keep the surface clean. The filtering medium is a special grade of cloth that does not act as a screen, but actually filters the oil largely by capillary action.

The water level in the precipitation compartment should be carried as low as practical. The gage shows the clean-oil level. The cock on the fitting at the bottom of this gage provides for withdrawal of clean oil to use in cans for hand oiling. The right-hand gage shows the level of the oil in the filtering compartment. This should at all times be full of oil.

All of the level gages have sheet-metal guards in back of them which are white enamel on the inside. This makes it easy to see at a distance the oil level and also protects the glass from breakage.

A thermometer shows the temperature of the oil before it enters the precipitation compartment, thus enabling the engineer to adjust the quantity of heat supplied so that the proper viscosity will be maintained. Another thermometer shows the temperature of the oil in the clean-oil storage compartment.

The filter body is constructed of galvanized sheet steel reinforced with channel and angle iron. All joints are lapped and closely riveted and soldered.

The only parts needing periodical cleaning are the filter cloths. The filtering units can be easily removed without interfering with the continuous operation of the filter and should be lifted out and set in a pan of kerosene or gasoline and brushed down with a stiff brush; this is possible because all the sediment collects on the outside of the cloth. Occasionally, the cloths can be removed and washed in gasoline or kerosene to thoroughly clean them.

The filter is built on the unit principle, and has been constructed with a capacity of 7500 gal. per hour in a single unit.

Don'ts for Refrigerating Engineers

By Thomas G. Thurston

SYNOPSIS—Thirty-four sensible "don'ts" for the operating engineer handling refrigeration machinery.

Don't start an ammonia compressor without first noting that the discharge valve is open. The writer remembers when this was overlooked in starting a 250-ton vertical machine, and two men who were working up under the ceiling above the machine came near being overcome with the gas. If the machine is not provided with a relief valve, the head is liable to be blown off.

Don't forget to turn the water on the condenser just before or immediately after starting the machine. If this is not done until the head pressure becomes high, leaks are liable to start in the condenser, both from the excess pressure and the increased temperature. If allowed to go too long the results will be as bad as forgetting to open the discharge valve.

Don't neglect to watch the head pressure while starting. The header valve on a condenser had been shut, and the operator, in a hurry to start, forgot it and blew the relief valves. Watching the head pressure will warn you, if you have forgotten it, to turn the water on the condenser.

Don't be in too much of a hurry to open the suction valve when starting, especially if the machine has been shut down for a long time, without pumping down the expansion coils and suction line. Open the valve slowly and keep your hand on the discharge pipe if possible. If this suddenly gets cold and the discharge valves begin to work unusually quietly, there is liquid coming back with the gas and the suction valve must be choked off until the machine begins to warm up again, otherwise it may wreck the compressor and may cause loss of life. If there is a slamming, or pounding, in the cylinder similar to an engine getting a dose of water, shut the suction valve until it stops, as this is an indication of a dangerous condition.

Don't forget to close the suction valve when shutting down even for a little while, and don't forget to close the liquid valve in the liquid line from the receiver to the expansion coils, or to close the expansion valve when shutting down a machine, if it is working alone. If these are not done the liquid will accumulate in the expansion coils and the suction line and make trouble when starting up again, or until it is pumped out.

Don't forget to watch the stuffing-box when starting up. This usually has to be tightened when the machine has been shut down for a long time, and it must be let out again gradually as the rod and packing warm.

Don't try to run the packing after it gets burned or hard and loses its resiliency. It will wear the rod and waste ammonia. Packing is cheaper than new rods or ammonia.

Don't run the crossheads too loose on an ammonia compressor, and don't tighten the crosshead shoes any old way. Either will make trouble in the stuffing-box. Put the compressor crank on the crank-end center and adjust the shoes so that the piston rod is the same distance from the guides at both ends of the stroke.

On the compressor the thrust of the connecting-rod usually presses the crosshead against the top guide except when the crank passes the center, when the weight of the crosshead drops it down on the bottom guide. If the crosshead is loose this will cause the packing to leak and wear it out quickly. This applies only where the engine and compressor are placed parallel, or side by side; if they are placed tandem, or opposite each other, the thrust on the compressor crosshead is the same as on the engine, and the guides should be adjusted accordingly.

Don't use more oil than necessary. If more is used it gets through the packing into the cylinder or goes out through the gas relief line into the suction pipe and the machine and out into the system, where it makes trouble.

Don't pump oil into the compressor cylinder. Usually enough oil leaks in through the stuffing-box and the gas relief line in addition to what circulates around the system to keep the compressor well lubricated. The only exception I have ever found to this was a 200-ton vertical double-acting machine. On this we had to pump about one-half pint every twenty-four hours into the top of the cylinders to keep the discharge valves working freely and to lubricate the cylinders.

Don't neglect to blow down the oil traps regularly. If you are not using more than a quart of oil every twenty-four hours, blow the traps at least twice a week, although every two or three days is better. If more than this is used, blow them at least every two days, and if the oil consumption is a gallon a day they should be blown every day.

Don't run the compressor excessively hot or ice cold; either one means loss of efficiency and capacity. The best results are had in the average plant by keeping the temperature of the discharge so hot that the hand can be held on it without burning.

Don't circulate water in the water jacket if the water is not warmer on leaving the jacket than on entering. To do so wastes water and refrigerating capacity.

Don't be satisfied with any suction pressure. Experiment with the expansion valves and see how high you can get the pressure without making the machine too cold; then try and keep it there unless the temperatures drop.

Don't run with a high head pressure unless it costs more for water to keep it down than for coal to pump against it.

Don't neglect to purge the air and foul gases out of the condenser regularly; this will help to keep the head pressure down. Any time the head pressure begins to climb without apparent reason or some of the coils get cold it is an indication of air or foul gas in the condenser, and the latter should be purged.

Don't neglect to pump out the air before starting in case any part of the system has been opened for alterations or repairs; it will save the trouble of purging it out of the condenser later on and save ammonia, as some ammonia always escapes with the air when purging.

Don't pump a vacuum on the system unnecessarily; it is likely to draw air into the system, and you will have to purge it out again.

Don't run with an insufficient charge of ammonia; keep enough in the system so that there is at least from four to six inches in the gage-glass on the ammonia receiver when running at maximum capacity. If the liquid level gets too low, some of the gas will pass over to the expansion coils with the liquid. Power has been used to compress this gas and water to cool it, and when it passes the expansion valve it will take some of the liquid that you have spent power and water to produce to cool it to the temperature of the suction gas. You are not only doing useless work in compressing and cooling the gas, but doing so absorbs some of the useful work already done, reducing the capacity and increasing the cost of operation.

Don't neglect the ammonia leaks. It does not take long for a dollar's worth of ammonia to leak out if there are a few small leaks in the system. Every week go over the points in the system with a lighted sulphur stick. The machine, and the high-pressure side of the system especially, need watching. Test the condensing water, jacket water and brine with litmus paper or Nessler's solution.

Don't neglect to shut the water off the condenser if it is shut down for any length of time, especially if it is old and subject to leaks; allowing the water to circulate over it cools it too quickly and may start a number of new leaks.

Don't neglect to clean the frost off direct expansion coils. The best way to do this is to run a hot gas connection from the discharge of the machine to the liquid line and pump hot gas into the coils; this will clean them quickly and thoroughly. Clean coils mean lower temperatures or the same temperatures at a reduced speed of the machine and therefore reduce the operating cost.

Don't neglect to inspect the valves and the false heads if there are any; see that they seat well, that the springs are not broken and are of the proper tension, and that there are no scored places on the seats and valves where the gas can blow through.

Don't neglect to pump out thoroughly before opening any part of the system for alterations or repairs; some men have a habit of letting whatever gas is in the machine blow to the four winds. It is just as easy to pump it out, much nicer to work around, and it saves the ammonia.

Don't break open an ammonia joint or any part of the system until you are certain the pressure is off, and don't be too quick in opening it even then. Loosen the bolts a little and open the joint easily. In case there should be pressure on it you can draw it up again before it gets too strong for one to stay around it. You will at least have a good chance to get away. Some men have lost their lives by neglecting to take this precaution.

Don't pull up too hard on a joint that is under pressure; you may break the flange, lose your life, and a part of the ammonia charge. If a joint does not stop leaking after it is drawn up reasonably tight, pump the line out and renew the gasket.

Don't get excited in case anyone gets a dose of liquid ammonia or ammonia-saturated oil; douse him with water. Turn the fire hose on him if there is one.

Don't connect a stop valve in an ammonia line so that the flow of the gas or liquid tends to close the valve. The writer remembers two cases where the valves came off the stems and caused much trouble. In one case the valve shut off the flow and blew the relief valve on the compressor. It took much time to locate the cause. In the other case the valve did not stop the flow, but hammered back and forth on the seat, wearing the disk and seat so much that a new valve was needed.

Don't neglect to keep the oil out of the expansion coils. If there are signs of oil in the system, open the coils as soon as they can be spared and blow them out, first with steam and then with air, and be sure they are thoroughly dry before closing them.

Don't open or shut a valve without first checking to make sure that it is the right valve.

Don't be in too much of a hurry when pumping an air-pressure test with an old machine on a system that has been in service for a long time. If there is oil in the machine or discharge line, it may cause an explosion due to the compressor getting hot enough to ignite the oil. Run the machine slowly and keep plenty of water on the water jacket if it has one. If the machine or the discharge line gets very hot, shut the machine down until it cools.

Don't forget to keep up a rapid circulation of water when pumping out a double pipe or a submerged condenser. Otherwise it will freeze and burst. The same also applies to a brine cooler.

Don't leave the suction lines uncovered outside of the coolers. It means extra work without anything to show for it.

Don't run an ammonia plant without an ammonia helmet. When something blows out some day it will save its cost in ammonia and may save life.

"Defender" Boiler-Room Appliances

The accompanying illustrations show the principal portable instruments recently developed by the Defender Automatic Regulator Co., Oriel Bldg., St. Louis, Mo. are made in two sizes, one for collecting over an 8-hr. period and the other over a 24-hr. interval. The collection chamber is tapered to compensate for the change in the rate of flow of the water from the chamber due to the decrease in static head as the water lowers in the

Fig. 4. Duplex Draft Gage

vessel. Consequently, the gas is drawn in at a constant rate and an average sample for the entire period is obtained. A gage glass on the collector is provided to indicate the height of the water at any time.

Fig. 4 illustrates a "duplex" draft gage for indicating the draft in the furnace and at the damper or stack, and the drop in draft through the boiler. Outlet *A* connects with the lower or longer tube, which has a range up to 1 in. and is generally used for the uptake

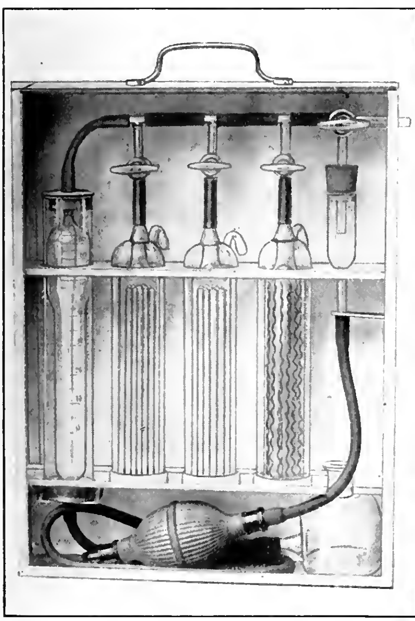

Fig. 1. Three-Pipette Machine

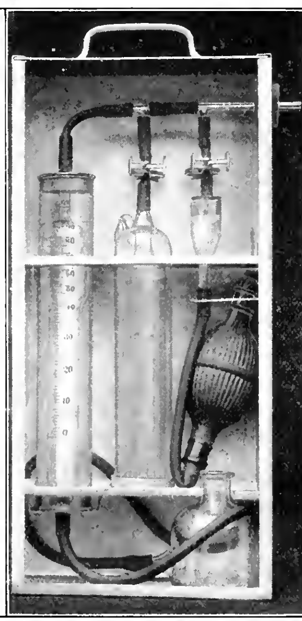

Fig. 2. Single-Pipette Machine

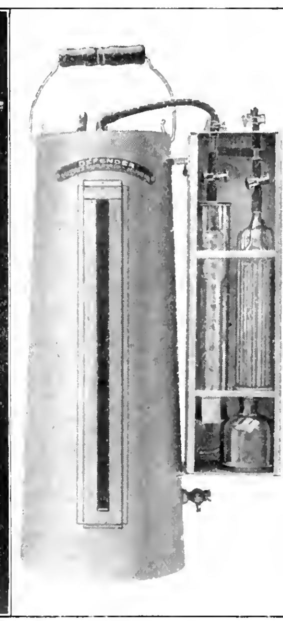

Fig. 3. Gas-Sample Collector

Fig. 1 is a modified type of Orsat with three pipettes for determining the CO_2, O and CO contents of the flue gases. The case and covers are of metal, and the header, ordinarily of glass, is here made up of rubber connections and glass tees, not subject to breakage.

A single-pipette apparatus for use where the CO_2 content only of the gases is required is shown in Fig. 2. Fig. 3 is a combination gas-sample collector and CO_2 analyzer. Where desired the gas-sample collector is furnished without the analyzer attached. The collectors draft. Outlet *B* connects with the shorter tube, which has a range up to 0.9 in. to measure the furnace draft. The difference between the two readings gives the drop in draft through the boiler. These gages are furnished mounted in either an inclosed or open aluminum case.

In addition to the instruments illustrated the company also makes a high-range brass-inclosed thermometer for flue-gas temperature observations, single-tube draft gages and a "multiple" type draft gage mounted on a wooden panel for direct attachment to the boiler.

Saving in Federal Building Plant

Since its inception in 1905 the Federal Building in Chicago has been equipped with a boiler plant to supply steam for hydraulic elevator pumps, engine-driven air compressors serving a pneumatic-tube service, fan engines, boiler-feed and service pumps, and some live steam for the heating system. The exhaust from the units just mentioned only supplied about half the heat requirements of the building in the colder weather. Current for light and power had been purchased from the central station at a price of 1.9c. per kw.-hr. for the first 100,000 kw.-hr. per month, and 0.9c. for all current in excess of this amount. Eventually, it was decided to install a generating plant that would produce all the current needed and at the same time furnish more exhaust steam to the heating system. This equipment was described in the Apr. 28, 1914, issue of Power, and from the saving made in the first month of operation it was estimated that the gross saving would exceed $14,000 a year. As shown in the accompanying table, this estimate has been exceeded by nearly $2000. In exact figures the gross saving effected by the plant during its first year of operation was $15,984.70. The total investment for the generating units and all additions to the plant was $43,000. Allowing 5 per cent. for depreciation and 3 per cent. for interest, which is more than the government usually receives, gives $3440 to be deducted from the total saving. This still leaves a balance of $12,544.70, which is over 29 per cent. on the investment and indicates that the plant will pay for itself in about 3½ years.

In the previous article the entire equipment was given in detail and in the following it is briefly summarized. The building is equipped with 45,000 sq.ft. of indirect and 65,000 sq.ft. of direct radiation on a two-pipe vacuum system. Seven passenger elevators of 3000 lb. capacity each, four 4000-lb. freight elevators and four 2000-lb. hydraulic lifts are served by one pumping engine, 16&20x20x5¼x24 in., and two duplex tandem-compound pumps, 16&25x7⅜x18 in., working against a water pressure of 750 lb. For the pneumatic-tube mail-handling system there are four air compressors driven by cross-compound engines ranging in capacity from 75 to 125 hp. There is also a 20-ton absorption refrigerating system to cool the drinking water. To serve this equipment, five 350-hp. water-tube boilers had been installed. This gave plenty of reserve capacity for the generating plant. Incidentally, its installation did not increase the number of boilers in operation. There was plenty of unused space in the basement for the four generating units which were eventually installed. Two of these are 200-kw. machines and two 100-kw. generators directly driven by four-valve engines.

Steam flow meters are installed for the different services, and a water meter measures the total amount of boiler feed. The monthly and yearly totals, as read from these meters, are given in the table. With more exhaust steam to heat the feed water, it will be noticed that the average evaporation per pound of coal is 8.18 for 1914-15, as compared to 7.3 for the previous year. About the same amounts of steam went to the elevator pumps and to the air-compressor engines. The live steam to the boiler-feed pumps, fan engines, heating system, etc., was considerably less, as there was more exhaust available for the

*Includes steam to generating units.

heating system. From the 1st of May to the end of February the engines used 52,827,122 lb. of steam. Dividing by the total kilowatt-hours generated in the same period, the consumption per kilowatt-hour is 15.8 lb. During the night hours the engines operated at light loads and the pressure was dropped to 140 lb., as compared to 160 lb. during the day. Besides, in the early part of the year all of the units were tuned up and more machines operated than were necessary. These factors account for a water rate which is higher than may be expected in succeeding years.

With the demands made by the other services about the same, the generating plant caused an additional operating expense of $8873.05, excluding the amount paid for central-station current. Dividing by the total output, the cost per kilowatt-hour amounted to 0.623c. The increase in coal consumption was 1926 tons, and to operate the generating units two extra men were required. The wages for these extra employees, coal at an average of $3.01 per ton and the additional oil and supplies required made up the excess in operating cost just referred to.

When the $24,857.75, the amount paid the central station for current, is added to the operating expenses of the plant, the total of $67,760.98 for the year ending February, 1914, exceeds the total expense for last year by $15,-984.70. It is true that the current used during the year was less by 85,620 kw.-hr. More current was used for lighting, but the power demand was considerably reduced owing to changes in the service and to doubling up motors, making one do where formerly two had been employed. Had it been possible to reduce the electrical service in 1913 to the same figure, the amount paid for current would have been reduced $770.58, as the excess came under the 0.9c. rate. Putting both years on an equal basis, the gross saving would then be $15,214.12. Deducting the $3440 for interest and depreciation leaves a net balance of $11,774.12, which is 27.4 per cent. on the investment of $43,000.

Ratio of Circumferential to Longitudinal Stresses in Boiler Joints

By J. K. Linderhurst

SYNOPSIS—The article considers those conditions which sometimes make the ratio of the circumferential to the longitudinal stresses more than two to one.

The average engineer who knows how to calculate the strength of boilers usually believes that estimating the strength of a cylinder to resist internal pressure is a simple problem. If all the factors are considered the problem is not simple, and the calculation of the correct efficiency of the longitudinal joint, usually considered the most difficult part of the problem, is one of the simplest.

Fig. 1, for example, is a part of a seamless cylinder, and if one were asked what is the relation between the circumferential and lengthwise stresses, he might state at once that the former is just twice the latter. The mathematical demonstration that this is so is apparently simple, for if the portion of this cylinder is taken of such length that the lines LM and KN equal the circumference of the cylinder, then the area on which pressure is exerted and tends to produce rupture is $2r \times LM$, when r is the radius of the cylinder.

The area exposed to pressure that will exert a lengthwise stress is the internal cross-sectional area of the cylinder, or $3.14r^2$. Now, since we have taken LM equal to $3.14r$, or one-half of the circumference of the cylinder, the first expression for area becomes $2r \times 3.14r$, or $6.28r^2$, which is twice the amount of the figure expressing the area of the internal cross-section, and therefore the lengthwise stress should be one-half of the circumferential.

No attention was given to thickness in making these calculations, for the shell was considered as a line without thickness. In Fig. 2, the thickness of the cylinder is indicated by the cross-section lines, and it is seen that if the circumference on the diameter KL is equal to LM and KN, the area of metal along LM and KN will not quite equal the cross-sectional area of the shell as indicated by the section lines, because this area equals the thickness times the mean circumference, which is halfway between the outer and inner surfaces, and not the thickness times the inner circumference.

Another factor not usually considered, and one which makes the difference between the longitudinal and maxi-

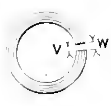

FIG 3

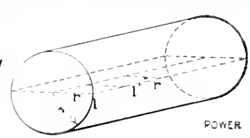

FIG 4

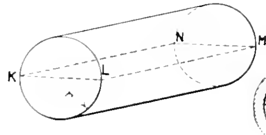

FIG 1

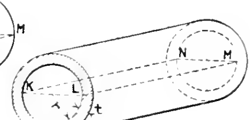

FIG 2

Illustrating Relation of Circumferential to Longitudinal Stresses in Boiler Joints

mum girthwise stresses greater than the one to two ratio, is as follows:

In considering the strength of cylinders, where the thickness is small as compared to the diameter, it is not customary to assume that the circumferential stress is unequally distributed over the thickness of the plate; but such is the case and, instead of the stress being equal throughout the plate thickness, it is greatest along the inner surface and least along the outer. No stress within the elastic limit of a material can be applied without producing corresponding stretch. Since a cylinder cannot increase in diameter without stretching the inner surface a proportionately greater amount than the outer, the stresses in the plate will not be uniform. This is evident, if we consider a cylinder made up of concentric layers, as in Fig. 3. If such a cylinder were cut open to be free to expand, internal pressure applied to increase the diameter would cause the dimension W, which is the amount of separation of the outer layer, to be equal to V, if the layers of material were very thin. This illustrates how the material is supposed to behave in a solid plate cylinder under pressure. Since the actual stretch of all layers is the same, the stress produced in them is not uniform, on account of their varying length. The difference in the strength of a cylinder calculated in this way and one figured in the usual way is expressed by the ratio between the length of the outer and inner circumferences of the shell; or, since these circumferences are directly proportional to their radii, the ratio would be that between the inner and outer radii. For example, in Fig. 4, if t were of such dimensions that it would equal one-quarter of r (r being the inner radius of the cylinder), then the strength calculated in the usual way would be

$$\frac{thickness \times strength\ of\ shell\ per\ sq.in.}{inner\ radius} = bursting\ pres.$$

Assuming r at 4 in. and, therefore, t at 1 in., and 50,000 lb. per sq.in. as the strength of the shell material, we have, as bursting pressure,

$$\frac{1 \times 50{,}000}{4} = 12{,}500\ lb.$$

If the fact that the circumferential stress is not evenly distributed in the shell is taken into account, the bursting pressure is found to be

$$12{,}500 \times \frac{inner\ radius}{outer\ radius},\ \text{or}\ 12{,}500 \times \tfrac{4}{5} = 10{,}000\ lb.$$

bursting pressure, which is a difference of 20 per cent.

In boiler shells, where the diameter of the boiler is large, as compared to the thickness of plate, neglecting this feature in estimating the strength is not of importance, but to show the effect it may be well to consider an example. Take a boiler of 60-in. inside diameter and made of ½-in. plate subjected to a pressure of 125 lb. per sq.in., the boiler being assumed to be seamless. The load carried in a girthwise direction is

$$125 \times 30 \times 2 = 7500\ lb.,$$

but as this load is not equally distributed throughout the thickness of the plate, the maximum fiber stress at the inner surface is about 7620 lb. per sq.in. The endwise stress is due to the pressure of 125 lb. on an area of 2827.43 sq.in., or a load of 353,428.75 lb. The area of shell available to support this load is 47.4 sq.in., which is the cross-sectional area of the shell. Therefore, the stress per square inch longitudinally is

$$\frac{353{,}428.75}{47.4} = 7456\ lb.$$

so that the highest fiber stress girthwise is something over 2 per cent. greater than the lengthwise stress in the shell of this boiler when considering it as a cylinder without tubes. As has been stated, the slight difference in calculating boiler shells by either method is not enough to warrant consideration. It is well, however, to know just what we are talking about when we state that the girthwise stress in a cylinder subjected to internal pressure is twice the longitudinal stress.

Some like to express the relative values of these two stresses graphically and state that, as in Fig. 4, if we take any horizontal length of the shell, as l, and a corresponding length on the circumference l, the pressure on the triangle inclosed by the two radii produces the stress lengthwise of the shell on the section 1 in. long, and that the stress in the circumferential direction is due to the pressure on the rectangle lr. Since the area of this rectangle is just twice that of the triangle, the stress due to the pressure is in the same proportion.

The difficulty in this case is the same as in the case of Fig. 1 as regards accuracy, for only lines have been considered without thickness. If the metal to stand the load is to be equal in both cases, the length l in the case of the circumference of the shell would have to be taken on the mean circumference, in which case the triangular area would not be one-half of the rectangular, and therefore the resulting stresses would not be in the ratio of one to two.

This latter method of comparing the values of the stresses in a cylinder is called the graphic method.

Specifications for Steam Lines

By D. Craft

In specifications for steam lines for power using high pressures of steam, a mistake is commonly made in calling for lines as large as the connections of all the engines and turbine. It appears to the writer that many of the small engines and turbines used in power-plant work are provided with connections which are made large enough to supply the steam required at the minimum pressure likely to be used by any purchaser for the maximum rated capacity.

In our plant the pressure carried is 175 lb. All of the smaller machines here were originally connected to steam lines out of proportion to their capacity. For instance, two 5-hp. Terry turbines driving hotwell pumps had 1¼-in. steam lines; a 6x8x6-in. air compressor compressing to 50 lb. had a 2-in. line; two 6x9-in. engines driving circulating pumps and carrying a 6-hp. load had 2½-in. steam lines, and there were several similar instances of excessive sizes of connections.

We have reduced some of these lines to one-sixth of their original capacity. In addition to reducing losses from saving radiation we have saved considerable in expense and annoyance of keeping large throttle valves tight, and there is a marked reduction of governor trouble. The large governor valves throttled the steam so closely that from wiredrawing of the steam the valves required frequent grinding, reseating and renewing.

By reducing the size of these valves and lines we have overcome our trouble. Where we made these reductions in pipe sizes the lines were made only large enough to transmit 30 lb. of steam per hour for each horsepower required, with an allowance of about 10 per cent. for drop in pressure.

The Most Economical Pipe Size for the average demand should be used, with provision for increasing the boiler pressure or opening a supplementary "booster" line during maximum demand when the engine cannot otherwise carry the load. Recent tests here and abroad prove that substantial saving may follow a reduction in pipe size or shutting off booster lines, thereby saving in condensation and radiation losses.

Editorials

Factors in the Engineer's Salary

What determines the contents of the engineer's pay envelope? Surely, in too many cases his salary, or whatever his remuneration may be called, is the result of custom on the part of the establishment which he serves—a sort of haphazard adherence to the "going" rate of pay in the local community in this occupation. Surely, there are other standards by which employers may fairly gage the worth of their engineers—standards which take into account their responsibilities, their service performance and powers of constructive suggestion.

Because a ten-thousand-kilowatt turbine today requires less attendance than a two-thousand-five-hundred-kilowatt engine-driven unit did a dozen years ago, some people doubtless think that the engineer has an easier time in a typically modern plant, and therefore is not entitled to higher compensation. Again, some hold that because a plant is put on an eight-hour shift where a ten- or twelve-hour schedule was formerly maintained, the engineer's duties are correspondingly lightened and he deserves little consideration in the direction of "raises."

If any single factor is to be picked out as paramount in rate-making for operating engineers, that factor should be responsibility. The value of the service rendered by the plant is one great test, and the value of the equipment in the engineer's charge is another. It matters little whether the machinery is highly automatic in its operation so far as engineering responsibility is concerned, compared with the amount of money invested in it and the penalties of service interruptions. There may be less manual effort in handling a fifteen-thousand-kilowatt turbine and its auxiliaries than in operating an engine-driven outfit of a fifth that capacity, but the risk of damage, the question of daily cost when such a machine stands idle, the importance of its output, and the value of technical judgment in inspection and maintenance, all tend to place the man in charge of high-powered units in a special class as regards payment—a class which is recognized in many concerns, but which on principle ought to be appreciated all along the line more than it is.

In a word, the hours of daily service should cut little figure in salary or wage determination, and the same may be said of the output per unit. At first blush, the plant turning out a big total of daily horsepower-hours might be set up as a standard of payment, but while peak loads increase the engineer's anxieties, the daily test of his work comes down to his ability to turn out whatever output the load demands, at the lowest cost consistent with reliable service. The ability to save the plant owner money, realized in the daily work of the engineer, should not go unrewarded. Profit sharing is just as good a plan in the power house as in the factory, but a good many employers have yet to realize it. Certainly, the engineer who works diligently to improve the efficiency of his installation, who studies how to make it yield the best possible service, and who knows from accurate records just what the physical results of those efforts are, is demonstrating his fitness for responsibility and is keeping his "cutting edge" sharp to good purpose.

Analysis of local conditions in power plants should accompany consideration of the problems of compensation in the future, and the farther the plant owner gets from mere imitation of what others are doing, the better it will be for all concerned.

Art and the Steel Stack

A chimney has two principal functions—one to produce a draft, the other to take the gases high enough above our heads so that we do not notice them. Until someone invents an invisible chimney we shall have to put up with tall tubes sticking up into the sky line.

Various attempts have been made to disguise chimneys in the interest of the artistic. Greek columns, campaniles and other architectural units have been pressed into service, but the incongruity of such works of art belching clouds of smoke has made them less artistic than the chimney which pretends to be nothing but a chimney. Brick and concrete afford materials which can be made more or less ornamental—the former by shape and color, the latter by shape alone. The steel stack seems seldom to be anything but a parallel tube without ornamentation.

A steel stack has very decided advantages from a financial point of view. If it had to be replaced every year it would cost only about what the interest would be on a brick stack and its foundation. As it lasts from five to twenty-five years, according to the coal and weather, there is little to be said against it except as a matter of looks. There is a prejudice on the ground that it will not draw, but that is probably ill-founded. If there were any great difficulty from radiation it could be helped by means of a jacket or an inner tube, neither of which is often resorted to. On the score of looks there is nothing that can be said in favor of the ordinary factory stack. A degree of ornamentation is sometimes attempted by painting colored bands or by lettering the name of the owner on the side, but that is bad in that it attracts attention to an ugly thing

It would seem as though a steel stack could be designed the lines of which would be at least pleasing when seen from sufficient distance so that the material was not in evidence. There is no insurmountable difficulty in making a tapering tube of steel. It is even possible to give it the slight swelling which appears to be necessary to make it look like a straight taper. The largest expense appears to be for an ornamental head, which may cost as much as the rest of the stack, but which, if made on simple lines relying on distance to obscure the lack of detail, should not be very expensive. Then if, instead of painting it a dead black, it could be made a gray or some neutral color, it would be still less noticeable, and that is the real object to be attained—practical invisibility, or making it attract as little notice as possible.

Looking Out for the Fine Points

The small details in the layout of a power plant, although often receiving scant attention, are important factors in its operation; and it is surprising how nearly every plant illustrates practice which is either worth following or which might well be avoided. Station lighting, for instance, too often receives insufficient consideration, particularly in the use of shades or reflectors capable of concentrating the light on machine parts needing frequent inspection or adjustment. Also, the use of unshaded lamps mounted low on columns in stations with high ceilings is extremely wasteful. Boiler rooms are notoriously ill-lighted in many stations, and here is a field for the practice of engineering skill along lines as yet relatively undeveloped. No lighting installation, however, will give adequate results if neglected as to periodical cleaning of fixtures.

The numbering of switches and motor starters to correspond with the apparatus controlled has important bearing upon convenience of operation. In emergencies requiring the sudden stopping of a motor-driven centrifugal pump and the starting of another, no time should be lost through the manipulation of the wrong switch. Similarly, the labeling of lighting switches with appropriately keyed circuit numbers, including specific areas covered, when feasible, is desirable. The mounting of generator field rheostats sometimes is a troublesome problem. In a recently completed station this apparatus was placed behind the switchboard, but so far above the floor as to obstruct the light from the windows, consequently it had to be blocked up with a wooden strut which obstructed the passage at the rear of the board. In a section of the plant containing refrigerating coils, lights were placed on the alternate stairway landings only, thus giving too dim an illumination for rapid and safe travel, and in the freezing room no effort was made to protect the local switches and fuses from vapors.

Although many of these loose ends are taken in hand after the plant is in regular operation, they are usually sources of inconvenience, extra cost, and danger, and should be guarded against wherever possible.

Making the Dollars Produce

Frequently, the operating engineer of a factory power plant is called upon to make changes or extensions to the existing plant, possibly occasioned by the addition of building or machinery made necessary by the desire of the owner for increased facility. At such times the importance of intimate knowledge of details of the existing power plant, together with the exact knowledge on the part of the operating engineer of the actual value utilized of the owner's dollar's worth of coal, cannot be too forcibly insisted upon.

The operating engineer who is content to just operate his plant without knowing exactly what part of the owner's dollar invested in the coal pile is being put to useful purpose, will fail when called upon for advice to meet the new conditions. He is the one who will sulk in the corner when the boss employs outside talent to solve his problems. In the corner with his face to the wall he will remain, for he has entirely neglected to grasp and use the opportunities given him.

How many operating engineers have traced the pound of coal fed to the boiler from the pile to the switchboard? How many ever stop to realize that only about fifteen cents out of a dollar's worth of coal actually reaches the switchboard? The missing eighty-five cents in too many instances is almost a total loss, whereas with proper knowledge and equipment as much as sixty cents of this can be saved and put to proper use.

The salesman who sold the engine and generator boasts about the combined efficiency of his apparatus being 95 per cent. This is not to say that the owner is getting ninety-five cents at the terminals of the generator on the dollar paid for coal. He is not. This combined efficiency means that for every hundred pounds of steam given the engine at the throttle, all the electrical energy that can be obtained from ninety-five pounds is realized at the terminals.

Possibly one will ask, why try to save the exhaust steam from the engine? The answer is that the steam exhausting from the engine contains more than twice as much heat value as is actually used in the engine and transformed into electrical energy.

The exhaust steam should be turned to good use, such as heating the buildings, or possibly supplying apparatus required in the process of manufacture, such as drying rooms and kettles, and also to heat the feed water supplied to the boiler, thereby reducing the work required from the coal.

Until recently, the owner invariably looked upon the coal bill as a necessary evil. Times are changing. The efficiency engineer is making rapid progress. Be in a position to tell the boss just where his dollar's worth of coal is going. Maybe, when he asks your advice on new equipment you can tell him that by making certain changes in the existing plant, there will be boiler capacity enough to carry the increased load, thus materially lightening the burdens on his pocketbook.

Don't wait for the efficiency engineer to tell your boss where his money goes; get there before him. You are the one that should tell him.

Is it any more onerous or less reasonable to require a user of a boiler to provide it with an adequate safety valve, than to require him to furnish an adequate fire pump; to insist upon an open exit from a fire-room which is liable to become a torture chamber filled with scalding steam from the bursting of a steam pipe or fitting or of a boiler tube, than from an ordinary workroom; to require the use of furnace doors which will not allow the fire to be blown out over the premises and the people, and to provide an outward escape for the steam and gas from a boiler setting in case of a bursting tube, than to insist upon guards around belts and flywheels? Has not "safety first" as much import in the power plant as elsewhere?

The head of an organization of steam-boiler firemen in New Jersey recently informed us that the educational work that has been vigorously conducted among engineers in that state during the past few years has had the effect of establishing unusually favorable relations between engineers and firemen. There is more thorough coöperation between the two today than ever before, he stated.

When the average man begins to educate himself he soon learns that he does not know as much about his calling as he thought he did. Once he is conscious of this, he is likely to be less arrogant and more helpful to his subordinates.

Correspondence

Maximum Lift of Steam Ejector

Referring to the request by Charles S. Palmer, as printed on page 481 of the Apr. 6 issue of POWER, and in particular to the question relative to the maximum lift that the steam ejector when applied to priming centrifugal pumps can be expected to develop, I offer the following:

The depth in feet from which the water can be raised to the pump by vacuum created by the ejector depends upon local conditions, such as tightness of piping and pump parts and the steam pressure used. Theoretically, it should be 33+ ft., which would indicate perfect vacuum, but in practice 25 ft. is near the maximum when the best range of steam pressures—40 to 80 lb. gage—is employed, and all valve stems, stuffing-boxes, pump and pipe joints are tight against air leakage. Usually considerable care must be exercised to keep the air leakage down to a minimum.

With Mr. Palmer, I should be much pleased to receive through your columns the common-sense explanation of the collapse of the discharge pipe on the pump mentioned in the article referred to.

PENBERTHY INJECTOR CO.,

Detroit, Mich.

Priming a Centrifugal Pump

Some years ago I had the pleasure—and the work—of spending a season at a fairly large-sized irrigation plant in the cane and rice belt of southern Texas. I do not remember the capacity of the pumps, but it was considerable. There were two centrifugal pumps, each driven by a tandem-compound Corliss engine of the nonreleasing valve-gear type; the speed was 175 r.p.m. Each had a separate suction and discharge, the former being 72 in. and the latter 45 in. diameter.

These two pumps formed one of the two plants that were necessary to put water on the rice lands. The plant at which I was stationed was called the lower lift. It was on the Brazos River and the engine-room floor was about 50 ft. below the surrounding land level. This was necessary, as the water level in the river became low during the dry season, and then the pumps had about 12-ft. lift.

From the river the water was discharged into a canal about 35 ft. above the pumps. At low water this gave a total lift of something like 47 ft. The shaft stuffing-box was, of course, water-sealed. These pumps would easily lose their suction if they slowed down as little as five revolutions per minute below their regular speed. They always had to be primed when the water in the river was lower than the engine shaft. There was no valve in the suction line. The discharge line was provided with a gate valve operated by hydraulic pressure, which was usually assisted by a half-dozen men with chain blocks and bars.

There was a 4-in. steam ejector connected at the highest point in the pump case. Whenever a pump lost its suction it was stopped, the discharge valve closed and the ejector started. Sometimes the air would be dispelled and the case filled with water in from 15 to 20 minutes, but generally it took over half an hour and sometimes longer, owing to leaks in the pump and piping. The ejector took more steam than the engine and the boilers were crowded during priming. Often, while priming one pump the steam pressure would become so low that the other would slow down and also lose its suction. There were times when the ejector would just begin to discharge water when it would have to be shut off owing to the danger of the other pump slowing down.

As soon as the ejector began discharging a full stream the pump was started and brought up to speed as quickly as possible. The discharge valve was never opened till the pump was up to speed and then opened slowly. It was inconvenient to start either of these pumps with the discharge valve open. Although the ejector was a veritable steam eater it was the best means of priming we could get.

The other plant of this irrigation system was located about 19 miles from the river and took water out of the canal and discharged it into the irrigation ditches which supplied the rice fields. This plant was known as the upper lift and the pumps were built on the ground level, so there was scarcely any suction lift.

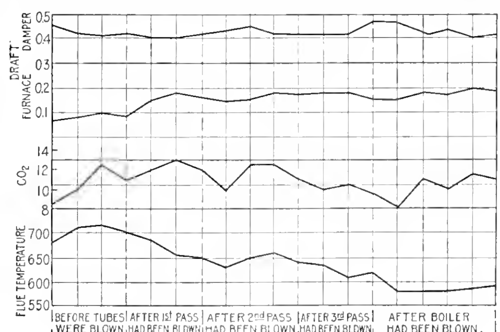
Soot Removal

In the Feb. 16 issue I read with interest the editorial "Soot," page 238.

Some time ago I made some observations on a horizontal, vertical-pass, water-tube boiler to determine the effect



EFFECT OF SOOT REMOVAL

of soot removal on the combustion and the temperature of the gases just after leaving the boiler.

It is our custom to blow the external surfaces of the tubes off with compressed air at about 100 lb. pressure. This is done daily except Sunday, which means that the boiler is accumulating soot and dust for 18 hours. The accompanying curves were plotted from data taken after each pass had been blown.

The draft pressures and condition of the fire were kept as nearly uniform as possible. The boiler is served by a front-feed inclined grate stoker. The temperature was taken at a point just after the gases left the last pass. The flue-gas sample was taken at the same place, and analyzed with an Orsat.

It will be interesting to note in these curves the peculiar relation between the draft pressures and CO_2.

H. R. BLESSING.

Philadelphia, Penn.

The editorial in a recent issue of POWER relative to the soot problem furnishes food for thought. Why is it that many power plants equipped with flow meters, CO_2 recorders, pyrometers, draft gages and other appliances designed to promote boiler efficiency still stick to ancient hit-or-miss methods of removing soot deposits from their boilers? In Germany power-plant operators realize that soot has about five times the heat-resisting qualities of asbestos, and most boilers have stationary soot-blowing equipment.

In this vicinity such installations are, comparatively speaking, few. The writer has in mind a plant where boiler tubes are blown twice a week. After this blowing, from 1½ to 2 tons of soot is removed from each boiler. The work is done by an attendant with a hand hose, and as such men are but human, and dragging a hot steam hose about a boiler room is anything but a pleasant job, more than one dust slide is skipped in the operation. The time saved between the opening of a couple of valves on a stationary equipment and the shifting about of a hand hose is so apparent that no comment need be made on it.

There have been numerous interesting and instructive discussions in POWER on flue-gas analysis, boiler settings and general power-plant practice, but this important subject of soot removal has not received much attention. Will not some who have equipment of this kind let us hear about it?

J. PRIEFER.

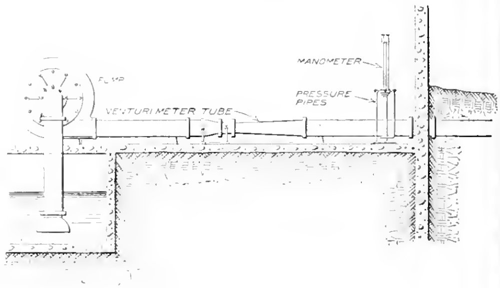
Brooklyn, N. Y.

Testing Small Centrifugal Pumps

I read with a great deal of interest the article by M. R. Blish in the Mar. 16 issue. Mr. Blish devotes considerable attention to the measurement of the discharge by means of weirs. I would like to suggest, however, that a much more convenient way of measuring the output from centrifugal pumps of either small or large size is by the use of a venturi meter tube with a mercury manometer. Such an arrangement is shown herewith. The tube is placed directly on the discharge from the pump and the pump performance may be tested under actual operating conditions if desired. This arrangement also has the advantage of being permanent if so desired, and a daily record of the pumpage may be kept. Any falling off in performance may be noted as soon as it occurs and the trouble corrected, if possible. If it is desired to test the pump under a greater range of heads than could be obtained at any particular time, the arrangement can be modified somewhat by placing a valve directly on the outlet cone and throttling it to obtain the head desired.

Mr. Blish in his article describes the use of a baffle plate to prevent serious velocity of approach of the water to the weir. With the Venturi tube this will not be required since the method of measurement by taking pressures at the upstream and throat or constricted portions of the tube is independent of the initial velocity of the flowing water.

The instrument is also considerably more convenient to read than the hook gage used with the weir. The manometer shown is a modification of the U-tube type and employs the same principle as the single-tube mercury barometer, the heavy pressure from the inlet of the meter tube being received upon the surface of the mercury in the



VENTURI TUBE AND MANOMETER FOR TESTING CENTRIFUGAL PUMPS

large well at the bottom of the instrument. The throat pressure is conducted to the top of the single glass tube. The scale may be graduated directly in gallons per minute. This type of instrument makes unnecessary the adjusting of the scale or rod and is particularly convenient in cases where it is desired to take frequent readings of suction and discharge heads, speed, temperature, etc., at frequent intervals with a small number of observers.

Providence, R. I.

Feeding Graphite to Boilers

The writer has experimented for several months to discover a satisfactory method of feeding graphite into stationary boilers and has found the following to be best. The feeder shown in Fig. 1 is used in plants where compressed air is available, and that in Fig. 2 where compressed air cannot be had.

Fig. 1 is composed of a 6-gal. galvanized-iron tank A with a loose-fitting lid on top; B is a 1-in. pipe extending through the bottom and three-fourths of the way to the top of the tank, with a tee on top to prevent the attendant from filling the pipe with graphite when he is charging the tank. A 1-in. gate valve or straight-way air-cock C is used as shown. A globe valve should never be used here on account of its liability to clog. A 1-in. line D should be connected to the suction of the feed pump. A sight-feed E, through which the attendant can see the amount of graphite being fed, is provided.

A ¼-in. line F should be connected to the city water line or to the discharge of the feed pump. A nozzle G is used with a ⅛-in. opening pointing to the bottom of the tank on a 45-deg. angle, to prevent graphite from settling to the bottom of the tank and keep it well mixed with water. A ½-in. valve *I* is used to drain the tank for recharging.

This feeder should be installed, so that the sight-feed is above the water line of the heater, and so that it will not fill with water.

To charge, close the valves *H* and *C*, open *I*, and drain water into the bucket. If this water contains graphite it

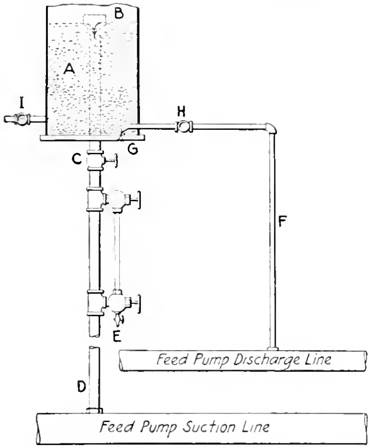

Fig. 1. Graphite Feeder Used Where Compressed Air Is Available

can be put back into the tank after charging. After putting in the required amount of graphite, pour the water drawn from the tank back into it, stirring the contents well to mix thoroughly, open valve *C* wide and regulate the feed with *H*.

Fig. 2 consists chiefly of a 150-gal. steel tank *A*, four ⅜-in. pipes *B* with $\frac{1}{32}$-in. holes drilled 2 in. apart on one

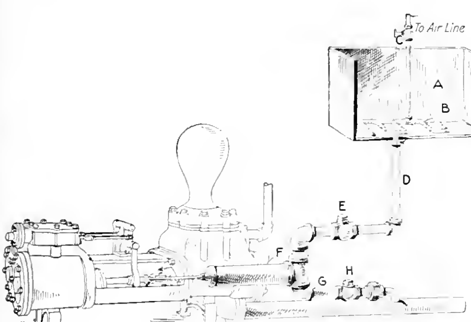

Fig. 2. Graphite Pump Operated by Boiler-Feed Pump

side and arranged in the tank so that the holes point downward, to keep the graphite from settling. A ½-in. air line *C* is connected to the compressed-air supply; *D* is a 1½-in. suction line; *E* 1½-in. swinging check valve; *F* a single-acting pump made of 2-in. brass pipe with a 2x1½x1-in. pipe tee on one end and the bonnet of a 2x2½-in. valve on the other. The piston head is made of brass, with two packing rings. The piston rod is made of ⅜-in. cold-rolled brass, with a permanent nut on the end of the rod and a sliding nut with a setscrew, so that the stroke of the pump can be adjusted to any desired length, regulating the amount of graphite fed with each stroke of the feed pump. The graphite pump is driven by the piston rod of the feed pump; *H* is a 1-in. discharge line, *G* is connected into the suction line of the feed and contains a 1-in. swing check valve.

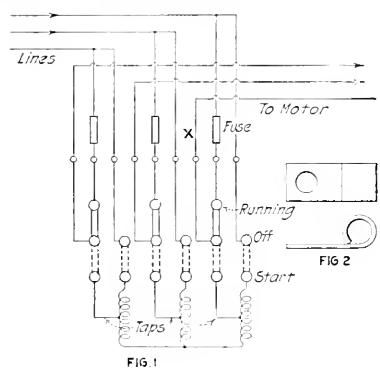
Pittsburgh, Penn

Open-Circuited Compensator

The diagram represents the connections of a three-phase compensator for starting squirrel-cage induction motors. The leads from the line and to the motor are flexibly connected to the rocker-drum contacts marked "off." When the handle is in the position marked "start," the rocker makes the connections indicated by the double dotted lines; and with the handle in the running position, the connections are as indicated by the double full lines. In the starting position the line wires connect to the autotransformer terminals and the motor leads to the autotransformer taps, thereby applying approximately half voltage to the motor. In the running position the line wires are connected directly to the motor leads so



Compensator Connections

that the motor gets full voltage. The autotransformer is then entirely cut out.

It will be noted that the fuses are in circuit only on the running side. Inspection of the diagram also shows that the three wires that connect the cylinder contacts to the motor are in use irrespective of the position in which the starter may be; therefore, an open-circuit that affects operation in both positions is either local to these motor wires or to the line wires beyond the compensator connections.

An operator complained that his motor would not start from either side of the compensator, but would buzz, thereby indicating single-phase operation. Just above the compensator there was a small panel carrying the fuses and studs by means of which the compensator wires were connected to the line wires and to the fuses and motor wires. Connections were made with terminals similar to that indicated in Fig. 2, the ends of the wires being soldered into the sleeves and the eyes being slipped onto the studs and held there with nuts. With a bell the open circuit was finally located in the sleeve of the terminal wire marked A, Fig. 1. This had been caused by a layer of resin between the wire and the sleeve, the resin having been used as a soldering flux.

Notes on Indicator Diagrams

In the Mar. 2 issue, A. R. Nottingham, under the above caption, discusses freak diagrams, particularly one that appeared in Power for Nov. 3, 1914. He states: "In the original diagram Fig. 1, the atmospheric line is $5\frac{1}{2}$ lb. too high. It should be where the dotted line is, though this does not affect the diagram so far as valve analysis is concerned."

Granting that the diagram was taken from the low-pressure cylinder, since neither the scale of the spring nor the vacuum line is given, how did Mr. Nottingham arrive at the conclusion that the atmospheric line is $5\frac{1}{2}$ lb. too high? As a matter of fact the diagram was claimed to have been taken from the high-pressure cylinder of a compound engine, and the atmospheric line should have been below the exhaust line, equal to the receiver pressure, which could not have been high in this case as most of the work was done by the high-pressure cylinder.

Boiler of a Traction Engine Exploded

The photographs reproduced show the general appearance of a traction engine after the boiler had exploded. The age of the boiler and the condition of the safety valve and steam gage are unknown to the writer. The shell was badly corroded and in one place had leaked and been patched, as may be seen at the lower part of Fig. 3. The weakest point seems to have been at the edge of the seam which joined the body to the firebox, where the sheet was corroded nearly through. There was but little scale on the surfaces.

The explosion occurred while the engine was standing on the public highway. The shell was carried 300 yards by the force of the explosion and the whistle was found one-quarter of a mile away. Fortunately, no one was hurt.

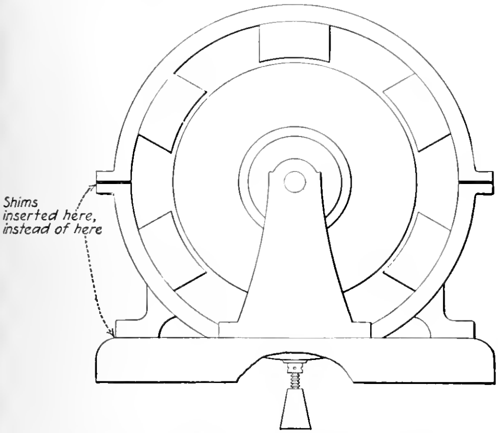
Unequal Air Gap

Some time ago the writer had some experience with a generator failing to operate correctly, the cause of which may interest readers of POWER.

The machine was a 100-kw. 220-volt shunt-wound generator direct-connected to a gas engine, and operated various amusement devices and lights at a summer resort. The rated voltage would build up readily, but as soon as any load was connected, the voltage would fluctuate and the brushes spark badly, and no amount of shifting would remedy the trouble. The engine was checked for its rated speed as shown on the nameplate and found correct, and no appreciable variation was noted when load was applied.



FRAME SHOWING WHERE SHIMS WERE INSERTED

Upon inquiry it was found that the generator had just been installed, having been purchased second-hand. The field frame was split horizontally, and in order to facilitate handling and shipment to its present location the generator had been taken apart. As the men who had set it up were not experienced in handling electrical machinery, the natural conclusion was that possibly the field coils had been wrongly replaced or the brushes improperly spaced.

The fields were tested for polarity and found correct, and the spacing of the brushes was also gone over. It was while the armature winding was being examined to determine the neutral position of the brushes, that the unusual size of the air gap became apparent. Further examination of the frame revealed the presence of shims between the halves of the frame. The men who had done the erecting then explained that after they had placed the top half of the frame in position they noticed that there was just sufficient room beween the top of the armature and the bottom of the field coils to prevent rubbing while the armature was turned, whereas the space between the lower side of the armature and the bottom coils was quite liberal. So they had cut up some sheet iron and inserted it between the halves of the frame to make the air gap on the top of the armature equal that at the bottom. Here was the cause of the trouble.

A hoist was rigged from one of the roof trusses above the generator, the bolts holding the halves of the frame were taken out and the upper half was raised enough to remove the offending shims. The halves were then tightly bolted together and the air gap at the top and bottom carefully gaged.

The bolts holding the frame to the base were then loosened, and while the frame was steadied on all sides a jack, placed as shown in the sketch, raised it enough to insert sufficient shims to make the air gap equal at top and bottom. This completed, the engine was started again and the generator carried full load without further trouble.

The next morning one of the men found the shims that were sent with the machine and that should have been placed between the base and frame in the first place, securely tacked inside of the crates, out on the rubbish heap.

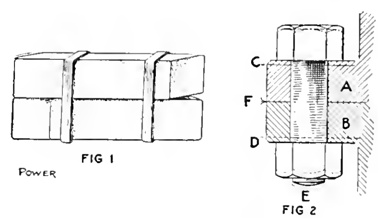
P. JUSTUS.

Cleveland, Ohio.

Holding Power of a Bolt

In deciding the size of a bolt to be used it should be assumed that it may be tightened by a helper who is instructed "to get it tight." To him this means that he is to put his whole weight on the wrench, if not extend the handle with a piece of pipe as long again.

To get a simple analogy to the action of a bolt clamping two pieces of metal together, take two erasers and fasten them together with a pair of light elastic bands, Fig. 1. Just as soon as a pull is exerted on the erasers they come apart enough to show light between them. The bands are more elastic, so they yielded more than the erasers were compressed by them in the first place. If very soft erasers and heavy bands are used, then quite a pull can be exerted on the erasers before any light will show, because they will go back to their original thickness before the same pull has stretched the elastics that much. This explains why it is necessary to have joint packings with some give to them to hold pressures. If the flanges and the bolts were of the same material it would be theoretically impossible to make up a tight joint without packing. Practically, it is feasible because the pressure of the bolts is hardest close to the bolt itself and the metal around the bolt hole is compressed more than that further away and more than the bolt is stretched.



RUBBER BAND AND BOLT ANALOGY

Fig. 2 shows this more clearly. The full lines show a bolt and nut drawn up just tight enough to touch the two flanges *A* and *B*. When the nut is drawn down hard the flanges are each compressed to the dotted lines *C* and *D* (exaggerated, of course) and the bolt itself is stretched to the line *E* at the same time. No matter how tightly the bolt is set up, it will continue to lengthen with additional pull. Now suppose that some pressure is brought to bear to separate the two flanges. It will stretch the bolt, but every particle that the bolt stretches, the flanges, which were compressed, tend to go back to their original thickness, so that there is a tight joint until the flanges have got back where they started from; then the opening is due to the additional stretch of the bolt. If an elastic packing is inserted at *F* it will also keep the joint tight until all the pressure on it due to the bolts is released. A corrugated copper gasket acts in the same way, the corrugations, which are flattened out under pressure, coming back when the pressure is relieved.

The longer the bolt, the more it will stretch under a given pull. An eight-inch bolt will stretch four times as much as a two-inch, but the packing has only so much give in it, hence the decided advantage in using short bolts where possible. The stretch also decreases as the square of the diameter increases. A one-inch bolt will hold four times as rigidly as a half-inch; not merely four times as much in pounds, but with only one-fourth the stretch for a given load.

There is, however, an advantage in a comparatively long bolt in places where it can act as a relief. If a cylinder is full of water the bolts may stretch enough to let it out without further injury, but, aside from this emergency, the use of short, thick bolts is good practice.

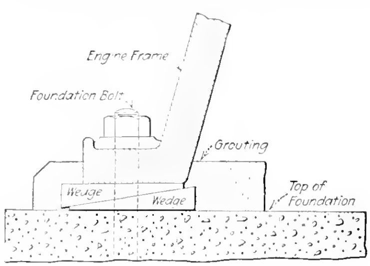
Worcester, Mass.

Grouting under Heavy Machinery

To the articles under this title in the issue of Mar. 2, page 310, and Apr. 6, page 482, much can be added and still leave the matter of grouting unsettled in the minds of many.

My belief is that at least an inch should be left between the top of the foundation and the machine, and that the



Another System of Wedges

latter should be leveled by means of wedges placed as shown on the illustration, one set on each side of every foundation bolt. When the leveling is complete, every bolt should be tightened, so as to hold the machine tightly against the wedges. The latter should all be left permanently under the machine; and they will not slip if they are made of cast iron with the surface left rough.

The grouting material may be either neat cement, a mixture of sand and cement, sulphur, or lead. It should be poured so that it will cover the top of the foundation under the machine, and also cover the ends of the wedges on the outside, as shown. If a mixture of sand and cement is used it should be sufficiently thin to flow easily. On account of the cost, lead is seldom used, but it makes a very satisfactory job. Sulphur cannot be used under machines where the heat will be so great as to melt it.

J. E. Poche.

New Orleans, La.

The Boiler Inspector Confesses

I have read the lurid description of a boiler inspector's confession as printed on the Foreword page of the Mar. 9 Power. There is one item in it which causes me to wonder how it ever "got by" the editorial force.

It is this: "Investigation showed that the fireman had opened the blowoff valve, and before closing it rushed away on a signal from the engineer. Before he returned the explosion had happened. This knowledge relieved my mind, but I had learned my lesson."

It is needless to tell you that an explosion might possibly be caused by a sudden opening of a blowoff valve, but if the valve had been open for any length of time and left open, as in this case, the pressure would have been gradually lowered and the boiler would not have exploded.

Charles H. Garlick.

Pittsburgh, Penn.

[The chance of avoiding the rupture of a boiler depends on the pressure being reduced to nearly zero before the sheet or sheets become bursting hot. This may happen with the blowoff valve open. But if two or more boilers under pressure are connected to a common header and one bursts a sheet because of low water, a violent explosion would likely follow, blowoff open or not. There was more than one boiler in the plant mentioned in the foreword.—Editor.]

Pulsations in Steam Pipes

Correspondence published in the columns of Power has quite frequently referred to the methods which have been employed, with varying success, to cure pulsations of steam pipes. The remedy most commonly suggested is to place a receiver of moderate size in the steam pipe near the engine.

I have designed and had built several receivers of varying capacities, the smallest having a volume twice that of the cylinder which it supplied. Others were much larger, but not one was big enough to show any appreciable diminution in the vibrations in the line. However, there were advantages gained, which more than paid for the work and expense of putting them in, such as drier steam, higher initial pressure and a better steam distribution in the engine cylinder.

But in no instance did I succeed in stopping the vibrations entirely, without throttling the supply to the receiver until the flow in the steam pipe was comparatively steady.

I have seen just one receiver placed in the steam line to an engine that was large enough to stop the vibrations entirely, and that one, I am sorry to say, I did not and would not at that time dare to recommend.

Two boilers cross-connected by a drum riveted to the shells supplied steam to a 14x42-inch Corliss engine running 80 r.p.m. The four-inch steam pipe to the engine was about forty feet long, and vibrated in spite of anchors to such an extent that calking and reriveting the drum nozzles was a serious matter.

The solution of the problem was finally left to the engineer, who had the steam drum (which was 42 in. dia. by 14 ft. long) taken from the boilers, set vertically and connected direct to, and placed directly at the top of, the throttle valve of the engine. There was no further trouble from vibration or leaking rivets, and the initial pressure in the cylinder was six pounds higher than before the change was made.

That was the only receiver I ever saw large enough for the purpose intended, and the only one I know of that proved to be a complete solution of the pulsation nuisance.

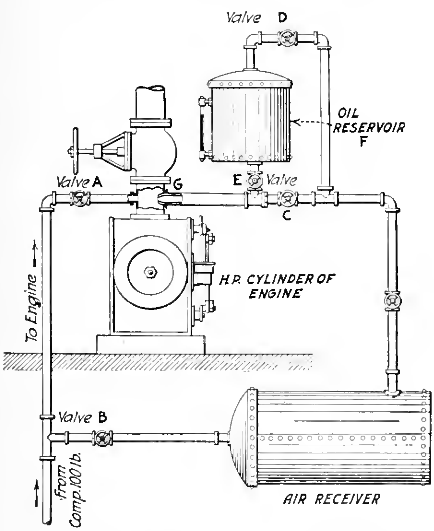
F. L. JOHNSON.

New York City.

Engine Operated with Compressed Air

The following scheme was worked out for turning over and lubricating a 15x32x36-in. compound engine, temporarily laid up, with compressed air instead of steam. Reference to the illustration will explain the piping arrangement.

All the fittings were in stock in the shop, and the job was done at little cost. To start up, fill reservoir *F* with



PIPING ARRANGEMENT FOR COMPRESSED AIR

light cylinder oil, open starting valve *A*, close receiver valve *B*, then open valves *C* and *D* slightly. Regulate the oil with valve *E*.

After the engine starts there is a fall of pressure in the line from the compressor on account of wire drawing in the small line. The receiver being closed off, the pressure does not drop rapidly and is higher at *C* than at *A*, thereby causing the atomized oil to flow through nozzle *G* into the engine.

C. H. REED.

East Chicago, Ind.

Telephone Receiver Connected to Calipers

A telephone receiver has been my constant friend about the plant for the past twelve years, for various uses, one of which is in connection with calipering, especially the work inside of engine cylinders, as in Fig. 1. The most convenient way is to have the two sides of the calipers insulated from each other. In Fig. 2, where the work in the lathe completes the circuit, causing a click in the receiver, an ordinary pair may be used with a cigarette paper between the work and one side of the calipers. This method is especially useful in aligning engines.

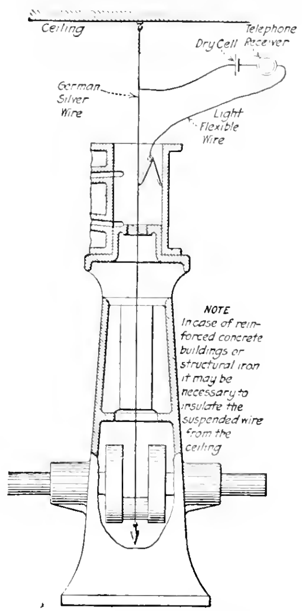


FIG. 1. ALIGNING AN ENGINE

Use a slender german-silver wire for the line, taking care that it is insulated from the ground if an ordinary caliper is used, or put a cigarette paper next to the cylinder wall; then, with one side of the circuit connected to the aligning wire and the other to the calipers, a circuit will be completed when the two come in

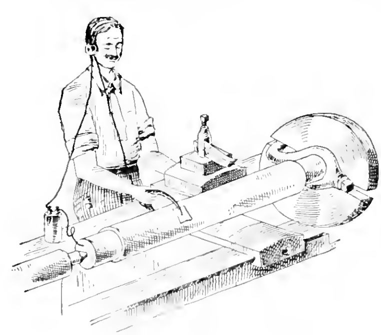

FIG. 2. GAGING OUTSIDE WORK

contact. A click will be heard when a contact is so slight that it cannot be seen or felt. Care should be taken not to use too much battery power, as it is annoying to the ear.

Fort McKinley, Me.

Heating Surface of Superheaters—Experiments prove that 5 B.t.u. per sq.ft. of heating surface will be transferred to steam for each degree of difference between it and the gases.

Easy Calculation of Steam Coal Required by Power Plants

By R. E. Horton*

The writer and his assistants have frequent need to calculate the cost of coal required by actual or hypothetical steam plants under comparison with proposed hydraulic stations. After a few laborious repetitions of computations going back to fundamental factors, the office practice was standardized in the interest of general economy and capacity. A table prepared is here given as of possible interest to others.

Computations were carried through and tabulated for the yearly coal consumption in tons at a rate of 1 lb. per hp.-hr. under various conditions. Now it is only necessary to ascertain or estimate and combine (1) the simplest unit coal consumption (per horsepower-hour, including allowance for shrinkage and waste if any); (2) the average horsepower in use when running; (3) the allowance for banking; (4) the hours' use per day, and days per year.

FACTORS FOR CALCULATING AMOUNT OF STEAM COAL REQUIRED PER HORSEPOWER-YEAR

	Gross Tons, 2240 Lb.		Net Tons, 2000 Lb.	
Method of Operation	310 Days	365 Days	310 Days	365 Days
10 hr. per day, no banking.......	1.38	1.63	1.55	1.83
10 hr. per day plus ⅓ for banking	1.84	2.17	2.07	2.43
12 hr. per day, no banking.......	1.65	1.96	1.86	2.19
12 hr. per day plus ⅓ for banking	2.21	2.61	2.48	2.92
24 hr. per day, no banking.......	3.32	3.91	3.72	4.38

For example: A plant runs 10 hr. per day and 310 days per year, produces 500 hp. average, uses 2½ lb. per hp.-hr. of steam coal, has ⅓ allowance for banking; coal costs $3.50 per gross ton. From the table, the proper unit consumption per horsepower year is 1.84 gross tons.

Then,

$$2.5 \times 1.84 \times 500 \times \$3.50 = \$7735 \text{ annual cost.}$$

Sometimes it is necessary to know the tons of ash that will have to be disposed of each year; then it is necessary only to substitute the decimal percentage of ash in the coal for the price per ton. For 15% ash the foregoing case shows

$$2.5 \times 1.84 \times 500 \times 0.15 = 345 \text{ gross tons.}$$

—"Engineering News."

Aneroid Calorimeter†

By H. C. Dickinson and N. S. Osborne

The term aneroid calorimeter is applied to a type of instrument in which equalization of temperature is secured by means of the thermal conductivity of copper instead of by the convection of a stirred liquid. The calorimeter, consisting of a thick-walled copper cylindrical vessel in the walls of which are embedded a coil of resistance wire to supply heat electrically and a platinum resistance coil for use as a thermometer, has been found useful over a wide range of temperatures and is applicable to a variety of problems.

For use at low temperatures the device is mounted in a jacket surrounded by a bath of gasoline, the temperature of which can be controlled thermostatically to within a few thousandths of a degree at any temperature between —55 and +40° C. or can be changed rapidly in order to keep it the same as that of the calorimeter when heat is being supplied to the latter.

Differences in temperature between the surface of the calorimeter and that of the jacket are measured by means of multiple thermocouples which have 10 junctions distributed over the surface of each, thus making it possible to apply accurate corrections for thermal leakage between the calorimeter and the jacket even when the temperatures of both are changing rapidly.

The platinum resistance coil (for use as a thermometer) embedded in the calorimeter shows slight irregularities in its behavior, probably due to the difference in expansion between the platinum and the copper which surrounds it. Uncertainties on this account, while in general negligible, can be avoided by measuring the temperature of the outer bath with a standard resistance thermometer, using the thermocouples to measure the small difference, usually not more than a few thousandths of a degree, between the calorimeter and the jacket. The thermometer could probably be improved by changing the construction.

Results of a series of experiments (page 565, Apr. 27, 1915, issue) give the constants of the resistance thermometer and the heat capacity of the calorimeter, including a tin-lined cell for use in determining the specific heat of ice and water and the latent heat of fusion of ice.

A series of check experiments on the specific heat of water shows the order of reproducibility of results which can be obtained with this calorimeter to be 1 part in 2000. Measurements made at temperatures between 0 and 40° C. gave results which agree to within the limits of experimental accuracy with the unpublished results of a long series of experiments made in the usual form of stirred-water calorimeter. The results are also in satisfactory agreement with the most probable values deducible from the data of the most careful investigations published by other observers.

†Abstract of a paper issued by the Bureau of Standards, Department of Commerce, Washington, D. C.

Influence of Indicator Connecting Pipes*

By Thomas W. Morley

It is usually stated that one of the conditions for accuracy in taking engine-indicator diagrams is that the connection between the engine and the indicator should be short, direct and of ample bore. The effect of bends, undue restrictions and excessive length of indicator pipes would be to delay the pressure change at the indicator, and hence to cause errors in the diagram. This resistance can best be investigated experimentally, and the author, having been able to find only very meager evidence as to the errors introduced by various connections, has conducted experiments to find out whether the arrangements commonly used are responsible for measurable errors.

A small steam engine was used to produce cycles of pressure change typical of those occurring in steam-engine practice. The engine employed was vertical, with a 6½-in. cylinder, 6-in. stroke, and ordinary slide-valve and link-motion valve gear. The cutoff was kept at about 0.4 of the stroke throughout the experiments.

Alternative indicator connections, long and short (Fig. 1), were arranged, and pairs of diagrams taken through these connections were compared. A and B denote the points at

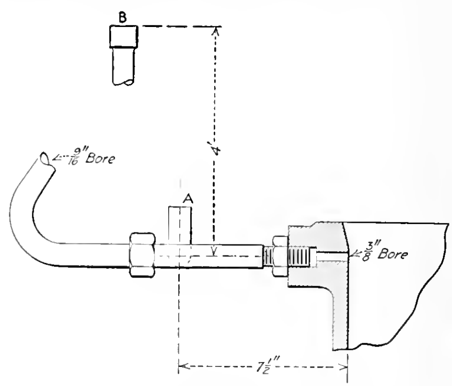

Fig. 1. Alternative Indicator Connections

which the indicator cocks were coupled. The upper end of the long pipe was, of course, suitably fixed.

At first, two similar indicators were placed at A and B, but it was found that, although of the same make, they did not give diagrams that admitted of convenient comparison. In subsequent experiments only one was used, care being taken that no change in the steam pressure or engine speed took place while the indicator was transferred from one position to the other.

Before the arrangement shown in Fig. 1 was adopted, preliminary experiments were made, using next the engine a two-way cock connection. The length between the upper and the lower positions was the same as in Fig. 1.

*From a paper presented before the Institution of Engineers and Shipbuilders in Scotland.

The diagrams thus obtained differed widely. For example, at 325 r.p.m. and a maximum pressure of 50 lb. per sq.in., the mean effective pressures were 36.4 for the lower and 20.4 lb. per sq.in. for the upper diagram. Even at 80 r.p.m. the difference was about 30 per cent. This was caused chiefly by the small bore ($\frac{3}{16}$ in.) of the two-way cock. After it was bored out to ⅜ in. the difference of the diagrams fell to 4 per cent. at about 300 r.p.m. The use of the two-way cock still had the drawback that, when the upper indicator was in use, the pipe connection formed an appreciable addition to the cylinder clearance volume. This in itself might affect the cycle of pressure change in the engine and so account for the difference in the diagrams.

In the final arrangement, shown in Fig. 1, the pipe connections to each indicator cock were constantly open to the cylinder, so that the pressures in the whole system were always unaffected. Also, except for the short ⅜-in. channel at the cylinder wall, the connections to the indicators were of uniform bore. Under these conditions a number of tests were made with gage pressure up to 75 lb. per sq.in., and speeds up to 280 r.p.m. Fig. 2 shows a typical pair of diagrams. The differences between them are so small that they would be concealed if one had been superposed on the other. The chief visible difference in the diagrams was that those taken with the long connection showed more waviness of outline, due, no doubt, to the oscillations set up in the long pipe.

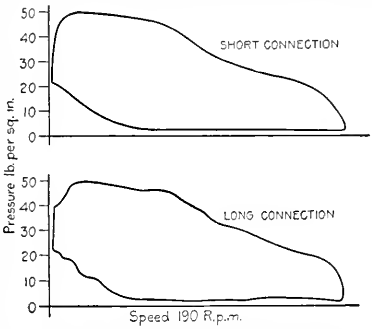

FIG. 2. INDICATOR DIAGRAMS FROM ALTERNATIVE CONNECTIONS

The following table shows the results of the experiments:

Speed of Engine R.p.m.	Maximum Pressure (from Diagram) Lb. per Sq.In.	Mean Effective Pressure Long Connection P_1 Lb. per Sq.In.	Mean Effective Pressure Short Connection P_2 Lb. per Sq.In.	Difference $P_1—P_2$ Lb. per Sq.In.	Difference per Cent.
150	48	27.32	27.48	—0.16	—0.6
153	29	15.46	15.46	...	...
178	76	49.44	49.44	...	...
182	73	49.9	49.9	...	...
190	25	13.15	13.15	...	...
190	31	17.75	17.6	+0.15	+0.85
195	40	24.4	24.0	+0.4	+1.6
190	48	29.65	29.9	—0.25	—0.85
195	55	35.1	35.1	...	...
190	60	38.2	38.2	...	...
190	60	38.6	38.2	+0.4	+1.1
190	68	44.9	44.9	...	...
272	25.5	12.24	12.44	—0.2	—1.6
240	70	43.2	42.8	+0.4	+0.95
254	66	42.12	43.02	—0.9	—2.1
284	38.5	22.1	21.5	+0.6	+2.8
280	42	24.8	25.2	—0.4	—1.6
275	47	27.7	28.1	—0.4	—1.4
280	53	32.6	32.3	+0.3	+0.95
270	62	37.9	37.8	+0.1	+0.25

The general conclusion to be drawn from the experiments is that the influence of the connecting pipes does not subject indicator diagrams to any appreciable error, except in abnormal cases. The difference of the mean effective pressures was always small, in only two cases exceeding 2 per cent.; and was in fact within the limit of probable error of the indicator itself.

In the discussion following the delivery of the paper the conclusions reached were questioned because the connection at A in Fig 1 had two bends and the long pipe was in communication with the cylinder while the indicator at A was in use. In answer to the latter objection the author explained that the arrangement used satisfied the real object of the experiments, which was to compare the influence of long and short pipes connected to a point at which a certain pressure cycle took place. The indicator at A need not give a faithful record of the cylinder pressures. Coming now to the other objection, the indicators at A and B were separated from the point where there was a constant cycle of pressures by a bend and a short pipe in one case, and in the other by an easier bend and a long pipe. Experiments other than those described in the paper had been made on this engine with connections of about the same length as that to A, but with a different number of bends. No appreciable difference in the results had been observed. It was therefore considered that any difference in the influence of the two connections would be due to their lengths alone and would not be obscured by the bends.

Why Should Such Things Be?

A leading machinery firm in Bombay expressed the opinion that American boilers could not be successful in India, because of the steel used not being of the right quality as required by government testers. American manufacturers do not follow Indian specifications, and offer openhearth steel instead of basic. The market in India is for boilers built for high pressure. The steel should not be too hard, but somewhat flexible. German boilers have sold well in India because they are made of steel that expands well. Nearly all boilers used in India are of Lancashire type. This firm states that it imported a boiler from the United States about 15 years ago and still has it on hand, being unable to sell it. Boilers in India are mostly used for cotton mills, ginning factories, etc. —Henry D. Baker, U. S. Consul, Bombay.

Blowout of Turbine Exhaust Casing

Although the local newspapers reported that an accident had taken place on Mar. 31 at the plant of the Boston Manufacturing Co., Waltham, Mass., the causes given varied from a blowout of the cylinder head of a turbine engine to a turbine explosion. Perhaps the most comprehensive was the statement that the explosion in a 750-kw. engine blew up the generator and badly damaged the boiler.

Further investigation has shown that at 5:45 p.m. on the date mentioned, the exhaust casing on a 750-kw. G-E Curtis turbine was blown to pieces, hurling through a window the engineer, William Finley, who was standing near. Outside of the turbine the damage was confined to the wrecking of the engine-room windows and the dislodging of a few bricks by pieces of the casing blown against them.

The accident is said to have been caused by the closing of the exhaust valve before the throttle was closed, the relief valve provided for such emergencies failing to operate.

PERSONALS

Messrs. John S. Griggs, Jr., and David Moffat Meyers have consolidated their consulting practices with offices at 110 West Fortieth St., New York City. Mr. Griggs was a member of the consulting firm of Griggs & Holbrook, New York, and has been in practice for the past twenty years. Mr. Meyers, who is the author of the recently published book, "Preventing Losses in Factory Power Plants," was formerly mechanical engineer for the United States Leather Co. The firm will specialize in mechanical and electrical propositions for industrial and other installations.

C. P. Poole, chief engineer of the Department of Mechanical Engineering of the City of Atlanta, Ga., has been appointed a member of the International Jury of Award in the Department of Machinery of the Panama International Exposition. Mr. Poole, who will be remembered as one of the editors of "Power," has been for some time in charge of what was known as the Department of Smoke and Gas Inspection of Atlanta, and under his direction the activities of the department have broadened out so as to make necessary the reorganization indicated by the new title.

ENGINEERING AFFAIRS

Stationary Engineers' Day at the Fair—The management of the Panama-Pacific Exposition has designated Saturday, May 29, as Stationary Engineers' Day. This will enable the delegates and guests of the California State Association of the N. A. S. E. to enjoy that day at the Fair, since the annual convention of this association will be held in San Francisco on May 27 and 28.

The Fifteenth Annual Summer Session of the College of Engineering of the University of Wisconsin will be held at Madison during the six weeks' period beginning June 21. Special courses will be given in electrical, steam and hydraulic engineering, gas engines, machine design, mechanical drawing, mechanics, shopwork and surveying. Further information may be obtained from F. E. Turneaure, Dean, Madison, Wis.

The International Engineering Congress which is to be held in San Francisco in September will issue in Vol. IV of its transactions the papers presented on "Railways and Railway Engineering." The field treated will cover the relation of railways to social development, present status of railways, economic factors governing building of new lines, location, physical characteristics of road including track and roadbed, bridges, tunnels, terminals, construction methods, signals, road equipment, including motive power other than electric, rolling stock, floating equipment, and electric motive power. W. A. Cattell, 417 Foxcroft Bldg., San Francisco, secretary of the Congress, will furnish particulars regarding membership and the securing of the transactions to those interested. These transactions will include nine or ten volumes, covering the various fields of engineering.

NEW PUBLICATIONS

MECHANICAL WORLD POCKETBOOK, twenty-eighth issue. Norman Remington Co., Baltimore, Md., American agents. Size, 4x6 inches; 330 pages. Price, 50 cents.

Besides the usual data given in previous editions of this well-known low-priced handbook, this issue contains an extended and rewritten section on toothed gearing and a more lengthy section dealing with structural iron and steel work. Also, new sections on limit gages and on the cost of power have been added.

ADVANCED ELECTRICITY AND MAGNETISM. By W. S. Franklin and Barry MacNutt. Published by the Macmillan Co., New York. Cloth, 5½x8½ inches; 300 pages; 217 illustrations. Price, $2.

This book is designed for students in colleges and technical schools. The subject matter deals with the elementary theory of magnetism and with advanced principles of the magnetic measurement of current, electromagnetic induction, electrostatics and electric waves. An outline is given of the electron theory and of its application to the vacuum tube and the electric arc. The historical development of the theory is entirely, and the mathematical largely, omitted, the treatment being confined to concrete presentations of a few principles. A number of problems (with answers) are given at the ends of the chapters.

HEATING AND VENTILATING BUILDINGS. By R. C. Carpenter. Published by John Wiley & Sons, Inc., New York. Cloth, 6x9 in.; 598 pages; 290 illustrations. $3.50.

Professor Carpenter's well-known treatise, now published in its sixth edition, is a manual for heating engineers and architects. It gives general methods of design and construction as well as the elementary principles applying to heating and ventilating apparatus. While the previous edition has been rearranged to a considerable extent, the additions in the sixth edition consist mainly of a chapter on air conditioning and of abstracts of heating and ventilating laws. The determination and regulation of humidity and the methods of purifying air are broadly described. Abstracts of the laws relating to the heating and ventilation of schoolhouses and public buildings in 17 states are given. The book has the disadvantages common to most technical treatises in which an attempt is made to keep them up to date by publishing new editions. Even with the best of intentions it is difficult to thoroughly revise an old book. This is evidenced in the present instance by the many results of tests and investigations made in the late 80's and early 90's. This material was adequate when the book was first published in 1895, but at the present time, although perhaps of historical value, is surely not indicative of the state of the industry. Another disadvantage is the difficulty in adding new material without affecting the unity of the original treatment. For example the present volume has two sets of sections numbered from 56 to 72 inclusive. Of course this is caused by carelessness in revision, but it goes to show a minor trouble experienced in forcing the original text to assume a new and different form.

Milestones

Steam Turbines--Their Principles and Operation*

By Charles H. Bromley

SYNOPSIS—The lecture is intended for operating men. It explains in simple words and diagram how a turbine makes use of the energy in the steam, what impulse and reaction are as applied to turbines, what staging is and why it is necessary; tells in a general way what to do when starting and stopping, and emphasizes the importance of careful attention to the oiling system and the blade clearances.

To understand the turbine it is essential that one be acquainted with the forms of energy of which it makes use. Energy is of two kinds, potential and kinetic. The former is rest energy, or energy capable of manifesting itself by reason of position, as the weight of a pile driver before it is released to descend, as steam under pressure, confined and ready to move on being released, or as a spring compressed or elongated. Things have potential energy by reason of their position or by the state of arrangement of their molecules. Kinetic energy is energy of motion, as the energy in a falling weight, a moving train, a jet of water or steam. When kinetic energy is mentioned velocity is always implied.

The reciprocating engine uses the potential energy in the steam, for the energy is given up by the steam as it expands, pushing the piston ahead of it. The potential energy is converted directly into mechanical work. A turbine changes the potential energy into kinetic before it does work with the steam. It may make the change complete before the steam enters the moving parts of the turbine, or it may make it in installments—in stages.

Difference between Impulse and Reaction

This brings us to the subject of impulse and reaction, that is, to the two ways in which the energy is extracted from the steam at the turbine blades. Impulse action, when related to turbines, means to force, to impel, by impact, as when you wash the floor with water from a hose. The blow, the impact, with which the water strikes the dirt drives it ahead. In an impulse turbine the steam does the same thing to the wheel. Examples of impulse and reaction are shown in Fig. 1. A good illustration of reaction is the common whirling lawn sprinkler shown. The water under pressure flows from the nozzles, causing them to move in a direction opposite that taken by the water. Reaction as applied to a turbine wheel may be explained as a backward push as the steam passing through the nozzles reduces its pressure. The wheels of reaction turbines have blades that form nozzles, and the pressure at the inlet side is greater than that at the outlet. This pressure difference in the wheel is what causes it to revolve. In an impulse turbine the pressure is the same on both sides of the wheel. The two kinds of blading, impulse and reaction, are shown in Fig. 2.

*From a lecture before the Modern Science Club, Brooklyn, N. Y.

Keeping in mind the two forms of energy, it is well now to understand what is meant by staging as applied to turbines. One of the definitions of stage given in Webster's Dictionary admirably suits our needs:

Stage: "A distance between two places of rest on a road; hence, a degree of advance in a journey."

Steam at high pressure enters the turbine, passes through it and comes out with most of its energy extracted. The steam is on a journey, the turbine is the road and the intervals between stages are the places of rest on the way. If the steam passes through the turbine from the high to the low pressure all at once, if it does not rest, as it were, between the two points, if there is but one distance between the beginning and the end of the journey (expansion), then that turbine is a single-stage machine. If the steam rests more than once on the way, then the turbine through which it passes is a multi-stage machine.

In Fig. 3, left, the pressure due to the total head is applied to the wheel. It is a single-stage machine. At the right the total head is divided into four parts. The machine is a multi-stage one. Each wheel has but one-fourth of the total pressure applied to it. The velocity of the water at the nozzles is less in the multi-stage than in the single-stage machine and therefore permits of running the wheels slower, although about the same amount of energy is taken out of the jets in both cases. The advantages of dividing the pressure or velocity drop in this way in steam turbines will be taken up presently. A stage in a turbine may also be considered as a compartment for a wheel where the steam decreases either its pressure or velocity, as shown in Fig. 4.

By properly graduating the cross-section of a nozzle you can expand steam from one pressure to another, making the drop between inlet and outlet as much as desired. Such nozzles form the communicating passages between the stationary and moving blades or between the stages or compartments of a turbine. It is in this way that the pressure and velocity are controlled in the wheels and the stages, or wheel compartments.

Single- and Multi-Staging

Primarily, it is the great amount of energy liberated by the expansion of a comparatively small weight of steam that makes staging in turbines necessary. A pound (weight) of steam at 150 lb. pressure expanded in a perfect nozzle to 1 lb. absolute (28 in. vacuum) gives up 325 B.t.u., which is equivalent to $325 \times 778 = 252{,}850$ ft.-lb. of energy.

In expanding between these two pressures in one jump the steam would attain a velocity of a little over 4000 ft. per second, or more than 2700 miles an hour. Nearly all the energy (potential) that was in the steam before its expansion is present after expansion in the kinetic (velocity) form. To convert the kinetic into mechanical energy the steam must be brought to rest by the turbine wheel or rotor.

In an impulse turbine expansion of the steam occurs only in the nozzles, or stationary blades, and in a single-

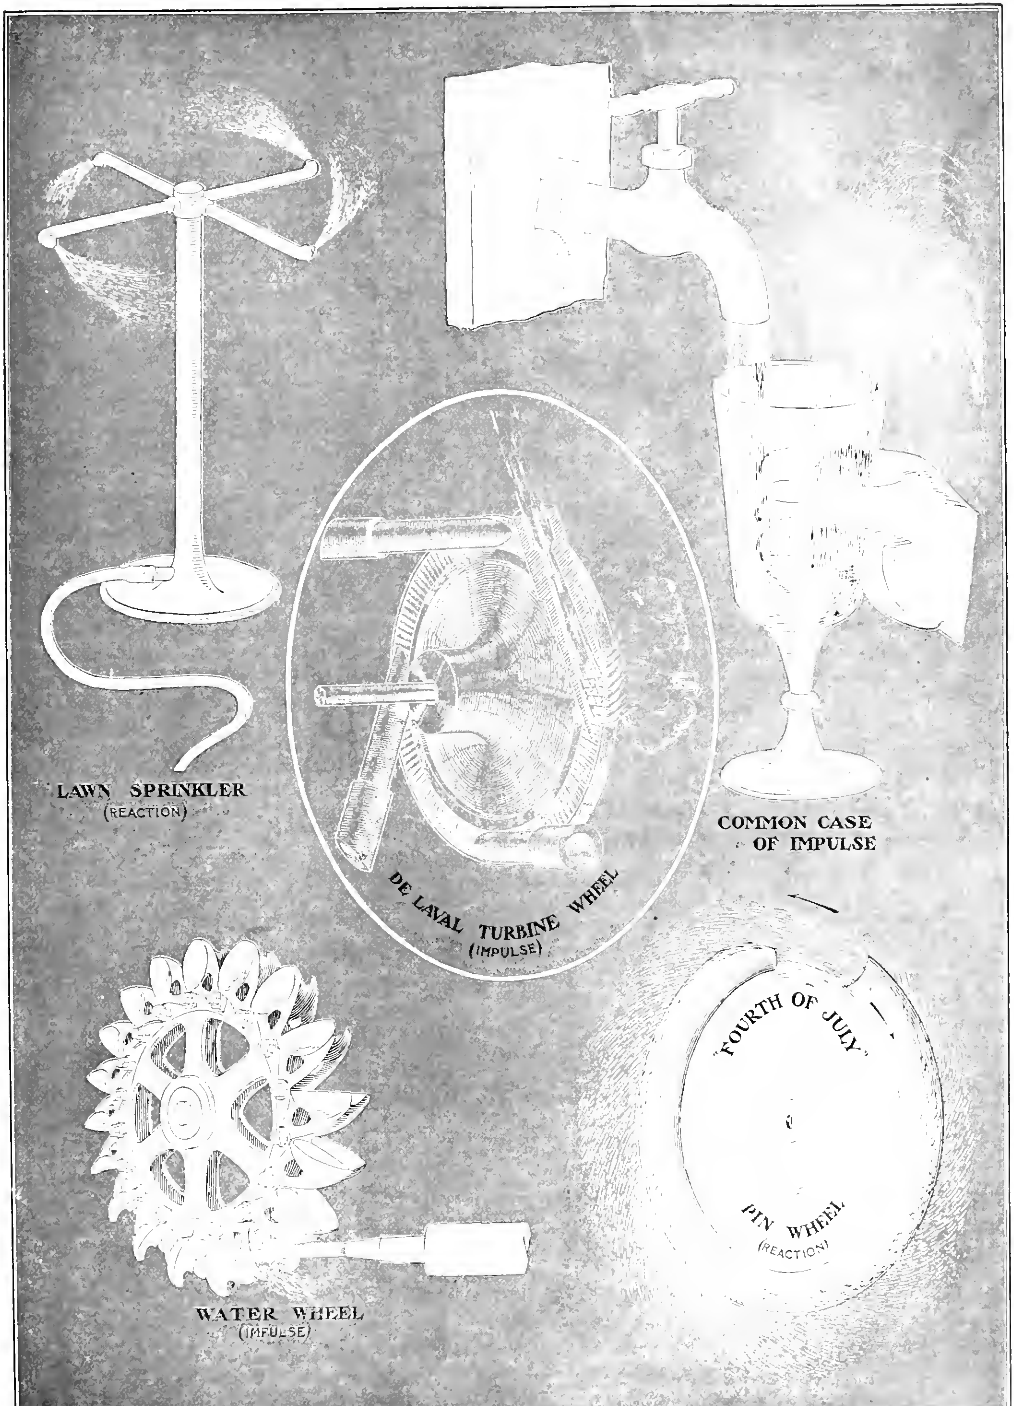

FIG. 1. EXAMPLES OF IMPULSE AND REACTION

stage machine, like the De Laval, Fig. 1, for example, the steam is fully expanded in the nozzles and therefore it strikes the wheel at the enormous velocity of about 4000 ft. per sec.

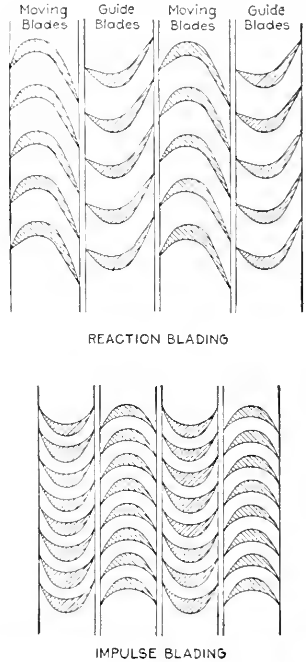
If the glass in Fig. 4 were moved in the same direction as the jet, or stream, of water and at one-half the velocity of the stream, the water would just flow over the side of the glass and all the energy in the jet would be extracted. To bring the steam to rest the wheel must run at half the speed of the steam jet, or, for the single-wheel turbine the peripheral speed of the wheel must be 2000 ft. per sec. Under these conditions the steam would leave the wheel with just enough velocity to force itself away from it. To produce this effect, i.e., to get the steam to leave the bucket with no velocity, means using an enormous wheel if a fairly low number of revolutions per minute is desired, or, if a small wheel is used it must run at an extremely high speed. Mechanical difficulties do not permit of obtaining slow wheel speeds, for the wheel would be too large (64 ft. diameter for 600 r.p.m.), so small wheels running as high as 30,000 r.p.m. are used in the small-sized single-stage De Laval machines. Gears are used to reduce the speed to accommodate the driven machine. About 500 hp. is the capacity limit commercially for a single-stage turbine.

Suppose all the velocity were not extracted by the wheel. Then there would still be energy in the steam which might be applied to another wheel and from the second to a third and then to a fourth, all on the same shaft; and so on until the pressure and velocity, and therefore the energy, were zero. With a suitable number and arrangement of wheels, nozzles and diaphragms (partitions forming the stage compartments) the pressure and velocity changes through the turbine may be controlled as desired. On page 630 the diagrams, Figs. 5, 6, 7, 8, and 9, show the different methods of extracting the energy from the steam. The page will make a good insert for your notebook. The tendency here and abroad is toward the wider adoption of the "composite" design, i.e., velocity staging in the high-pressure end and pressure staging in the low-pressure end. A good illustration of this design is shown in Fig. 9. Note the large drop in pressure in the impulse, or velocity, chamber.

For a simple and entertaining explanation of steam speeds and bucket speeds the reader is referred to the article by F. R. Low in last week's issue.

Starting and Stopping

When steam is turned into an engine it fills the space back of the piston and in some cases the whole cylinder, warming it uniformly and therefore minimizing strains due to expansion. In most large turbines steam would not be admitted around the whole circumference of the rotor when the turbine was standing still unless special "warming pipes" were provided, as they sometimes are. So, to warm a turbine, large or small, it is always best to have all drains open and admit steam quickly enough to revolve the turbine, letting it warm while running. If allowed to stand still with warming steam on, the steam will flow along through the blading in a path, thus creating unequal expansion of, and imposing objectionable strains in, the rotor and casing. If the sealing-gland water is admitted under pressure created by a pump, a tank or from the city mains the turbine may be started condensing. If the gland-seal water pressure is created by an impeller on the shaft whose speed is that of the rotor, and there is no means of sealing, then it is best to start noncondensing, putting the condenser in service slowly after the turbine has attained normal speed. In this way excessive amounts of air are not carried into the machine. Turbines using steam-sealed carbon-ring packing may be started condensing. It is



Cross-Sections of Turbine Blades

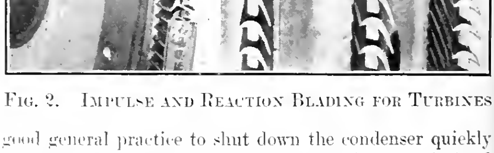


Fig. 2. Impulse and Reaction Blading for Turbines

good general practice to shut down the condenser quickly when stopping a turbine, for with some designs of gland seals cold air would be drawn in when the steam was shut off the machine if the condenser were left running, exposing the rotor to distortion, which is objectionable.

Turbine Lubrication

Lubricating oil for large turbines, vertical or horizontal, is supplied under pressure, the oil being forced by at least two pumps, one driven by the turbine shaft, the other a small, usually duplex, steam-driven pump. The latter should be started before the turbine is turned over to insure good circulation for starting. When the turbine is up to about normal speed the shaft-driven pump goes into useful service and the steam-driven one may be stopped. When shutting down, start the steam-driven pump and let it run until the turbine stops. Sometimes an elevated tank is used for supplying oil for starting and stopping. The aim always should be to have the oil and the oil-cooling water circulating before starting, and continue flowing without cessation until the machine is at a standstill. This is important.

The importance of a continuous oil supply to the bearings of a turbine is much greater than for a reciprocating engine. This is because of the small clearances between the stationary and rotating parts, because the speed is much greater, and because the bearings are near the high-temperature parts of the machine. All of these conditions make a hot bearing much to be feared. Should the babbitt or white metal in the bearings reach the melting point and become plastic, the rotor will drop, owing to its weight, and if not stopped in time many blades may be ripped off, and if it is a single-flow Parsons-type machine the dummy pistons and rings will be seriously damaged. The oil circulation system—the reservoir, the pumps, the filter,

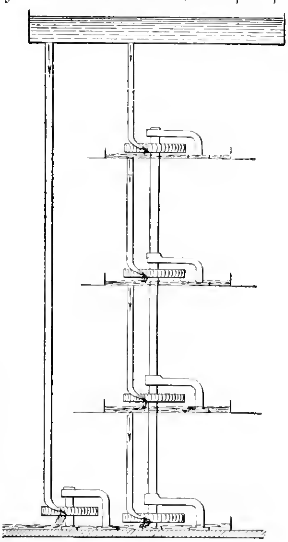

FIG. 3. INSTEAD OF APPLYING THE TOTAL PRESSURE ON ONE WHEEL (ONE STAGE), THE MULTI-STAGE MACHINE USES MORE THAN ONE WHEEL, APPLYING ONLY PART OF THE TOTAL PRESSURE ON EACH

the cooler, the pipe lines and the oil grooves—must be given the most thorough attention.

As the oil consumption of turbines is low on account of no oil getting in contact with steam or condensate, and because of the circulation system, it is good engineering to use a high-grade mineral oil, free from acids, thickeners, tarry, slimy and saponifiable substances. The General Electric Co. recommends that the flash-point, open-cup test, should be below 331 deg. F. and that the viscosity should not be more than 228 sec. at 10 deg. C. (101 F.), as shown by a Saybold viscosimeter, which is the kind used by the Standard Oil Co.

Good general instructions for starting are: Have all glands sealed at about 5 to 10 lb. pressure; the atmospheric or free exhaust valve is usually water-sealed. Have it sealed. Have the oil circulating through the bearings. If the turbine is a Curtis vertical, start the step-bearing and valve-gear pumps and maintain the necessary pres-

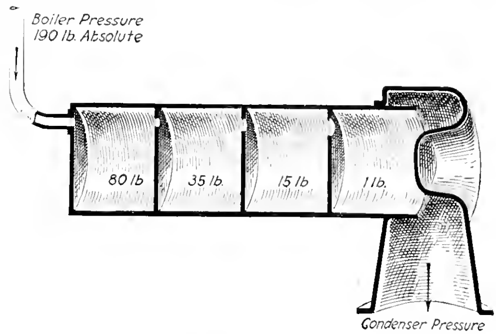

FIG. 4. TURBINE STAGING CONCEIVED OF AS COMPARTMENTS

Note that the openings between compartments increase from the high- to the low-pressure end to pass the increasing volume of steam.

sure—750 to 1500 lb. on the bearing, depending on the size of the turbine. Now start the dry-air pump, the hot-well pump and the circulating pump. Usually, there is a pipe leading from the condenser to the top of the circulating pump. Open the valve in this line (priming line), as it allows air to be exhausted from the pump and suction and assists the pump in picking up its water. Slowly bring all pumps up to speed. If there are drains for the different stages of the turbine, open them. Now start the main turbine slowly, increasing the speed and letting the governor get control.

Look around to make sure that the oil and water circulation is good, that the circulating-water pressure and step-bearing oil or water pressure are right, and that the governor has control. Next close the circulating-pump priming valve. Now put on the load. If there are steam-sealed glands, shut off the steam to the high-pressure packing, for the pressure in the first stage prevents air getting in. It may be necessary to regulate the pressure on the low-pressure packing. Now close the drains of the stages. The gear may then be oiled. The main turbine may vibrate considerably while being brought up to speed. Do not be alarmed at this. When this occurs admit a little more steam quickly to get the rotor above the "critical speed," when the vibration will ordinarily cease. Acquire the habit of shutting down the turbine by tripping the emergency governor, which should automatically operate at 10 to 12 per cent. above normal speed.

Sometimes, just after the machine gets its load it will lag, i.e., be slow or "jerky" with its speed. Frequently, this is due to the pilot valve for the main steam-admission valve sticking, owing to carbon which has collected on the stem. Pour on some kerosene for the time being, but clean the valves as soon as the unit is stopped. In case of any unusual disturbances inside the casing, as the noise due to rubbing of the blades, trip the emergency governor to avoid serious damage or, perhaps, a wreck.

For best economy the clearances between the tips of the blades and the casing and between the sides of the station-

PRESSURE AND VELOCITY CHANGES IN STEAM TURBINES

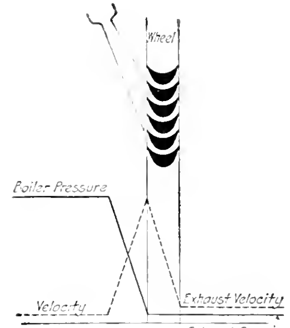

FIG. 5

Fig. 5. Pressure and velocity changes as they occur in single-stage turbines, which type most small turbines represent. Notice that the pressure drops completely in the nozzle and the velocity completely in the moving wheel.

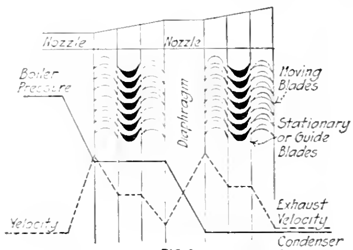

FIG. 6

Fig. 6. Multi-pressure, multi-velocity staging. The pressure in each stage is constant, but is dropped in a nozzle before each stage. Large Curtis vertical machines use the energy in this way. The turbine is an impulse machine.

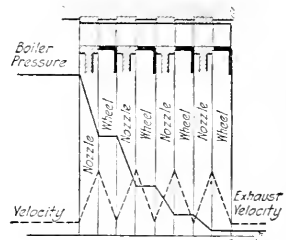

FIG. 7

Fig. 7. Pressure and velocity changes as carried out in the multicellular (impulse) type. This kind of turbine is a multi-pressure, single-velocity machine, of which some of the De Laval, Zoelly, Kerr, Rateau and others are representative types.

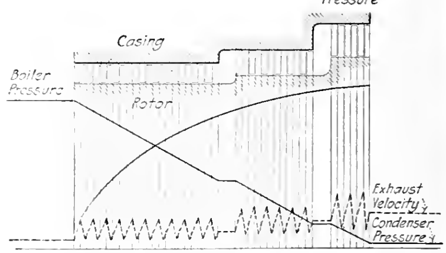

FIG. 8

Fig. 8. Shows how the "pure" reaction, or Parsons, types of turbines use the energy in the steam. The pressure is dropped very gradually through many rows of blades, there being no large increase in velocity anywhere in the machine.

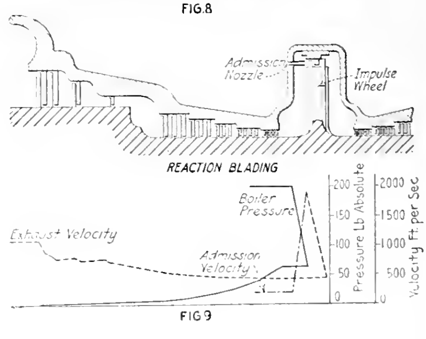

FIG 9

Fig. 9. Pressure and velocity changes as made in the composite design, with velocity staging in the high-pressure element and pressure staging in the low-pressure element. The diagram relates particularly to the Westinghouse double-flow turbine. Many turbines here and abroad are of the composite design.

ary and the moving blades, and between the dummy pistons and their rings, if a single-flow Parsons-type machine, must be small, a comparatively few thousandths of an inch in all cases. Because of the high speeds at which turbines run and because of the small clearances, it is essential that the rotor be in mechanical balance. Adjusting clearances and putting a rotor in balance are jobs requiring skill carefully applied. Time does not permit of taking up these subjects in this lecture, though they are of much interest and importance to the operating engineer.

Steam-Generating Methods, Cleveland Municipal Plant

By A. D. Williams

SYNOPSIS—This large central plant uses economizers. The gates in the hopper outlets of the coal bunker are opened and closed by compressed air, the control being in the hands of the coal-telpher operator. Detray-type boilers are used. Stoker and draft controls are interesting.

In designing the new, or East Fifty-third Street Cleveland municipal lighting plant, F. W. Ballard has used motor-driven auxiliaries throughout, but has provided a steam-driven boiler feeder and a turbo-exciter for emergency service. This plan has simplified the piping systems and eliminated the exhaust steam feed-water heater. Large-sized, high firebox boilers are used, with induced- and forced-draft fans, and the waste gases from the boiler are passed through an economizer for heating the feed water.

The plant is on the shore of Lake Erie at the foot of a steep bluff on the top of which are the tracks of the Lake Shore R.R. and a siding from which two spurs extend over the coal bunker. The height available at this point was not sufficient to permit of placing the bunkers above the boilers without excavating to a considerable depth below the water level of the lake. As the result of this condition, the station practically consists of three parallel structures—the coal-bunker section on the east, the electrical section on the west and the boiler section in the center.

The bottom of the bunker consists of 40 steel-plate hoppers, each provided with a gate opened and closed by a compressed-air cylinder whose operation is controlled by the coal-telpher operator. The telphers run on transverse tracks below the east section of the bunker and are carried by a transfer crane below the west section, an arrangement which permits coal to be drawn from any section of the bunker and delivered to any boiler. Each telpher is provided with a weighing hopper, and the operator on each watch turns in a report of the amount of coal and the time at which coal was delivered to each boiler.

Fig. 1. Aisle below Bunker Showing Hopper Bottom with Air-Operated Gates for Loading Telpher

The present installation comprises five Delray-type Stirling boilers, each fired by two six-retort Taylor stokers. Exceptionally large structural-steel coal hoppers are provided for each stoker, from which the coal flows by gravity to the grates. The central space between the two stokers is closed by dump plates, from which the ashes and clinker are dropped into an ashes hopper. An industrial track is laid in the concrete floor of the boiler-room basement, and upon this are operated steel side-dump ash cars and a storage-battery-operated electric ash car. These cars are used to carry the ashes outside of the building to a point where they can be used in filling in and extending the city property to the harbor line established by the United States engineers.

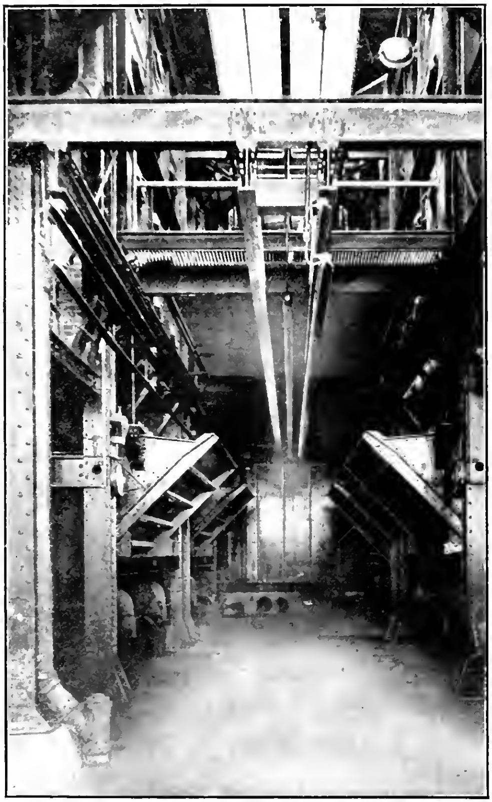

Fig. 2. Firing Aisle. Note Large Stoker Hoppers

The fire area below the boiler is approximately 200 sq.ft., for an average height of about 10 ft. to the bottom of the two mud drums. From this height up the combustion chamber is shaped like a wedge, point up, with a height of nearly 20 ft., the two sloping sides being formed by the tubes of the first pass. This arrangement gives ample space for the flame to form, and the combustible gases are not chilled below the igniting temperature by the comparatively cold tubes of the boiler. In operation the interior of this chamber shows a clear white flame at the lower portion and transparent orange above. As one pound of gas occupying a unit volume in the blast main will occupy five volumes in the combustion chamber and one and one-quarter volumes at the uptake, there are some reasons for providing space for this expansion. The second pass of the gases brings them in contact with the superheater tubes, and at the end of the third pass they flow into an overhead smoke flue. On test the gas temperatures at this point ranged from 510 deg. F. at 106 per cent. rating to 832 deg. F. at 273 per cent. rated load.

In this plant the stokers and the forced-draft fans are operated by separate motors. The speed of the fan motors is governed by controllers operated by changes in boiler pressure, while that of the stoker motors is controlled by changes in blast pressure. The small houses which protect these speed controllers are shown at the left side of the aisle in Fig. 2. Additional control of the draft is supplied by the induced-draft fans, which are operated by motors with manual speed control by means of which the boiler tenders can keep the combustion chamber close to or slightly above atmospheric pressure. This method of operation obviates any tendency of air to seep into the settings through the brickwork or around the cleanout doors and is particularly desirable when it becomes necessary to bar the fires, as there is no tendency to either chill the furnace or burn the firemen. In practice this plan seems to work out well.

From the boilers the waste gases are carried to the economizers and the stack by sheet-steel flues. The stack provided is not designed to supply draft, and for that

PRINCIPAL STEAM GENERATING EQUIPMENT OF EAST 53RD STREET STATION, CLEVELAND MUNICIPAL ELECTRIC LIGHT PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
5	Boilers	Stirling, Delray type	10,134 sq.ft. heating surface	Steam generation	225 to 275 lb. pressure; 125 deg. to 150 deg. F. superheat	Babcock & Wilcox Co.
10	Stokers	Taylor underfeed	6 retort	Under boilers	From standby to 275 per cent. boiler rating	American Engineering Co.
6	Motors	Variable speed	10-hp	Stoker drive	725 to 1125 r.p.m., 220 volts, 37.5 amp., direct current	Diehl Mfg. Co.
6	Speed controllers	Pressure controlled	10-hp	Stoker drive	220-volt	Cutter-Hammer Mfg. Co.
6	Speed controllers Operators			Stoker drive	Controlled by air duct pressure	Mason Regulator Co.
5	Fans	Multivane	36,000 cu.ft. air per min.	Forced draft	7 in. of water pressure	B. L. Sturtevant Co.
5	Fan motors	Variable speed	75-hp	Forced draft	600 to 730 r.p.m., 220 volts, 282 amp., direct current	Allis-Chalmers Mfg. Co.
5	Speed controllers	Pressure controlled	75-hp	Forced draft fans	220-volt	Cutter-Hammer Mfg. Co.
5	Speed controllers Operators			Forced draft fans	Controlled by boiler pressure	Mason Regulator Co.
2	Fans	Steel housed	16x7-ft.	Induced draft	Belted to motors; 70 to 210 r.p.m.; 101,000 to 325,000 cu.ft. per min., 1 in. draft at economizer inlet	Green Fuel Economizer Co.
[illegible]	Fan motor	Induction variable speed	200-hp	Induced draft	695 r.p.m.; 3-phase; stator 2300 volts, 47.5 amp.; rotor 479 volts, 207 amp.	Allis-Chalmers Mfg. Co.
[illegible]	Fan motor	Variable speed	200-hp	Induced draft	540 to 740 r.p.m., 220 volts, 745 amp.	Allis-Chalmers Mfg. Co.
[illegible]	Speed controll	Manual	200-hp	Induced draft		Cutter-Hammer Mfg. Co.
[illegible]	Economizer		2 sections in multiple, 27,000 sq.ft. heating surface	Feed water heater	Waste gases from boilers	Green Fuel Economizer Co.
1	Scraper motor	Induction	3-hp	Economizer soot scrapers	1200 r.p.m., 3-phase, 60-cycle, 220 volts	General Electric Co.
1	Scraper motor	Induction	7.5-hp	Economizer soot scrapers	1200 r.p.m.	
1	Chimney	Concrete lined	13-ft. diameter, 150 ft. high	Removal of waste gases	Induced draft	General Concrete Cons. Co.

reason has been made only of a height sufficient to carry the waste gases up to a point at which they will not become a nuisance to neighboring property. The two induced-draft fans are close to the base of the stack and discharge into it, each being of a capacity sufficient to handle all the load.

The normal operation of this plant provides for the heating of the feed water by the economizers. This installation is divided in two sections, each containing 824 twelve-foot tubes, the total heating surface in both sections being 27,000 sq.ft. Each section of the economizer can be operated independently or may be cut out by dampers. A bypass flue is also provided to lead the waste gases direct to the induced-draft fans.

SPACE AND VOLUMETRIC DATA OF THE STATION

Turbine room and switch gallery		8100 sq.ft.
Sq.ft. per normal kw	0.54	
Sq.ft. per maximum kw.	0.36	
Boiler room		9230 sq.ft.
Sq.ft. per boiler hp. installed	1.82	
Sq.ft. per boiler hp. (6 boilers)	1.52	
Sq.ft. per kw. normal	0.615	
Sq.ft. per kw. maximum	0.410	
Boiler room plus bunker space		15,330 sq ft.
Sq.ft. per boiler hp. installed	3.02	
Sq.ft. per boiler hp. (6 boilers)	2.52	
Sq.ft. per kw. normal	1.024	
Sq.ft. per kw. maximum	0.682	
Total ground area of station		25,360 sq ft.
Sq.ft. per kw. normal	1.68	
Sq.ft. per kw. maximum	1.13	
Volume turbine room and switch gallery		500,000 cu.ft.
Cu.ft. per kw. normal	33.33	
Cu.ft. per kw. maximum	22.22	
Volume boiler room		567,000 cu.ft.
Cu.ft. per boiler hp. installed	11.19	
Cu.ft. per boiler hp. (6 boilers)	9.34	
Cu.ft. per kw. normal	37.80	
Cu.ft. per kw. maximum	25.20	
Volume boiler room plus bunker space		841,000 cu.ft.
Cu.ft. per boiler hp. installed	16.55	
Cu.ft. per boiler hp. (6 boilers)	13.85	
Cu.ft. per kw. normal	56.10	
Cu.ft. per kw. maximum	37.40	
Volume of building		1,420,000 cu.ft.
Cu.ft. per kw. normal	95.00	
Cu.ft. per kw. maximum	63.20	

The present installation comprises:

3 main generating units, normal rating	5000 kw. each
maximum rating	7500 kw. each
Five boilers, each having 10,134 sq.ft. heating surface. Space has been left for a sixth boiler.	
Coal storage capacity in bunker	3400 tons
Coal storage per boiler hp.	1114 lb.
Coal storage per kw normal	454 lb.
Coal storage per kw. maximum	304 lb.

The total length of the economizer is 55 ft. 7 in. and it is so designed that the free area between the tubes is reduced as the gases become cooler.

ECONOMIZER DATA

Number Sections	Number Headers	Tubes per Header	Tubes per Section	Total Number Tubes	Free Area Each Section, sq.ft.	Total Free Area Both Sections, sq.ft.
2	16	6	96	192	56.7	113.4
2	16	8	128	256	49.9	99.8
2	60	10	600	1200	42.9	85.8
2	92	..	824	1648	....	..

Under present conditions only five boilers are installed and there are 4.75 sq.ft. of economizer heating surface per nominal boiler horsepower. When the sixth boiler is in place this will be reduced to 4.44 sq.ft. At present the station is operating considerably below its capacity, and only one section of the economizer is in use at a time. Owing to this condition it is not fair to present the operating results obtained.

[As told in other issues of POWER describing other features of this plant, the station is the largest municipal electric plant in the United States.—EDITOR.]

What Causes the High Efficiency of Locomobiles?

By E. R. PEARCE

To what is the high efficiency of the locomobile mainly due? Some are under the impression that it is due to there being practically no steam pipe between the engine and boiler to cause radiation and condensation. This opinion does not appear to carry much weight when one considers that there are many independent engines working with the steam conditions at the cylinder, both as to temperature and dryness, the same as on the locomobile and yet not having anything like its high efficiency.

In the locomobiles the engines are of the piston-valve type, identical in all respects except for a few minor details. Some of these sets, as built by Wolf and Garrett, have the high- and the low-pressure cylinders placed on the boiler at the firebox end, side by side, and are simply jacketed with live steam at boiler temperature, so that any flow of heat through the high-pressure cylinder walls due to the superheat is not lost, but is taken up by the jacketing steam, eventually passing back into the engine.

That which appears to be the biggest factor in securing high economy is the resuperheating of the steam between the cylinders. There seems to be very little difference in the results obtained whether the cylinders are arranged as mentioned, and steam jacketed, or in tandem, with the high-pressure cylinder jacketed by flue gases. This alone tends to point to the gain being derived in the reheating, thereby preventing condensation in the low-pressure cylinder, which is undoubtedly responsible for the bad performances given by many well-designed engines.

On the smaller sizes there is no reheater, the low-pressure cylinder being jacketed with live steam. Usually, these are very efficient, but do not come up to those having reheating. In the latter type the consumption shows marked reduction as the superheats increase, which, in the case of a Wolf engine of the tandem type rated at 60 hp., is as follows:

I

Temperature of saturated steam	190.9C
Temperature of steam entering the high-pressure cylinder	340.0C
Temperature of steam entering the low-pressure cylinder	171.0C
Superheat entering the high-pressure cylinder	151.9C
Superheat entering the low-pressure cylinder	57.9C
Steam consumption at 43.2 b.hp	10.9 lb.

II

Temperature of saturated steam	190.9C
Temperature of steam entering the high-pressure cylinder	360.0C
Temperature of steam entering the low-pressure cylinder	191.0C
Superheat entering the high-pressure cylinder	172.9C
Superheat entering the low-pressure cylinder	71.4C
Steam consumption at 55 b.hp	10.29 lb.

The difference in the two cases is undoubtedly due more to the increased superheat than to the heavier load, as after the half-load point has been reached the consumption is nearly constant. Like the locomotive, the greater part of the evaporation takes place at the firebox, but averages about 4 lb. per sq.ft. for the total heating surface. This type of boiler has two other strong points in its favor—there is no chance of leaky brickwork, and the end plates and tubes being removable for cleaning purposes, all parts are easily examined and kept in order.

The question now arises as to whether like results could not be obtained on well-designed existing engines by introducing a reheater between the high- and low-pressure cylinders and carefully lagging them, assuming that the gain in efficiency would warrant the expenditure.

Hill-Tripp Centrifugal Pump

The Hill-Tripp Pump Co., of Anderson, Ind., has recently placed on the market a centrifugal pump designed for a number of uses. One- to six-stage pumps are made with capacities ranging from 10 to 20,000 gal. per min., and these pumps are designed to pump against heads of from 10 to 1000 ft. The double-suction single-stage pump is designed for a maximum head of 300 ft. and multistage pumps for heads up to 700 ft. For higher pressures an extra heavy multistage pump is built.

The special feature of these pumps is the impeller, with sides extending a certain distance beyond the vanes, as shown in Fig. 1. The passage formed between the two sides beyond the vanes is flared out, increasing gradually to larger area. In all centrifugal pumps the water leaves the vanes in a tangential direction and at practically the circumferential velocity of the wheel at the extremity of the vanes. This being the case, the relative velocity between the extended sides of the impeller and the water is low and, as a consequence, there is little friction. The shape of the extended sides of the impeller is much the same as the secondary part of a venturi tube, with the added advantage that the tube travels with the water. Owing to the design the velocity head of the water is transformed into pressure before the water leaves the impeller, and as it passes out into the casing the movement of the water is slower than in the suction or discharge pipes. The loss occasioned by stationary vanes is obviated and, consequently, an efficiency as high as 72 per cent. is claimed for these pumps.

As indicated in the drawing at the left of Fig. 1, single-stage pumps have a newly patented balancing device consisting of a central rib in the pump casing, which will deflect the water discharged by the impeller in such a way as to cause increasing or decreasing pressure in the two sides of the casing. If the impeller should move to the left the pressure would increase on the same side and force the impeller in the opposite direction, or *vice versa*. In other words, the pressure against the two sides of the impeller must balance and hold the rotating element in a central position.

For the multistage pump a hydraulic device has been adopted of the general type commonly employed by builders of multistage pumps, with the exception that the present arrangement is double-acting. As shown in Fig. 2, a piston with a renewable ring is secured to the shaft and rotates with the impeller. A pressure chamber is located between this rotating piston and a stationary part, also provided with a renewable ring opposing the ring on the piston. Through a running clearance between the stationary part and a covered sleeve on the shaft, water from the high-pressure end of the pump gradually finds its way into the balancing chamber.

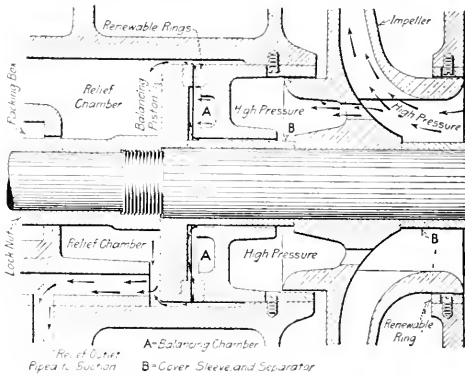

Fig. 2. Details of Balancing Device

Eventually, the pressure in this chamber builds up enough to force the rotating piston away from the stationary element. In this way a circular passage is opened up between the rings, and water flows from the balance chamber to the relief chamber behind the piston. The relief chamber is connected with the suction of the pump, as indicated in the drawing. As the water escapes between the rings the pressure in the balance chamber is reduced until a balance is established. A thin film of water is maintained between the rings, and the rotating parts float continuously at a certain distance from the stationary element. The balancing chamber is made large enough to care for large differences in pressure, which in high-lift pumps may amount to several

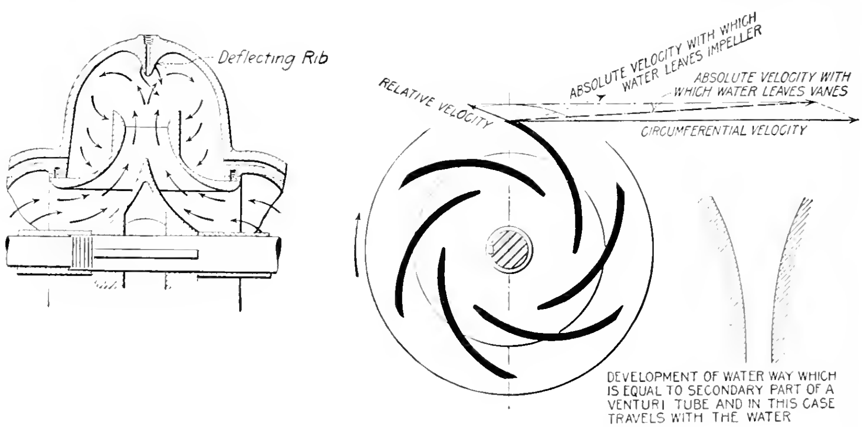

Fig. 1. Showing Special Features of Impeller Design

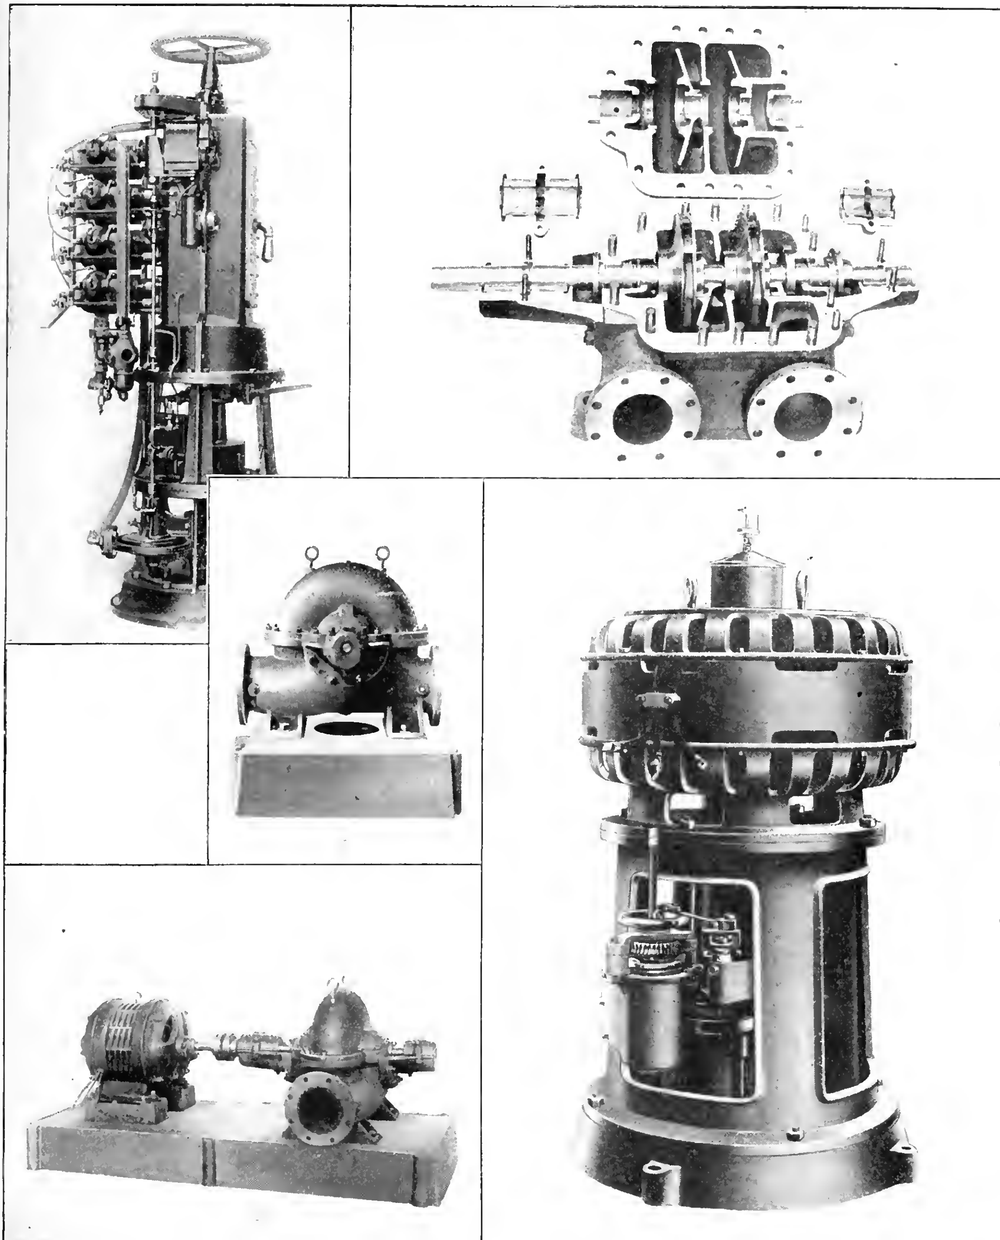

Figs. 3 to 7. Showing Various Applications of the Pump to Deep-Well Head, High-Lift Centrifugal Pump, and Vertical Discharge Head, Motor Driven

tons. It has been found desirable to make this provision in spite of the fact that each impeller is itself hydraulically balanced independently of the balancing system.

Should the piston have a tendency to move too much toward the relief chamber, it will approach the outlet to the suction of the pump and automatically reduce the amount of water escaping. The pressure in the relief chamber will then build up and force the piston in the opposite direction, relieving the outlet and again establishing a balance.

Figs. 3 to 7 show a variety of applications of the pump. Fig. 3 is a deep-well pump head equipped with a four-cylinder high-speed oil engine, fitted with an automatic cutoff for control in case the pump loses its suction or the load is dropped for any reason. Fig. 4 shows a standard multistage high-lift centrifugal pump with the upper half of the casing removed. The construction of the impeller and the balancing and relief chambers is clearly shown in this view. Fig. 5 is a side view of the double-suction impeller split-case centrifugal pump, and Fig. 6 shows the same pump directly driven by an electric motor. Fig. 7 shows a vertical discharge head equipped with a motor for driving and a hard oil pressure pump.

The Government as a Buyer of Power

By A. P. Connor

Some of the conditions of the contract under which the United States Government buys electric current within the District of Columbia are given herewith.

Schedule No. 1 provides that for a monthly current consumption up to 3200 kw.-hr. the rate shall be 6c. per kw.-hr.; up to 4545 kw.-hr., 5½c.; 7500 kw.-hr., 5c.; 12,500 kw.-hr., 4½c.; all current in excess of 12,500 kw.-hr. per month, 3c. But separate buildings (not connected by a covered passageway) must be metered separately, so that the total current used in a group of detached buildings occupied by one department might entitle that department to the minimum rate, yet by the separate metering process the maximum rate would be collected. Schedule 4 is a work of art, as will be seen by careful reading.

SCHEDULE NO. 4—FOR BUILDINGS WHERE PRIVATE GENERATING PLANTS ARE NOW INSTALLED

For electricity used during months from April to September, inclusive, $0.025 per kw.-hr.

This service to be entirely optional with the Government, and will become operative only upon the written request or authority of the particular department or governmental establishment desiring it, and it will be furnished only during the period from Apr. 1 to Sept. 30, inclusive, or for such portion thereof as the service may be required; in cases where service is furnished under Schedule No. 4, during the period from July 1 to Sept. 30, inclusive, or any part thereof, and where any service is required from the contracting company at any time during the period from Oct. 1 to Mar. 31, inclusive, the charges for the service furnished during the period from Oct. 1 to Mar. 31 shall be in accordance with Schedule No. 1, 2, 3 or 5, as may be applicable and selected by the Government, and the charges for the service furnished during the period from July 1 to Sept. 30 shall be adjusted to conform to the rates of charge in force during the period from Oct. 1 to Mar. 31, or any portion thereof, and the contracting company shall be paid the full amount of the difference. Schedule No. 4 is not to be available during the period from Apr. 1 to June 30, inclusive, for buildings where any service has been required during the period from Oct. 1 to Mar. 31, inclusive.

By the terms of this schedule, suppose during the six summer months current to the moderate total of $2500 had been used at the 2½c. rate, and that during the winter for a short period (a single day) it became necessary to obtain current from the electric service company, the only such contractor in the field, the answer according to the schedule would be: "Yes, we will furnish you the current (service lines already in) for 6c. per kw.-hr. provided you pay a penalty of $3500 for having taken current from us during the summer (which we were glad to sell at that time of the year) at 2½c. per kw.-hr."

It seems beyond the belief of a reasonable person that such rates have been approved by the Government. This is probably the most flagrant case of a contract unfavorable to the Government that can be found, and since it has existed for a long period there is reason to believe that it may be continued for many years.

Is it advisable for the engineer of a department to accept and insist on the 2½c. rate (after the apparently sincere advice of an official close up to the Secretary not to attempt to save money for the Government at the risk of his personal welfare and possibly his position), or should he permit the handing over of more than double the money for the service during the summer in order to avoid the personal risk? If he succeeds in the saving, what is there to it for him except "art for art's sake?" If he fails to get through the winter without a holdup, what then? Perhaps a little light obtained in a court proceeding in a test case in which the subject matter was the rate and the apparently piratical charge for back service, would clear up the situation. It has been established beyond a doubt that 2c. a kilowatt-hour is a familiar rate of the same utility for current in buildings in the immediate vicinity of Federal buildings. The rates which the same utility charges other parties is a matter of record with the Public Utility Commission of the District of Columbia (and easily obtainable), and under the control of the Government.

The time of the day in which the greater part of the current is used by the Federal departments is certainly favorable to a central station carrying a substantial commercial and street-railway load, and in this case the utility has one of its power stations located most centrally with respect to the governmental buildings and departments.

The State Department recently rented a certain hotel building and by means of a few feet of conduit and rewiring, it was possible to get power (electrically) from the plant of the State, War and Navy Building at a cost of about $30 a month, but the Comptroller of the Treasury decided that there was no authority of law for extending the government service or system to a "private building," although the hotel was used by the department for office purposes. The current bought from the Potomac Electric Power Co. will cost about $100 a month.

It is gratifying to learn that the project to erect a central power station by the Government which has so long met with steady opposition from certain quarters is progressing and the initial bids will soon be opened. The hydro-electric project to utilize the enormous water-power possibilities of the Potomac River in the District of Columbia does not progress. The curious might ask, "Why are these things thus?"

Correctly Designed Steam Lines skillfully erected are no more likely to fail and interrupt the service than other features, not duplicated. It is a matter of common experience that the hydraulic piping in a plant causes less trouble than the low-pressure house-service piping, because of the difference in installation. The same is applicable to steam piping.

A Sulzer Diesel Engine, built for Messrs. Harland & Wolff, for generating electricity in that firm's shop at Belfast, is said to be the largest Diesel yet constructed to a definite order. It is of the two-stroke cycle, single-acting type with six cylinders, and was designed to develop 3750 b.hp. at 142 r.p.m., though on trials 4500 b.hp., or about 750 b.hp. per cylinder, was maintained for a long period. The cylinder dimensions are approximately 30 in. bore by 40 in. stroke.—"Gas and Oil Power."

Chimneys for Oil- and Coal-Burning Plants

By F. H. Rosencrants

SYNOPSIS—Available data on chimney design relate almost solely to coal-burning plants, while little is applicable to oil burning. For given conditions a much smaller chimney is required for oil.

That a difference exists in the requirements in stack dimensions for a plant burning coal and for one burning oil is generally understood. Most available data on draft requirements and stack dimensions are applicable to coal-burning plants, so the designer of an oil-burning plant must rely upon his experience and judgment and on the meager amount of serviceable information in designing this important part of the plant. The most comprehensive treatment of stacks for oil-burning plants that the writer knows of is that written by C. R. Weymouth, presented before the American Society of Mechanical Engineers and published in bulletin form by Chas. C. Moore & Co., of San Francisco, Calif.

In a coal-burning plant it is important that the draft shall be sufficient to burn the maximum desirable amount of coal per unit of time per unit area of grate. Draft in excess of this merely provides additional overload capacity which may or may not be desirable. The objectionable feature to excessive draft in a coal-burning plant is the interest and depreciation charges for the increased cost of the stack to produce the excess of draft. However, engineers are more afraid of a deficiency than of an excess, and formulas deduced are usually liberal.

In a coal-burning plant the rate at which the boiler is steaming will demand a certain rate of combustion which requires a proportionate increase in draft. Therefore, the dampers will demand the required amount of attention from the attendant.

In an oil-burning plant the rate of steaming demands the combustion of oil at a certain rate, but this is dependent upon the position of the oil-control valve and not upon the existing draft. The boiler might be operated from no load to full load with the same damper setting, provided that setting would furnish the required amount of air for the maximum load. So at all loads below the maximum there would be an excess of air, and the smaller the load the greater the excess and consequent decrease in boiler efficiency. This condition would be accompanied by a smokeless stack and a careless or ignorant fireman might be led to think that he was running the plant economically. The trained fireman of an oil plant knows that a faint haze at the top of the stack is desirable, as that tells him that if he admits less air the stack will smoke and if more the stack will be clear and an unknown amount of excess air entering the furnace.

If the possible draft of a stack for oil burning is in excess of that required to produce the maximum desirable load, it has the double disadvantage of possible large excesses of air and of possible overloads on the boiler which might be destructive to the settings. In addition to this, there is the same disadvantage that exists with coal-burning plants, namely, the interest and depreciation charges on the cost of the excess stack capacity.

Comparative Cross-Sectional Areas of Stacks

Assuming the same velocity of the gases up the chimney for oil as for coal stacks, the former need be much smaller in cross-section than the latter for the same capacity.

Assuming an excess of air of 50 per cent., the weight of flue gases per pound of oil will be about 22 lb. Assuming a heating value of 19,000 B.t.u. per pound and a boiler efficiency of 75 per cent., the weight of flue gases per 1000 effective B.t.u. will be

$$\frac{22}{19{,}000 \times 0.75} \times 1000 = 1.544 \textit{ lb.}$$

Assuming values for coal which are attainable with the same amount of skill as those quoted for oil, we have, allowing 100 per cent. excess air, 25 lb. of flue gases per pound of coal; 12,500 B.t.u. heating value per pound; and a boiler efficiency of 70 per cent. Using these figures, the weight of gases per 1000 effective B.t.u. becomes

$$\frac{25}{12{,}500 \times 0.70} \times 1000 = 2.857 \textit{ lb.}$$

It follows from the preceding calculations that, assuming the same rate of steaming in both cases, the amount of gas which will pass up the oil-burning stack will be only $1.544 \div 2.857 = 0.541$ as much as that which passes up the coal-burning stack, therefore an oil-burning stack for a given capacity need be only about 0.54 as large in cross-section as a coal-burning stack.

Comparative Heights

It is impossible to give any hard and fast rule for the height of a coal- or oil-burning stack, as so much depends upon variable factors, such as altitude, length of breeching, character of fuel, rate of combustion, etc. However, it can be conclusively shown that in any and all cases the height of an oil-burning stack will be much less for the same set of conditions than that of one burning coal.

The draft in any case must overcome the resistance of (1) the furnace, (2) the passes of the boiler, (3) the damper box, (4) the breeching including its turns, and (5) the stack itself.

Comparing the oil-burning with the coal-burning plant with reference to the first, it is evident that the furnace resistance of the former is much less than the latter. Due to the injector action of the oil burner, the furnace resistance in the case of oil burning often is negative; i.e., the injector action of the burner produces a slight pressure. The furnace resistance when burning coal varies with the character of the fuel and the variation in thickness of fuel bed and with the rate of combustion. With average bituminous coal and a rate of combustion of 20 lb. of coal per square foot of grate per hour, the furnace resistance amounts to about one-quarter inch of water.

With reference to the second element of draft, the oil-burning plant again has the advantage. As shown, the weight of gases for oil as compared with those for coal for the same rate of steaming is a little over one-half as much; so the velocity of the gases through the boiler is a little over one-half as great. Since the resistance to the flow of fluids varies with the square of the velocity, the boiler resistance for oil burning will be not over one-third of that for coal.

The resistance of the breeching and stack will, of course, depend upon the velocity of the gases through them, but assuming the velocity to be the same in the two cases, the resistances would also be equal, or nearly so.

It is evident from the above that the draft requirement for burning coal is in excess of that required for oil and since the draft of a stack varies with the square-root of its height, the height of a stack for burning coal is much greater than that for burning oil. It will nearly always be twice as high or more for the same rate of steaming.

It might be suggested that an oil-burning boiler could be operated at a higher rate of evaporation per square foot of heating surface than is usual for coal, since the weight of gases is so much less for the same rate. It has been found in many tests that the efficiency is improved when so operated, but the temperature produced in the furnace is destructive to the setting and this disadvantage more than offsets the slight gain in efficiency.

It would seem that, inasmuch as the factors affecting draft resistance in oil burning are so much less variable than with coal, the problem of stack design could be made exact, which is desirable.

Graphic Representations of Power-Plant Losses

By E. D. Dreyfus

SYNOPSIS—By means of a set of charts the operator is apprised directly of the approximate loss incurred, in dollars and cents, through failure to maintain the prescribed conditions.

The large central power plant usually employs a small army of operatives. Those who supervise are generally conversant with the technical requirements necessary for the highest efficiencies, but the force as a whole does not appreciate the significance of the different engineering factors involved; although from a strictly mechanical and operating viewpoint, the men may be capable and trustworthy. Taking cognizance of this, the West Penn Traction Co., of Pittsburgh, set about to devise a remedy by displaying graphically the necessity for observing conditions that have been found to produce the most efficient results. The accompanying charts show the attempts made to fasten the attention of the power-plant employee upon the enormous losses that accumulate during the year when the best working conditions are not maintained.

The object in Fig. 1 is to impress upon the firemen the importance of a high CO_2 percentage. First, it is assumed that an instrument has been installed which will give a direct reading of the CO_2 in the flue gas. Then the "burette" of the CO_2 apparatus is reproduced on the chart, with a simple scale. A standard rule is drawn opposite, with a dollar and cents scale substituted for the customary inch and fractions. The normal, or standard, percentage has been taken at 15 per cent., although a slightly lower rate may prove best in practice. Since this represents the most economical working condition, it is made to correspond to the line of zero waste, or avoidable losses. The rise of the liquid in the "burette" (imaginary, of course, while considering the chart) will be read on the "measuring stick" as indicating greater and greater unnecessary losses.

Owing to the losses in dollars and cents increasing (inversely) more rapidly than the changes in CO_2 percentage, the measurements cannot be taken on the horizontal line since plain scales are used in both cases. Hence, slanting lines are drawn to connect corresponding values.

The charts are constructed upon a simple basis. A fair estimate of the coal to be consumed during the coming year under favorable operating conditions is the foundation upon which rests all the percentages for the different operating factors. Each case is treated independently to avoid complication, although to have dealt with these factors in a cumulative manner would be the technically correct way.

Each plant must, of course, be individually considered when arriving at the percentages in any case, and the figures in the charts are merely indicative of the method.

In view of the quality of the coal and the flue temperatures, the following CO_2 percentages were determined upon:

CO_2 Percentages	Percentage Loss in Fuel	CO_2 Percentages	Percentage Loss in Fuel
15	0.000	9	7.580
14	0.808	8	9.660
13	1.750	7	13.020
12	2.840	6	16.320
11	4.130	5	21.650
10	5.690		

Coming to Fig. 2, giving the losses for operating prime movers at less than normal rated capacity (usually the economical point), it is presupposed that there are a number of units installed which may be cut in and out to conform to the load, so as to maintain a high load factor on the individual machines. Unless a separate chart is provided for each unit, a single one must necessarily be of a compromise character in view of the different sizes and types. Such a compromise curve must be employed with discretion.

Fig. 3, for feed-water temperatures, is similar to Fig. 1, but the losses have been represented by heavy black columns intended to display proportionate waste of coal, each block having its money value indicated. This variation was introduced to ascertain if the one arrangement would possess more force and effect than the other.

In condensing-turbine stations the importance of high vacuums is now fully appreciated. In this case the compromise chart of Fig. 4 was arranged. Other charts may be made if further refinements are carried out in the station.

The power-plant operator has not the same direct appeal to the personal interests of his men as is possible in

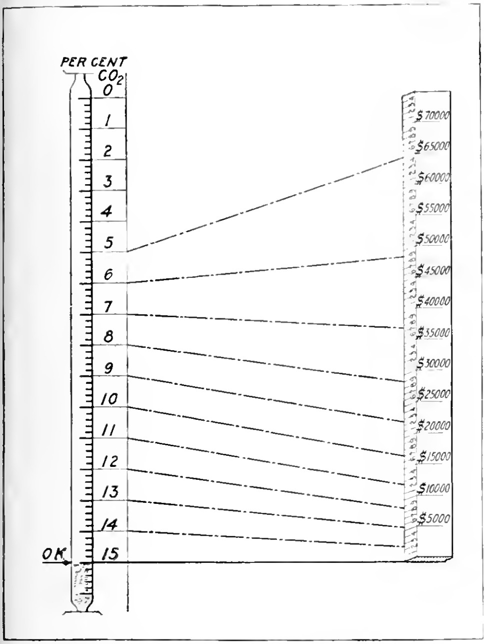

Fig. 1. Chart for CO_2, Showing Money Lost in Wasted Coal through Careless Firing

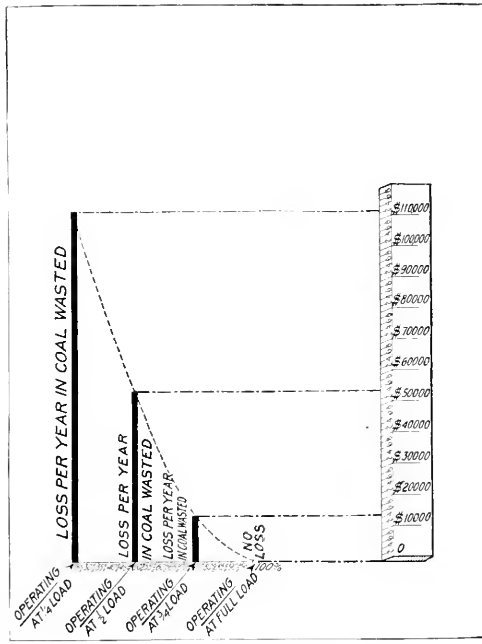

Fig. 2. Chart Showing Money Loss Due to Operating Turbines at Partial Load

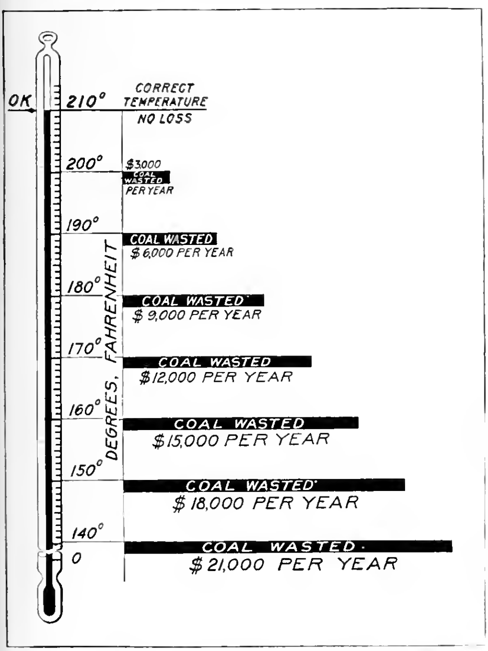

Fig. 3. Money Loss Due to Low Feed-Water Temperatures

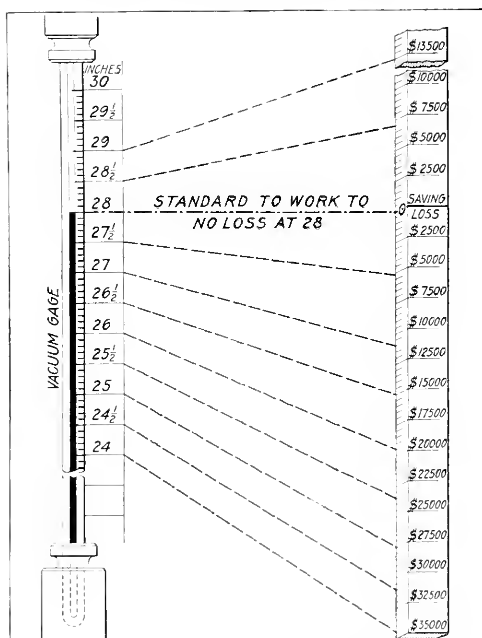

Fig. 4. Vacuum Chart, Showing Money Loss per Year for Variations below 28 In.

some other lines, but the security of the employee's position and, accordingly, his source of livelihood are inseparably linked with the best interest of the owner and his inherent value is gaged in proportion to what he accomplishes compared with the best practicable results obtainable within his sphere of duties.

Interior Wiring for Lighting and Power Service—II

By A. L. Cook

SYNOPSIS—Branch circuits and feeders, insulation, wire sizes, fuses, panel-boards, switches, etc. The first article of the series (May 4 issue) covered voltages and systems employed, the "National Electric Code," the types, number and spacing of lamps, and the determination of the lighting load.

When the size and location of the units have been settled the branch circuits can be arranged. The "National Electric Code" specifies that a branch circuit which is dependent upon a cutout shall not carry more than 660 watts or have more than 16 sockets and receptacles, except by special permission in cases where No. 14 wire can be carried directly into keyless sockets. Under these conditions, 1320 watts and 32 sockets may be used. The arrangement of these branch circuits should be such that the lamps on one branch are grouped as closely as possible. The lamps near the windows should be controlled separately. It is also best to so plan the branch circuits that the wires will not have to cross heavy beams or girders. Details regarding various arrangements of branch circuits will be taken up later.

Incandescent lamps are so sensitive to changes of voltage that it is necessary to maintain a steady and as nearly as possible constant voltage on them, irrespective of the load on the system. The tungsten lamp, however, is not as sensitive as a carbon lamp: for a difference of 1 per cent. in voltage the 12-volt tungsten lamp changes 3.6 per cent. in candlepower, while for a carbon lamp the change is

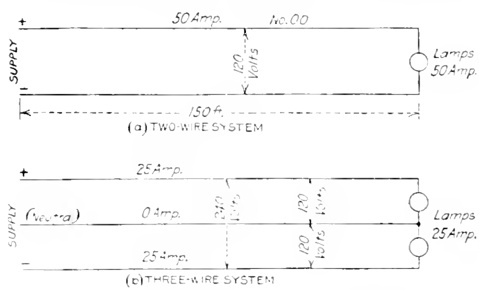

FIG. 3. TWO- AND THREE-WIRE SYSTEMS

5.6 per cent. Because of this effect, lighting circuits should not be supplied from motor circuits, but should be run independently. The voltage drop in a lighting system carrying full load should not exceed the following: Branches, 1.5 per cent.; mains, 0.7; feeders, 1.3; total, 3.5 per cent. When there are no mains, the drop allowed for the mains is included in the feeder drop.

Lamps used for indoor lighting should always be operated in multiple, as a series system with arc or incandescent lamps is not desirable, because of the high voltage necessary and lack of flexibility. Even the operation of 120- or 240-volt lamps in series on a 550-volt system is not good practice except in special cases, such as railway power houses or car barns. Because of the limitations of the incandescent lamp the lighting system must employ about 120 or 240 volts, the former being preferable.

The systems of distribution include two-wire and three-wire circuits, either direct or alternating current, and

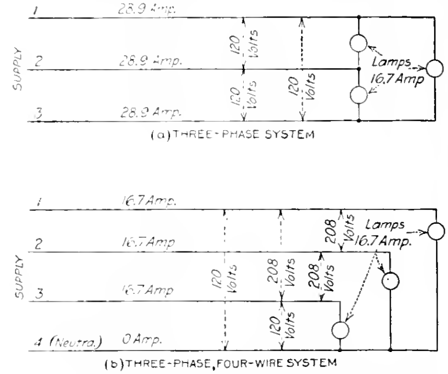

FIG. 4. CURRENT AND VOLTAGE RELATIONS IN THREE-PHASE SYSTEM

three-phase or two-phase. The branch circuits are generally two-wire and will be so considered in the present discussion. The feeders and mains, however, may be arranged on any of the systems mentioned. The two-wire is the simplest, but the voltage is limited to that of the lamps, which cannot exceed 240. When it is remembered that by doubling the voltage, only one-fourth as much copper is required for a given percentage drop, the advantage of using as high a voltage as possible is apparent. On the other hand, the use of 240 volts on lamp circuits increases the cost of maintenance, and the efficiency of the lamps is lower, so that 120 volts is more satisfactory. By means of the three-wire system, with 120 volts between each outside wire and the neutral and 240 between the outside wires, 120-volt lamps may be used; but the power will be transmitted at 240 volts and the copper required will be three-eighths that required for a two-wire 120-volt system. The amount of copper would, of course, be greater than if a 240-volt two-wire system were used, as this would take one-quarter of that necessary for a 120-volt two-wire system. The advantages in the use of 120-volt lamps will, however, generally justify the extra cost of the three-wire system. Fig. 3 represents a two-wire and a three-wire feeder system carrying a load of 50 amp. at 120 volts. One-half of the lamps would be connected across each side of the three-wire circuit.

The three-phase system is sometimes used for lighting, three wires being used, with the same voltage between any two; see Fig. 4. The lamps are divided equally between the three phases. Sometimes a fourth wire, called a neutral, is provided, as shown at *b*. In the arrangement shown at *a*, the copper required is three-fourths that for the two-wire system shown in Fig. 3-*a*, and in the four-wire, three-phase system the copper is one-third that necessary for the two-wire.

The two-phase system is illustrated in Fig. 5. The lamps are distributed equally across the two phases, and it will be seen that the arrangement is the same as two single-phase circuits. There is no electrical connection between the two phases, and consequently no voltage between them. The copper required is the same as for the two-wire system in Fig. 3-*a*. Frequently, two of the wires are combined, as shown at *b*. The copper required for this arrangement is 0.73 times that for the two-wire system. Further details of these systems will be taken up when the method of calculating the circuits is discussed.

Conduits

In the majority of installations rigid, unlined iron conduit is desirable, although the first cost is greater than where the wires are run exposed. The greater freedom from damage to the circuits and the improvement in the appearance of the wiring will generally justify its use. In factory wiring, it is sometimes better to run the feeders exposed, using iron conduits for the mains and branches, particularly in an extensive plant where the feeders can be so located that they are not likely to suffer damage. The conduits must be large enough to allow the wires to be pulled in after the conduits are in place without damaging the insulation. The size depends, therefore, upon the number of bends. The "Code" requires that the maximum number of bends shall not exceed the equivalent of four right-angle bends, and if more are necessary a pull-box must be inserted in the run so that the wire may be pulled in sections. It is desirable to make the radius of the bends as great as is consistent with other limitations. The stock bends, which can be purchased from the conduit manufacturers, can be used, except in special cases, where a longer-radius bend is desirable. The ordinary iron conduit consists of soft-steel pipe made

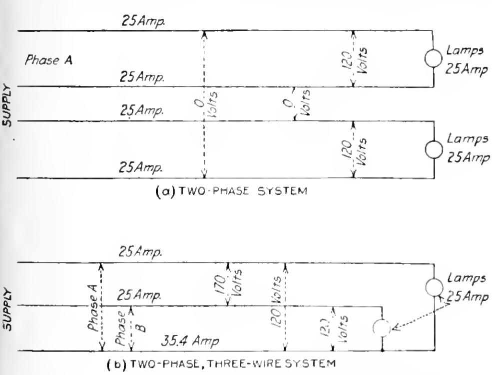

FIG. 5. CURRENT AND VOLTAGE RELATIONS IN TWO-PHASE SYSTEM

in standard-weight iron-pipe sizes and threaded the same. It has a heavy, smooth coating of enamel on the inside to facilitate pulling in the wire and is either enameled or galvanized on the outside. The galvanized conduit is more desirable where it is to be painted after installation, and it can also be more easily grounded as required by the "Code."

In Table 6 are given conduit sizes for various sizes of wires, covering most of the conditions met in practice and suitable for fairly long runs. For longer runs, if the number of bends is decreased, the same sizes may be used; for shorter runs, the size may in some cases be reduced. An approximate rule is to choose such a size that the wires will just be contained inside a circle three-quarters the outside diameter of the conduit. For alternating-current work all the wires of a circuit must be contained in the same conduit. This is required by the "Code," because if run in separate iron conduits there would be excessive

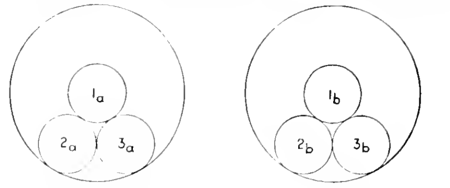

FIG. 6. ILLUSTRATING WIRES IN CONDUIT

heating of the conduits and a greatly increased drop due to the alternating magnetic field produced by the current flowing in the wire. This effect will be greater the larger the current, but even for the smallest wires the rule should be followed. If the conduits are of brass, fiber or tile, the wires can be safely separated in different ones, but even then the drop is so great that it is generally better to combine the circuit in one conduit. If the current is so great as to require more than one wire for each lead of the circuit, and it is not feasible to put them all in one conduit, the leads should be divided into two or more groups, each containing all the poles of the circuit. The proper arrangement for a three-phase circuit is shown in Fig. 6, where the leads of the three phases are 1, 2 and 3 respectively, 1-*a* and 1-*b* being of the same polarity. This rule applies for all types of alternating-current systems except the two-phase four-wire, which is practically the same as two single-phase circuits, and phases *A* and *B* may be run in separate conduits. For direct-current circuits it is satisfactory to employ separate conduits for each wire, if of large size, unless there is probability of a change being made to alternating current.

TABLE 6—SIZES OF UNLINED IRON CONDUIT FOR 600 VOLT N. E. C. STANDARD RUBBER WIRES

Size of Wire	Number of Wires in One Conduit			
	One	Two	Three	Four
14*	½ in.	½ in.	¾ in.	¾ in.

14 duplex*	......	½ in.	......	......
12 duplex*	......	½ in.	......	......
10 duplex*	......	¾ in.	......	......

Based on runs not over 100 ft. long and not over four standard bends.

*These sizes are solid; all other sizes are stranded.

Exposed wiring may be run on porcelain cleats, or insulators, the spacing being as follows:

Voltage	Distance from Surface	Distance between Wires
0—300	½ in.	2½ in.
301—550	1 in.	4 in.

For wires not less than No. 8 B. & S. gage in locations where they will not be disturbed, the spacing may be made 6 in. and the wires run from beam to beam, without breaking around. By this means, feeders and mains may be run in a direct line the entire length of a building and supported by the beams or roof trusses. This results in minimum cost and makes a very satisfactory arrangement.

Insulation

Wire for interior work may have two kinds of insulation—rubber or weatherproof—depending upon the method of running the wires. Rubber wire must be used if installed in conduit, but for exposed or so-called cleat wiring, a cheaper insulation is allowed. The rubber insulation used in most installations is called "Code" wire and is manufactured in accordance with very rigid rules contained in the "National Electric Code." Every coil must bear the stamp of the inspection department of the Board of Fire Underwriters, so there is no difficulty in identifying such wire. Sometimes, for important installations, a quality of rubber insulation which is better than "Code" wire is used, and its greater cost is often justified by the resulting reduction in breakdowns on the system. Public buildings, railway stations, office buildings, and sometimes industrial plants can afford to use this better quality for greater insurance against interruptions to the service. No insulation poorer than "Code" wire should ever be used, even if the work is not inspected by insurance representatives.

The insulation used for exposed work consists of two braided-cotton coverings over the copper conductor, the inside covering being impregnated with a weatherproof compound, and the outside one filled with a fireproof compound. This is called "slow-burning weatherproof" wire. Sometimes another type, called "slow-burning," is used, this being similar to the other except that the entire insulation is fireproof. This is satisfactory for dry places where the wires are run exposed on insulators.

In Table 7 are given the safe carrying capacities for various sizes of wire used for interior work as specified in the "National Electric Code." Column A gives values for rubber and column B for "slow-burning weatherproof" and for "slow-burning." It will be noticed that for rubber wire the current allowed is less than for the other insulation, because it is necessary to keep the rubber-covered wires at a lower temperature to prevent damage to the insulation. The currents specified for rubber insulation will cause the wire to run at about 29 deg. F. above the surrounding air.

The "Code" makes no distinction in carrying capacity between alternating and direct current. For alternating currents, especially at 60 cycles, there is a greater drop, particularly for large wires. Even with 500,000-circ.mil cables, the resistance is 2½ per cent. greater and for 1,000,000 circ.mil it is about 11 per cent. greater. This would result in the wires running somewhat hotter when carrying alternating current.

Fuses and Circuit-Breakers

All wiring must be protected by fuses or circuit-breakers in such a manner that the circuit will be opened if the rated current is exceeded. The size of the fuse must not exceed the carrying capacity of wire as given in Table 7. For example, a No. 1 wire, if rubber covered, would be protected by a 100-amp. fuse, and if "slow-burning weatherproof," would have a 150-amp. fuse. When circuit-breakers are employed without fuses, they must not be set more than 30 per cent. above the rating of the wire as given in the table. The excess current which the fuses will carry continuously is about 10 per cent. for inclosed and 25 per cent. for link fuses, which allows small overloads without interrupting the service. The rating in Table 7 is based only on the safe current-carrying capacity of the wires, and should not be exceeded; but it takes no account of the drop in the wires. In many cases, the length of the run is so great that the drop with the rated current would be excessive, in which event a larger wire must be used.

TABLE 7—CURRENT-CARRYING CAPACITY OF WIRES FOR 600-VOLT INSULATION, N. E. C. STANDARD FOR INTERIOR WIRING

Size, Circ. Mils	Size, B. & S. Gage	Rubber Insulation, Amperes A	Other Insulations, Amperes B
1,624	18*	3	5
2,583	16*	6	10
4,107	14	15	20
6,530	12	20	25
10,380	10	25	30
16,510	8	35	50
26,250	6	50	70
33,100	5	55	80
41,740	4	70	90
52,630	3	80	100
66,370	2	90	125
83,690	1	100	150
105,500	0	125	200
133,100	00	150	225
167,800	000	175	275
211,600	0000	225	325
300,000		275	400
400,000		325	500
500,000		400	600
600,000		450	680
700,000		500	760
800,000		550	840
900,000		600	920
1,000,000		650	1000
1,100,000		690	1080
1,200,000		730	1150
1,300,000		770	1220
1,400,000		810	1290
1,500,000		850	1360
1,600,000		890	1430
1,700,000		930	1490
1,800,000		970	1550
1,900,000		1010	1610
2,000,000		1050	1670

Note—Voltage drop is not considered in the above table.

*Wires smaller than No. 14 B. & S. gage should not be used except for fixture wiring and pendant cords.

In lighting installations of any considerable size, there will be a large number of branch circuits, each provided with the proper fuses. For convenience these are grouped, as far as possible, in a panel-board, containing the necessary branch fuses and in some cases the control switches. For industrial plants, slate panel-boards contained in steel cabinets with steel doors are the most satisfactory. For office buildings, etc., slate panel-boards with steel cabinets set flush with the surface of the wall are generally required. The doors are preferably made of wood to match the trim of the building, although steel doors are sometimes used. While economy demands as few panel-boards as possible, a single board should not contain more than 30 branch circuits. If more must be supplied from the same point, it is better to use a double panel-board with two sets of busbars and two doors. Each branch should contain fuses for protecting the circuit and in many cases a branch switch is also provided. These switches should be placed next the busbars, so that when open, the branch circuit fuses may be replaced without danger of short-circuit or shock. Branch circuit switches are not really necessary, except when used to control the branch circuits. In many industrial establishments, it is best to keep the panel-boards locked and provide switches outside for controlling the lights. This arrangement should also be used in office buildings. For public buildings, such as railway stations, most of the lights are controlled directly from the panel-board switches and in many factories this is done to save the cost of additional switches. The feeders supplying the branch circuits must be run to some central point of supply such as panels on the switchboard. If central-station service is used, it is best to install a regular switchboard except when the number of feeders is small, in which case a panel-board can be used. In every case, a suitable switch disconnecting every wire of a feeder should be provided for each circuit. The largest size of fuse allowed by the "Code" is 600 amp. for voltages up to 250 and 400 amp. for 600-volt circuits. Circuits requiring more current than this have to be protected by circuit-breakers. Lighting circuits are not subject to large overloads, so that the fuses should not blow unless there is a short-circuit. If circuit-breakers are used in place of fuses and are arranged to automatically trip out when closed on an overload, the switch may be omitted. Fuses or circuit-breakers should be large enough to give the full carrying capacity of the wires, in accordance with Table 7, even if the actual load on the feeders is considerably less.

Wiring Accessories

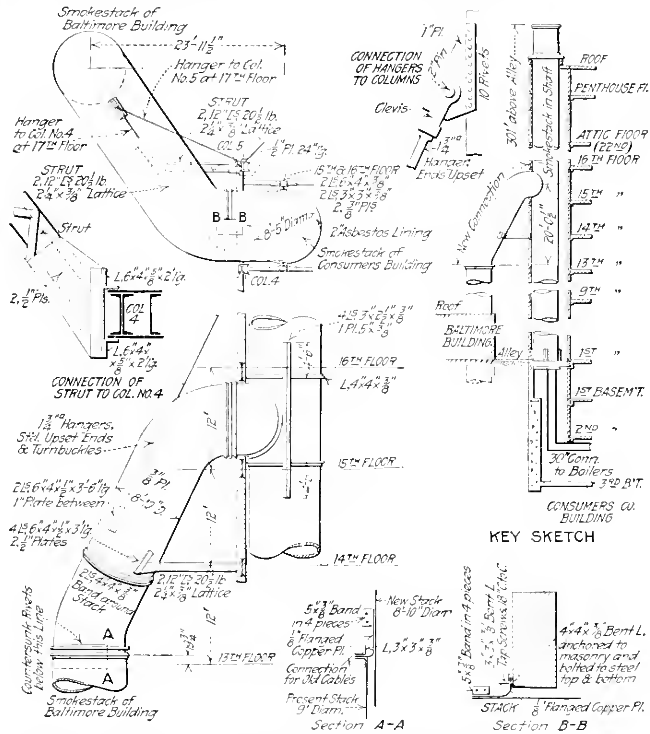
A detailed discussion of the wiring fittings, such as sockets, switches, outlet boxes, and the like, does not properly belong in this article, but a few suggestions may be of value. For exposed conduit work, complete lines of devices such as condulets have been developed to meet almost any requirement, and their use assists greatly in making neat work. For ceiling outlets, where there is no danger of the lamps' being hit, a "T" fitting may be conveniently used, the drop to the lamp consisting of a piece of half-inch conduit. Enameled reflectors are provided complete with sockets, which can be attached directly to this pipe. Glass reflectors require the use of an ordinary keyless socket with a suitable shade holder. Tungsten lamps will operate satisfactorily in this type of fixture, unless there is excessive vibration, in which case it may be necessary to use flexible cord for the drop. For concealed rigid conduit work, the outlets are provided with pressed-steel boxes, which should be galvanized rather than japanned, to assist in grounding the conduit system. Control switches outside the panel-boards may be either of the rotary or push-button variety; the latter is better for offices and the rotary switch, which is somewhat cheaper, is satisfactory for industrial establishments. Nothing smaller than a 10-amp. switch should be used, for the sake of mechanical strength.

Conductivity and Resistance are relative terms. It is customary to divide all material into three groups depending on their relative conductivity: First, metals and their alloys are good conductors; second, electrolytes, so called because they may be decomposed by passing electric current through them, are poor conductors; third, resistance, bad conductors or good insulators consist of such well-known materials as rubber, glass, ebonite, shellac, mica, etc.

Complicated Smoke-Stack Connection

The new 22-story Consumers' Building, State and Quincy St., Chicago, has an 8½-ft. asbestos-lined steel stack in a shaft at the rear of the building. This stack, 301 ft. high above the street, was originally intended to serve a heating plant in the building, but later service was secured from a plant in the Baltimore Building, an older eight-story structure at the rear.

In the basement of the Baltimore Building is one of the heating plants of the Illinois Maintenance Co., which supplies steam for heating throughout the block and also for the Fair, a large building occupying the adjacent



Connection between an Outside Smoke-Stack and an Inside Smoke-Stack at Two Adjacent Buildings in Chicago

block. The smoke flue from this plant extends in the building only to the third floor, where a connection is made to an unlined outside steel stack supported on cantilever brackets. It was realized that with this large power plant it would be impossible to control the smoke to such an extent that it would not be obnoxious to tenants in the higher adjacent Consumers' Building, while it would soon blacken the white glazed terra-cotta facing of the rear of that building. In order to forestall these difficulties the Illinois Maintenance Co. made arrangements to connect its outside stack on the Baltimore Building with the inside stack of the Consumers' Building.

The arrangement and the details are shown in the illustration. As the two stacks are not in line the connection is inclined from north to south as well as from east to west. A special feature of the construction is that the connection (which weighs about 11 tons and extends across the alley) is supported from the framing of the Consumers' Building, so that no part of its weight is carried upon the lower stack. The bottom of the connection simply telescopes into the latter stack, a flashing being arranged in the joint. This allows free expansion and contraction of the stack, while in case of fire and the fall of the walls of the Baltimore Building (a nonfireproof structure) the stack would drop away without affecting the Consumers' Building.

The connection between the two stacks is a shell 8 ft. 10 in. diameter, with an elbow at each end. The bottom elbow enters the top of the shorter stack, and the upper elbow connects to the side of the stack in the Consumers' Building. The weight is carried by $1\frac{3}{4}$-in. hangers with 2-in. pin attachments to brackets on the stack connection and pin plates on the columns of the building, as shown in Fig. 2. The lateral thrust is taken by a pair of horizontal box-lattice struts bearing against the columns of the building at the level of the 14th floor.

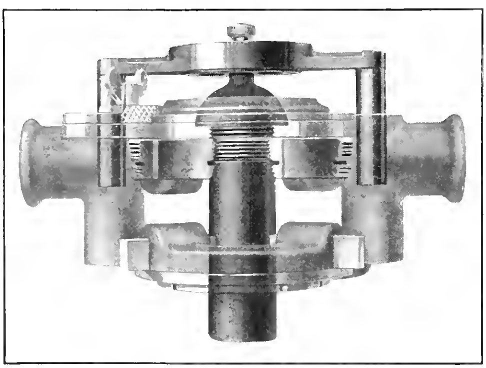
The design for this stack connection was made by Mundie & Jensen, of Chicago, architects for the Consumers' Co. Building. The steelwork was built and erected by the Hansell-Elcock Co., also of Chicago.—*Engineering News.*

Beaver Crossbar Die Stock

The Beaver crossbar die stock, manufactured by the Borden Co., Warren, Ohio, differs from other die stocks in several important features.

A bar extends across the top of the tool, carrying a plug which rests on the end of the pipe. The dies are made in two sections. The lower one does the rough work of starting on the pipe with teeth especially formed for this purpose. The die remains stationary during starting and after the upper section begins to cut this lower die gradually withdraws from the pipe, until it no longer touches, as shown in the illustration.

The upper die is a narrow receding die and constantly opens as the thread is cut, producing a perfect standard



Beaver Crosshead Die Stock

pipe thread. These dies have the further advantage of following the partial threads cut by the first section, which reduces the labor and insures a correct thread pitch without a leader screw.

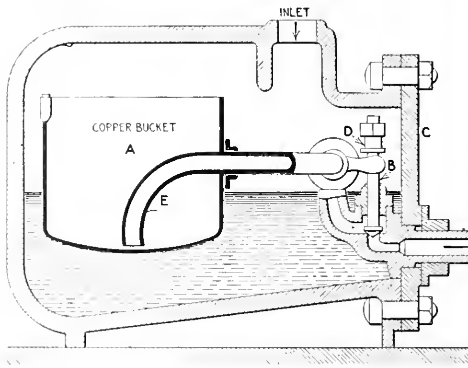
The principle involved is as follows: A swiveled plug extends down between the dies to the bottom of the upper section in starting. The pipe is started and threaded as usual. When the work of the lower stationary die is completed the pipe end comes in contact with the swiveled plug, raising it as the second set of dies cut the thread. Raising the plug lifts the side posts, turns the engaged die cam, and gradually opens the dies at the pipe taper until the thread is completed, when the dies are released; there is no backing off.

The operation of the tool is simple. The dies are set by the handle shown, and the pipe is threaded without the attention of the operator. To cut another thread the crossbar is simply pushed down, which re-positions the tool. The body of the tool is made of practically one piece with wide openings to allow chips to get away and for free oiling facilities.

A universal guide centers all sizes $\frac{1}{4}$- to $1\frac{1}{4}$-in. The tool is regularly furnished with double-ended, reversible dies $\frac{1}{2}$- to $1\frac{1}{4}$-in. Extra $\frac{1}{4}$- by $\frac{3}{8}$-in dies can be furnished, also all sizes of dies, either right- or left-hand.

Dinkel Steam Trap

The Dinkel steam trap, illustrated herewith, employs an open, copper-float bucket *A*, a valve *B* and connections, all of which are inside the trap chamber. The valve is held closed by its own weight and the pressure



Section through the Dinkel Steam Trap

within the trap chamber, and is opened by an increased pressure exerted upon it by the action of the float. As the working parts are attached to the end plate *C*, they are easily removed.

As water fills the trap chamber it raises the float until it strikes against the top of the chamber. As it can go no further the water continues to rise and overflows into the bucket, which, when full, sinks to the bottom of the chamber. This action brings the projection of the lever arm against the thimble *D* on the top of the valve stem and lifts the valve from its seat. The water in the bucket and that above the top of the bucket is then discharged through the connection *E* and through the valve. When the discharge ceases the bucket rises until it floats and the valve closes.

A body of water is always left above the valve seat after each discharge, which prevents the escape of steam.

This trap is manufactured by the Flushovalve Co., 536-538 Broome St., New York City.

Editorials

Government Fuel-Test Reports

The coal that produces the largest net returns per dollar invested is the coal to burn. If the right kind of furnace is not under the boilers to burn the coal used, it is good business to put in that furnace and make all other necessary changes.

All of the various grades of coal mined in the United States must be and will be burned in some way or other, and it is the engineer's part to burn it with the greatest economy, both for the sake of the owner and for coming generations.

To burn coal with maximum efficiency, exhaustive tests have been and are being made by competent engineers under United States Government supervision. By studying their reports one can decide with certainty on the kind of grate and setting to install. To make such tests oneself would be out of the question, because of the expense. Government reports should be studied.

It Is the Little Things

"It is the small details which go toward making perfection; and this last is no small thing." An artist said this when asked why he was taking such care in the representation of a familiar object forming but a minor portion of the work under his hand. What he replied is a truism, something we are inclined to admit in the abstract and prone to forget in the concrete. Perfection, one-hundred per cent. efficiency, is the unattainable; yet that should not and does not usually prevent striving for that goal. But what is it that stands in the way, barring the attainment of perfection? Just a little thing, the small fractions of that last one per cent. between the attainable ninety-nine and the unattainable one-hundred. Small and insignificant in themselves, those figures that represent the gap are the wondrous monument that marks the progress of the world, of science, of engineering, of chemistry. They are the fruit of the toil and the study of the ages. Looking back upon the methods of a few years ago with the searchlight of today, it is difficult to remember that, in their time, those methods formed the apex, that those who strove to surpass them were pioneering in the same way as those who now strive to pass the mark.

Today, as yesterday, all of the works of the world are but aggregations of the small details, their components; and none of them is without significance. And as the great work stands as the monument of its builder, so does each of its components. Each small detail as it lacks perfection contributes to the imperfection of the aggregate, and still more will it detract if, inherently imperfect, its functions have not been properly coördinated with the other components. Just as the weakest link governs the strength of the chain, so is the validity of any structure dependent upon its weakest component. In itself of little account and of small moment, when located at a strategic center it becomes the keystone of the arch. If it fails, then the deluge and the storm, the wreck; and then, sometimes, rebuilding.

All the lessons of the ages are bound up in a few words, easy to remember, easy to forget. But to those who can read their story it is written in letters of flame, "Forget you not of the details, nor of the end thou wouldst attain."

Examination

The safety of life and property demands that only careful, experienced men shall be allowed to operate steam plants.

The temptation to hire cheap help or to give a deserving friend a job is too much for many employers. They welcome an excuse which enables them to send the importuning candidate to some disinterested board or commission, with instructions to get a license or to get placed on a civil-service list.

But how is this disinterested board to find out if the man is qualified?

Most such boards have members who are educated, in the common sense of the word—that is, they have been to school. An examination to them means a written test in which all the candidates are asked a given set of questions on which they are marked like so many school children.

If they stopped to think, they would realize that it is nearly impossible to get up a single examination that will tell a true story of the candidate's fitness. When it is necessary to offer examinations every few weeks, each of which must be different from those which have preceded it, the problem becomes wholly impossible of solution along these lines. The result is that a few questions are thinly disguised and made to answer for a series of examinations. Shrewd men can pick out the few questions and see through the disguises, and armed with the knowledge that there will be little variation, they coach men who are normally unfit, so that they can get licenses. Likewise, it is just as necessary for the men who are fit to take this same coaching in order to pass, for the questions of necessity have little connection with the everyday practice of their trade.

How the essential qualities that make a successful engineer can be truly judged except on the job has always been more or less of a puzzle to us. What a man will write as an answer to a question dealing with a blown-out tube, and what the man will do when confronted with the actual accident, are two different things. It is very much like training soldiers by giving them written examinations. Instead of that, they are drilled until their work becomes automatic and their officers know that as a matter of habit they will obey orders and obey them in the same way every time.

Just so an engineer should be trained so that if he hears the sound of escaping steam in any direction he will unconsciously do the right thing, and do it at once. It is better for him if he understands the reason why and does it intelligently, but as a matter of safety the important thing is that he shall do it without stopping to think.

The question of the competence of the man to produce the maximum amount of service from the minimum of coal is also something that can be told only on the job, and in which he can be trained only on the job. No amount of questioning, nor even of preparation for examination, will add to the power produced per pound of coal, nor will it give much of a line on what the man will do once he gets on the job.

We suggest to the various legislatures which are annually struggling with this problem, that they investigate the means of training engineers in safety and efficiency and then fit their laws to what is possible.

Safeguarding the Bus Room

Close scrutiny of the arrangement of busbar compartments in a number of power stations indicates the desirability of paying more attention to safety features in laying out and operating this important part of the plant. In high-tension installations adequate space is generally conceded to busbar and oil-switch equipment, for the two are closely related and there is economy in copper where short and symmetrical connections are possible between disconnecting devices and busbar sections. It is the good mechanical job that best serves the needs of a high-tension gallery or switch room, and straight, simple runs of wire or copper tubing, combined with what might be called a clean-cut switching arrangement without complications in its apparent relations to the circuits, generating units, transformers and busbars, make one of the best possible designs.

In lower-voltage work it is not uncommon to find the space assigned to switches and busbars cramped in the extreme. Week after week these portions of the equipment stand the demands of service without a "hitch," and then, without an instant's warning, a heavy short-circuit on the distribution system or possibly on some interstation tie line, backed up by the generating capabilities of perhaps half a dozen units, transforms these compartments into a spectacular sample of the lower regions. The manner in which arcs backed by ample generating capacity will at times communicate to neighboring switch cells, accompanied by the carbonization of cable insulation, need not be detailed here, but the initiated appreciate the wisdom of allowing plenty of space in passages around such compartments and of using barriers of substantial thickness in providing accommodations for this sort of equipment. To the casual visitor to a plant the allotment of liberal space to busbar and switch mechanism housed in by concrete or other barrier construction appears almost needless, but when operating emergencies occur plenty of elbow room is invaluable.

Too little attention has been paid in many plants to the lighting of such rooms by permanently installed lamps wired in conduit and controlled from outside the room itself, and often, where permanent lamps are used, the sizes are too small for throwing the necessary light into recesses of cells. Moreover, it is petty economy to install a low-powered unit without a suitable reflector in this part of a station. Switch mechanism is almost always painted black with asphaltic compound, and the point is worth looking into whether it would not pay in some cases to use white enamel paint or a judicious combination of the two, in order to make the adjustable parts and points of lubrication stand out more prominently.

In stations where two or more men are on duty per shift it would not be a bad plan to provide outside the bus room a pilot lamp which will show the presence of anyone within, and in not a few stations too little care is taken in admitting visitors to this part of the building. If there is any place in a station outside the main operating and boiler rooms where first-class lighting, ample space, local telephone service and dual means of exit are desirable, it is the bus room.

The Noise Question

Present-day engineers, machinists and others who work in the midst of noise seem to regard it as a necessary evil. Pump operators who are working beside noisy, nerve-racking metal gears—so clamorous that it is impossible for them to hear spoken words without having them shouted into their ears—should look about for means to reduce the din. These noises can be lessened if not totally eliminated.

It has been demonstrated repeatedly that when harassed by noise the average man cannot concentrate on his work as well as he can in quiet surroundings. Then why not make shop and plant conditions favorable to maximum work and production by cutting out all unnecessary noises?

It is difficult to make workers in offices consider this problem, because there is comparatively little noise in an office. Office men who once worked in noisy places should appreciate the difference and be keen to take advantage of every possible point helpful to the highest economy and maximum production, and at the same time if they wish to do a good turn for humanity they will do all in their power to promote quietness for their subordinates who are now compelled to put up with disagreeable surroundings.

Quietness is a factor of efficiency that is too frequently completely overlooked.

One of the greatest benefits of classroom lecture or lodgeroom study, as against self-education by solitary study, is the spoken word when correctly spoken. In classroom recitation or discussion the free and familiar use of terms becomes a habit, while in study at home the utterance of the same terms may be only at rare intervals if at all. Should occasion arise for comparison, which will "show up" to the best advantage, granting an equal knowledge of the subject matter? Unless words and terms are used with assurance they cannot carry the weight of conviction and will, therefore, serve to defeat the object of their use. A splendid exercise for the lodgeroom is the use of a good pronouncing dictionary, every fellow to take a turn at the definition and pronunciation of words and engineering terms more or less commonly used. Many perfectly good words will go lame and be so disguised by improper accent as to be hardly recognizable.

The prompt adoption by the Ohio Board of Boiler Rules of the Code of Specifications for the design, construction and operation of steam boilers and other pressure vessels is very gratifying. It is hardly believable that either inertia or opposition can long prevent its universal enforcement.

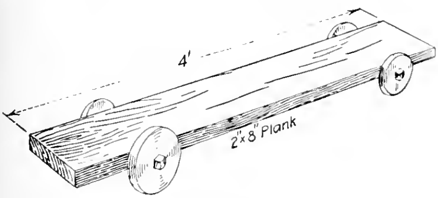
A Handy Car for Inside of Boiler

The illustration shows a handy device for the boiler cleaner or inspector. We used a 2x8-in. oak plank 4 ft. long and beveled the ends on the under side. The wheels used were old worn-out valve disks from a feed



Boiler Cleaner's Car

pump put on with lagscrews about 6 in. from the end, as shown. In this way we have a car that can be propelled to the back end of a boiler in a jiffy and we can come out dry.

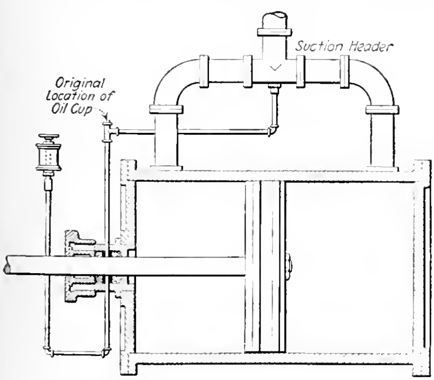
Lubricating Compressor Piston Rod

The stuffing-boxes on two ice machines in a small refrigerating plant gave considerable trouble. Unless three or four times as much oil as is usually needed was supplied, the rods would either run hot or leak and the pack-



Lubricating Ammonia-Compressor Piston Rod

ing would soon wear out. It was difficult to keep engineers for a time after the plant was started, and most of them kept out of trouble with the ammonia rods by using excessive quantities of oil.

Finally, a man came along that stuck to the job. As soon as he was settled he turned his attention to the ammonia rods. The oil-cup connections to the stuffing-boxes struck him as peculiar and not according to the best practice, so he decided to change them.

The sketch shows the oil cup in the changed position and also shows its original location. The machines were of the horizontal double-acting type. In this machine there is usually more or less gas escaping through the connection to the suction line. With the original connection the escaping gas carried much of the oil along with it into the suction line and into the system; in fact, the system was loaded with oil, as was found later. Connecting the oil cups to the under side of the stuffing-box overcame this defect and thereafter a small amount of oil was needed.

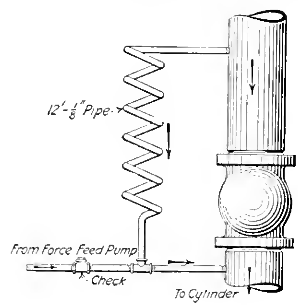
Condensing Coil on Oil Feed

At the request of an oil salesman we experimented with a 1/8-in. copper coil 12 ft. long in connection with the force-feed lubricator, the object being to break up the



Condensing Coil as Connected

oil by the addition of a little moisture. The steam pressure carried was 140 lb. gage, superheated to about 440 deg. F.

The result was so surprising that we think it will interest the readers of Power. With the same amount of oil formerly used the valves appeared to stick. Doubling the quantity of oil took care of that trouble, but the piston became noisy and developed a decided pound at each end after a 12-hr. run, and it was decided the steam-ring springs were too stiff. New springs were put in, but this did not stop the noise.

An examination 12 hours later proved the lubrication was deficient, and there was no vestige left of a glaze on the cylinder wall of six years' standing. The oil atomizer was removed, and the engine again operated with the original amount of oil with the most gratifying results. The question is, what effect does the superheat (80 to 100 deg. F.) have on an emulsion of cylinder oil and water? The oil is a standard high-grade article made from Pennsylvania crude and for superheated steam. The object of the condenser coil was to cut down the amount of oil used or to substitute a lower grade.

Metallic Packing for Valve Stems

About a year ago it became necessary to renew the metallic packing on the Corliss type valve stems of a large pumping engine. To get a tight job with such packing it

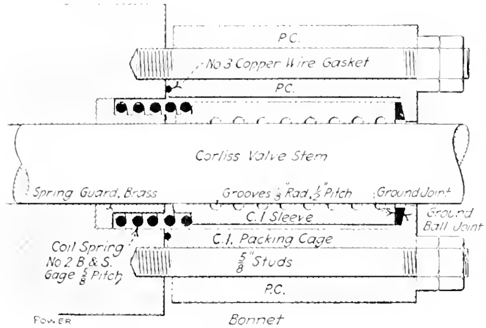

Fig. 1. With Packing Case

is necessary to take great care in truing and grinding the rings and ball washers, and the job is expensive. The superintendent objected and said: "We want something we can make ourselves; it is up to you to dope out a design that is simple, steam-tight and cheap." My first attempt is shown in Fig. 1. I don't pretend to be able to say what happens in the grooves and nozzles, but the steam is so busy chasing itself in and out of the grooves that little finds its way to the end of the sleeve.

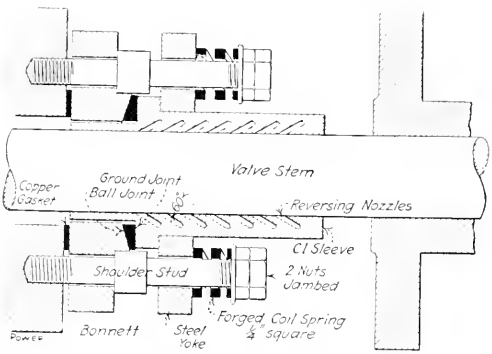

Fig. 2. Modified Form

Fig. 1 is on the exhaust valve stem of a high-pressure cylinder working steam at 200 lb. pressure. It was put in on Feb. 10, 1914, and has run 24 hours every day since and is practically steam-tight.

Fig. 2 does away with the packing case and need not fit the stem so closely. It is best for stems that do not run true. Fig. 3 is now used on the low-pressure exhaust valve stems and is sealed with steam from the low-pressure receiver at 6 lb. gage through the pipe shown, or in other cases this may be used as a drain pipe.

For all other stems the nozzles all point toward the

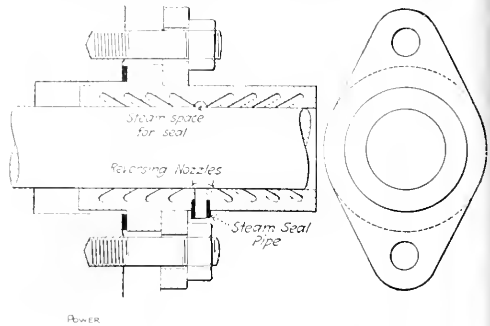

Fig. 3. Low-Pressure Type

valve. If anyone is interested in the details of the machine work I will be glad to supply them.

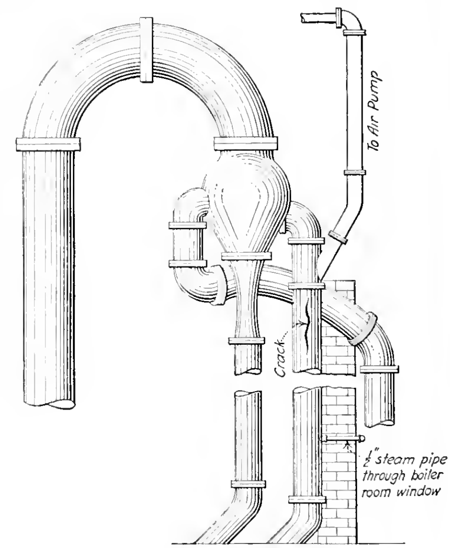
Vacuum Pipe Repaired

Early in the forenoon one day last winter I discovered the vacuum had dropped from 28 to 27 in. and was still going down, and when we shut down at noon it had reached 25 in.



Condenser Pipe Split

Such unsatisfactory vacuum denoted something wrong, so I investigated the outside piping of the barometric condenser and found a crack 4 in. long and 1/4 in. wide in the overflow pipe about 25 ft. from the ground. To avoid a shutdown before the end of the week various schemes were tried. First, the millwright filled the crack with waste and covered this up with brown paper shellacked to the pipe, then tried sheepskin, but that also was disappointing. Glazier's putty was next tried and it held. This soon brought the vacuum to 27 in., but it had to be renewed every day.

The plumbers were finally given the job of putting on Smooth-On cement for a permanent job. We then saw what had caused the pipe to burst—it was full of ice—and to prevent its recurrence, a small supply of steam was piped in to keep the water above the freezing point. I wrapped canvas round the pipe from top to bottom of the crack in the shape of a bandage, then had it painted over.

It is about a year since this happened and the vacuum is as good as it was before the pipe was ruptured.

Connecting Resistances

When all the terminals of a resistance and the corresponding controller fingers are numbered and the resistance boxes are the same in number and of the same relative size as the ones indicated on the controller-connecting diagrams, then the procedure of connecting the devices is a simple matter. On controller prints, however, the resistances are often so indicated as to make it difficult for the uninitiated to identify corresponding sections and points of the conventional print and of the resistance boxes as received.

A mill operator who was familiar only with continuous-current operation, installed a three-phase, slip-ring induction motor to drive the cylinders for the glazing of gunpowder. His print gave the connections as indicated

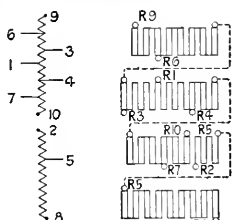

FIG. 1 FIG. 2

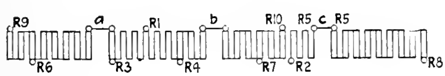

FIG. 3

Figs. 1 to 3. Diagrams Representing Resistance Connections

in Fig. 1 and the resistance boxes as received were in four units, or boxes, as in Fig. 2, in which it will be noted that all the terminals intended to receive controller wires are numbered accordingly, but that the end terminals are not numbered unless they are to receive controller wires. Thus, in Fig. 2, the top box has one unmarked terminal; the next, two and the third, two; and apparently there are no wires to fill them. The unmarked terminals are for the jumpers that connect the several boxes together. On a less involved resistance layout, the object and the manner of realizing it would be more evident. In the present case, the correct location of the jumpers was obtained as follows:

It was noted in the sketch (Fig. 1) that from R_1 one path led to the left through R_3 and R_6 to R_9, and that another path led to the right through R_4 and R_7 to R_{10}. Accordingly, the box with R_1 in the central part, with R_4 to one side and R_3 to the other, was placed upon the floor. It was plain that the next box to be handled had to have R_6 or R_7 in it; therefore, the R_6-R_9 box was laid end-on to the box already placed. As Fig. 1 showed the marks to progress toward the higher number, the second box was placed with the R_6 toward the R_3. Installing jumper *a*, as in Fig. 3, then gave a continuous path from R_1 to R_9. The third box with R_7 and R_{10} in it was then placed end-on to the first box, so that by employing jumper *b*, a continuous progression from R_1 to R_{10} was had. This completed what seemed to be a single long box in Fig. 1, but which was really two boxes and part of another.

There was now only one more to handle and only one place for it. One end was marked R_5, as was also one end of the last box handled. As the latter box had insulation washers that divided it into two parts, it was so placed as to bring the two terminals marked R_5 together; these were then connected by jumper *c*, which gave an independent path from R_2 through R_5 to R_8, just as in Fig. 1. The coils were then marked 1, 2, 3, 4, the jumper connections marked for identification and the boxes placed one above the other in their marked order. It was then noticed that the nameplates were numbered, and if the boxes had been assembled in the order of those numbers in the first place, the positions of the jumpers would have been evident, as the nameplate order was the same as that worked out.

Putting New Headers in Water-Tube Boilers

In most boiler rooms, the renewal of burnt-out or broken headers in horizontal water-tube boilers is a long and hard job. The following method, requiring little skill and small expense for special tools, has been successfully used.

Two 1-in. steel rods are needed, each long enough to reach from the outside of the front header through the tube to the outside of the rear header, leaving about six inches surplus on either end. Both ends are threaded and fitted with heavy square nuts.

The water tubes, circulation tube and mud-drum nipple are carefully crimped inside the header with an ordinary crimping tool. The header is raised sufficiently to free the mud-drum nipple, by using a crowbar and blocking up with wood blocks. If the tubes have been crimped sufficiently, little trouble will be experienced in drawing the header from the tubes. Some of them may stick occasionally, however, and then one of the rods is run through the tube and used as a battering ram from the other end, knocking the inside of the header and tending to knock it away from the tubes. After it has been loosened in this manner, a slight downward pull will remove it from the circulation tube.

One of the rods is then put through one of the top tubes and the other through one of the bottom tubes. Each rod is run out through the handhole on the other end and, if the boiler is of inclined-header type, through one of the ordinary handhole caps so that the turning-nut will have good bearing surface. If the boiler is of the vertical-header type, the handhole caps cannot be used, as they are not set in alignment with the tubes. In this case, pieces of ½-in. iron faced with a wood block to prevent damage to handhole faces must be used. The new header is then fitted into the circulation tube and brought as nearly into position as possible, with the ends of the rods protruding out through the handholes. The caps are fitted over the rods and the nuts put on. Then, by simply tightening up on the nuts and guiding the other tubes into place, the header is drawn up into position and placed over the mud-drum nipple. The tubes are then ready for rolling and flaring, after which the rods are removed and the boiler is again ready for service.

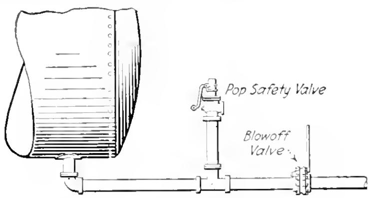
West La Fayette, Ind.

Preventing Water-Hammer in Blowoff Pipe

The illustration shows a scheme to prevent blowoff failures from water-hammer. An ordinary pop valve is placed between the boiler and blowoff valve on a short riser, to prevent scale from lodging under the valve seat.



Safety Valve on Blowoff

The pop should be set about three pounds heavier than the safety valve on the boiler. On vertical boilers having a greater head of water in the boiler, this will have to be increased to correspond to the head of the water above the valve. The area of the pop should be equal to the area of the blowoff pipe.

Charles Fenwick.

Wapella, Sask.

[There would appear to be objection to the foregoing, because the boiler might be drained of water if the safety valve on the boiler should be slightly sluggish or stick at some time. Also, the man blowing down might be scalded if not carefully protected.—Editor.]

Oil-Engine Piston Trouble

A short time ago I was called in to locate, if possible, the trouble with an 11x9-in. two-stroke-cycle oil engine. It had recently been installed and was built by a steam-engine company that had entered the oil-engine field. The engineer's explanation of the trouble was that, after starting, the engine would run for about a dozen revolutions and then stop and was even much harder to turn over by hand than when cold.

The engine was one of the hot-ball semi-Diesel types with a long piston. Upon examination I found that the piston diameter was 0.01 in. smaller than the cylinder bore when both were cold, and when heated the head end of the piston expanded more than the cylinder and stuck. I turned the piston down to $\frac{1}{32}$ in. smaller than the cylinder bore, both being cold, and the engine operated satisfactorily. It might be well to add that many oil-engine builders do not allow sufficient side clearance between the piston rings and the grooves, and as a result the rings soon bind and become ineffective, due to carbonization, etc.

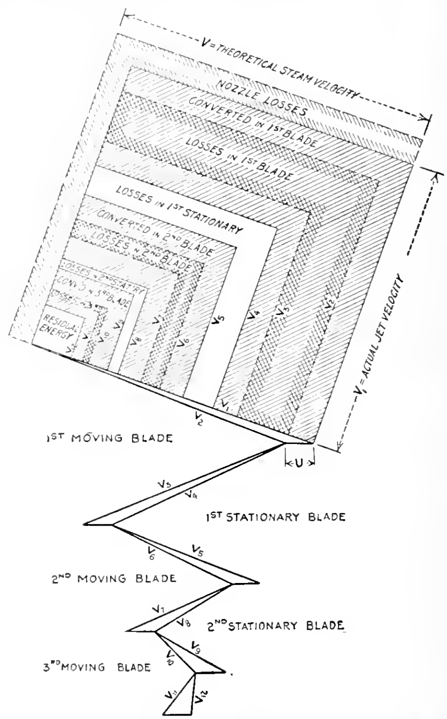
Franklin, Penn.

Steam-Turbine Diagrams

Mr. Low's article on turbine-velocity diagrams, May 4 issue, considers only the theoretically perfect turbine, when there is no friction or other losses.

It occurred to me that it might be worth while to go a step further, so I have plotted the actual-velocity diagram of a small single-stage turbine having three rows of moving blades. The bucket speed is 225 ft. per sec. The steam is supplied to the nozzles at 160 lb. per sq.in.



Velocity Diagram for Single-Stage Turbine

absolute and expanded therein to atmospheric pressure. The theoretical steam velocity resulting from this pressure drop is equal to about 2920 ft. per sec., but losses in the nozzles reduce this considerably.

The other losses shown are the friction and eddy losses, etc., which occur as the steam passes through the blades. These are proportionally very large in a machine of this size, because the attempt is made to utilize the large energy drop in a single stage. Besides this, the coefficients of loss in this case have been taken well down.

The figures show that about 40 per cent. of the energy of the steam is converted into useful work. This is represented by the areas shown in simple cross-sectioning. And the water rate of such a turbine would be approximately 40 lb. per horsepower per hour.

New York City.

Difficulty in Rotating Piston to Unscrew the Rod

Not long ago I found it necessary to remove the crosshead from a 16x18-in. engine in order to babbitt the shoe. Arrangements had been made at the shop for this work to be done on the following day, and as it was necessary to keep the engine running as long as possible, about an hour's time was allowed to take the crosshead out. The $2\frac{3}{8}$-in. piston rod was screwed into the crosshead about $3\frac{1}{2}$ in. It was known to be an easy fit and no difficulty was anticipated.

The start was made quite easily, but the second quarter turn and every turn for the full length of thread was about all that two men could pull on a four-foot bar. After the first few turns I concluded the trouble was due to the piston rings. There were six cast-iron eccentric snap rings $\frac{3}{8}$ in. wide and about $\frac{5}{8}$ in. deep, tapering to $\frac{7}{16}$ in. at the joint. These rings were doweled to the piston, so that when turning it was necessary to turn them also, and the force being applied to their ends caused them to expand and greatly increase the friction.

This was relieved considerably by turning the engine slowly and turning the piston at the same time. Under these conditions it took nearly four hours to unscrew the rod. The reason this difficulty had not been encountered before on this engine was because the rings had been doweled when the cylinder was removed to make other changes and the cylinder had been slipped off and back on over the piston.

Gas Explosions in Boiler Furnaces

Mr. De Blois' letter in the April 20 issue, page 553, regarding his experience with a gas explosion in a boiler furnace, and the letters of comment thereon are highly interesting. The writer's experience, covering many gas explosions of various kinds, leads him to offer another explanation as to the cause.

Taking the conditions as they existed: The ashpit doors were sealed, which would mean that no air could reach the fuel except from the tuyeres or through the door. The boiler was being forced and the coal fed rapidly. From this we must assume that the furnace was more than usually hot and that there was a large quantity of green coal on the side on which the door was closed. As there was no possibility of air getting to this coal from below, it would be subjected to destructive distillation with the consequent evolution of a large volume of gas of a high calorific value. This gas, undiluted with air, would be drawn by the stack draft through the setting, mingling with the air and possibly burning in the rear of, or beyond, the setting. (It is quite possible for two streams of gas and air to exist in adjacent and clearly defined areas, without forming an explosive mixture, particularly if moving in one direction.) The sudden admission of a large amount of air caused a disturbance that resulted in the breaking up and intermingling of the gas and air stratas and the instantaneous formation of an explosive mixture. From the violence of the explosion it would appear that the explosive mixture had filled the setting before ignition took place.

As to preventive measures, one can only suggest that under similar circumstances the other fire-door be left slightly open, to allow sufficient air to burn whatever gas is being formed. The writer would like to know the style of setting, the nature of its connection to the stack, and the amount of stack draft at the fire-door.

S. M. QUINN.

Detroit, Mich.

Commenting on the letter by L. A. De Blois, on the subject of gas explosions in boiler furnaces, it seems that the information given in response to the inquiry sent is not conclusive. Obviously, however, the explosion was due to an improper gas mixture. The writer believes that the importance of proper regulation of draft to meet changes in load has not been given as much attention as it deserves. Most manufacturers of damper and fan regulators emphasize the sensitiveness of their apparatus. Regulators of the open-and-shut, or noncompensated, type are inherently sensitive and will, if in good working order, cause a complete travel of the damper or fan-regulating valve with a slight change in boiler pressure, sometimes under 1 per cent. The writer is of the opinion that, while such regulators make a good-looking record on a pressure gage, their use is rarely justified, and this for the reason that it is not good practice to force a fire of either anthracite or bituminous coal up to brilliant incandescence and then shut the draft off entirely or merely leave the draft due to a short stack. Regulators of the compensated type which cause only partial travel for slight changes in steam pressure are better, but in general they are not compensated enough to prevent results somewhat similar to those produced by the open-and-shut type. Compensated regulators, as received from the manufacturer, will generally give complete travel with steam-pressure variations of less than 2 per cent., and in many plants where the load variation is frequent and considerable this practically amounts to open-and-shut regulation. This type of regulator also makes a good steam-pressure record.

While criticizing the use of such apparatus, the writer is most emphatically in favor of the use of automatic regulators designed so that a considerable variation in pressure will be required to cause total travel of the damper or fan-regulating valve. In most plants a variation in steam pressure of 5 or 6 per cent. is not objectionable, and a regulator which is compensated to require as much variation as this for total travel will subject the fire to much less fluctuation in temperature and in gas composition than a regulator of the type mentioned above. The steam-pressure chart, however, will not be as near a true circle as with the other type; but the charts from the CO_2 recorder will be uniformly higher, and the furnace economy will be perceptibly better.

Emphasis should also be placed upon complete automatic regulation as against a makeshift device such as mentioned in one of the letters published. A control which requires frequent juggling by the attendant in order to make it cover the requirements is unsatisfactory, because no two attendants have the same ideas and many of them have wrong ideas as to the proper control of draft.

The writer appreciates that the statements made may not apply directly to the conditions described by Mr. De Blois and does not feel qualified to express any opinion as to the probable cause of the accident. There is, however, a point in the design of boiler-flue dampers which should not be lost sight of; that is, that a flue damper should be made short enough so that when it is in the extreme closed position there should be a considerable percentage of opening either at the ends or around the outside edge of the damper. Most manufacturers provide this, but the percentage of opening seems to vary considerably with different makers. I believe that gas explosions, which occur so frequently when banked fires are suddenly put into service, are often due to a lack of sufficient space around the flue damper. This is an interesting and important question, and I hope that it will be thoroughly discussed in POWER.

D. L. BELLINGER.

Glens Falls, N. Y.

In the issue of Apr. 20, page 553, L. A. De Blois gives an account of trouble from gas explosions in a boiler furnace and he invites comment. The installation consisted of three boilers connected to one stack by a breeching, each boiler being fitted with an underfeed stoker. A fire-door was provided on either side of the stoker in each boiler front. One engine-driven blower was connected to the three stokers. It is not stated what type of blower, but I assume that it is of the fan type. It is assumed that the boilers are set in brick and also that there are dampers in the throat connections between the boilers and the breeching.

One boiler only was being operated, the others presumably being cold. Usually, steam is carried on two at a time. The main-stack damper was open and the ashpit doors were sealed. Consequently, the only regulated air inlet is through the blower duct and through the fire-doors when open. The boiler was being forced, and the stoker was feeding coal rapidly. The fireman opened one of the fire-doors and removed a clinker which obstructed the blast tuyere. On the removal of the clinker a gas explosion followed, injuring the fireman. The stack clean-out door was blown open.

We may assume that the explosive was of a mixture of CO and other gases with air. Further reference to other combustible gases than CO will be omitted. If combustion were perfect there would be no CO. If combustion is incomplete we have both CO and CO_2 in the escaping gases; and when the proportion of the CO to the CO_2 is about six to one we have a condition desired in a gas producer. When a fan-blower discharge pipe is closed or obstructed the quantity of air flowing is reduced. This condition is often met with in cupola practice. A tuyere becomes obstructed with slag, cooled by the blast; and until the slag is removed the flow of air is reduced and, consequently, the temperature of the bed.

If we are correct in our assumption of the quality of the explosive mixture, where does the mixture come from? Much coal is being fed into a hot fire; the admission of air is checked, CO is produced, and the temperature of the furnace drops. On opening the fire-door more air is admitted and the furnace temperature is further lowered. Probably, if nothing more were done at this time and the door were left open, there would be no explosion, as the increased draft would carry off the combustible gases. But if the air flowing in at the door and the CO already generated do not immediately make an explosive mixture, one must look for another air inlet. There remain two other possible sources—the throat dampers of the cold boilers and leaks in the boiler setting. Under proper forced-draft conditions there is one of two conditions in the boiler spaces—a plenum or a balance. Under either there will be little or no inflow of air through leaks. But there is no plenum and no balance, because the proper openings for the admission of air are obstructed and because the stack is trying to pull as the damper is open. There is a partial vacuum in the boiler spaces. My recollection is that tests carried out by Professor Breckenridge on a new battery of brick-set boilers at the St. Louis Exposition showed that the inflow of air through the settings was large, and that he mentioned a case in which the quantity of air so inflowing amounted to 30 per cent. of the total stack gases.

Assuming that air did flow in through the settings or through the throat dampers of the cold boilers, or both, there is a mixture of CO and air, and possibly in proportions necessary for rapid combustion. The temperature in the boiler spaces is comparatively low, the draft is reduced, and the gases are not promptly removed. There is now an explosive mixture awaiting some condition necessary to combustion. The fireman removes the obstructing clinker from the blast tuyere, intense heat and flame are produced locally, the flame and the explosive mixture come together, and an explosion follows.

I have said that the air flowing in through the open fire-door probably did not mix with the CO to form the explosive gas in large or dangerous quantity, for the reason given, and for this additional reason: In hand-firing fresh fuel is added through an open door, air also enters through the opening, but a heavy explosion does not always follow. Therefore, fresh fuel and an open door are not necessarily the cause of an explosion. Yet with heavy hand firing and checked draft, even in the case of internally fired boilers, there do occur "puffs," which are due to the rapid burning of a small quantity of comparatively confined gas. If there is a quantity of explosive gas in the boiler spaces, there will be explosion on the introduction of flame.

It may be suggested that I have not given a sufficient reason for the checking of the draft. Possibly there is another reason. The throat connection between boiler and the breeching may have been large enough for the normal rating of the boiler, but not quite large enough when it was steaming at much above rating. Again, when three boilers are connected by a breeching to one stack set at one end of the breeching, the cross-section of the breeching at the further end is usually calculated for one boiler at a little above normal rating. We do not know that the connections were arranged in this way, but we know that the boiler was being forced.

Because the foregoing is largely conjectural and inferential, I cite the following experience: In 1888 I was assistant engineer on some tests instituted in order that the best way to fire boilers with oil-gas might be learned. One of the boilers used was a two-furnace Scotch boiler. The furnace mouths were closed by removable iron plates.

Oil-gas and air were introduced through mixer burners; the oils experimented with were Astatki and American crude petroleum. These tests were made at North Greenwich, London, Eng. Oil from abroad was usually shipped in barrels. The Baku oil line had not then been built, and tank ships were not in general use. The tests were successful so far as evaporation of water per pound of oil was concerned, but were stopped when the price of crude petroleum jumped to 6d. (12c.) per gallon on the dock; the price of London steam coal being at the time 17s. ($4.08) per long ton.

The oil was vaporized in a producer by steam, in some tests superheated (with results which those who have tried it know), in others saturated, and in still others saturated with a later addition of superheated. We learned that a brick baffle before the burner or, better, around it was necessary. Pockets of water which were present in the oil of course gave no oil-gas; the flame went out; and when the pocket was exhausted and oil-gas again flowed from the burner the incandescent brickwork reignited the gas. It should be said that what we called gas was in reality a vapor and not a fixed gas.

On one occasion, soon after lighting off, the flame went out for a moment. The coverplates had not been put in place. An attendant threw a bunch of lighted oily waste into the furnace to ignite the gas when it came on again. But it had already arrived. The explosion was violent, and the brickwork in the combustion chamber (dry) was loosened. I had other proof of the force of the explosion, for I was standing immediately in front of, and only a few feet from, the boiler when the bunch of waste was thrown into the furnace. There was no other explanation than that the furnace and the combustion chamber were filled, the former partly and the latter probably completely, with an explosive gas. Did not the combustion chamber, breeching and stack base mentioned by Mr. De Blois contain an explosive gas? The stack clean-out door was blown open.

A later experience, and one more like that of Mr. De Blois, was as follows: About eighteen months ago I was asked to make an investigation and report on a case of boiler-furnace explosion. There were two boilers connected through a breeching to a brick stack, and both were hand fired. This fact is of some importance. When both were under steam firing was light and no trouble was experienced. To save fuel it was decided to try to use only one of the boilers at a time, holding the other in reserve, and cold. The fuel used was bituminous run-of-mine, with an occasional addition of wood shavings and sticks. A pile of shavings had stood on the boiler-room floor about ten feet from, and opposite to, the first boiler. On one occasion there had been an explosion, and flame had leapt across the boiler-room floor and had set fire to the pile of shavings. On the latest occasion, coal only being used as fuel, the fireman had covered the fire with a layer of rather fine coal. A little later he opened the door, and finding the fire deadened, stirred it with a poker or slice bar. Immediately, there was an explosion. The fireman was thrown across the room and was badly burned.

The manager of the plant argued that the cause could not be poor draft due to insufficient stack capacity, as this particular boiler installation had been in use for about twenty years and furnace explosions had been a recent experience. On examining the settings I found clean-out doors in the rear which could not be closed tightly (one could see about three-eighths of an inch of red light through the opening of the door of the live boiler); several large cracks in the brick walls; unnecessarily large holes in the walls where the water-gage connections and other pipes entered; open joints and empty rivet holes in the breeching; front doors not fitting closely. I advised that all setting leaks be stopped and the results noted. I heard of no further trouble. On reading Mr. De Blois' letter I called up the manager of the plant, and he told me that he had had the leaks stopped and that while there were little puffs or explosions now and then, they were neither as severe nor as frequent as they had been. Other running conditions were about the same as before.

I have said that the fact that the boilers were hand-fired was of some importance; it shows that explosions are not characteristic of stokers. The stoker was not necessarily at fault.

It is interesting to note that in this, as in Mr. De Blois' case, one boiler only was being operated. In this case it will be seen that there was no blast tuyere to become obstructed, but there was what amounted to the same thing—heavy firing with a close-lying coal, which obstructed the air passages through the grate and fire; and insufficient draft to pull air through the fire. There was also enough air leakage through the settings to make an explosive mixture with the CO and other gases generated, and there was sufficient local heat at times to fire the explosive mixture.

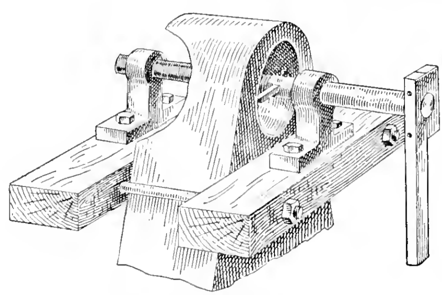
ARTHUR SCRIVENOR.

Richmond, Va.

Enlarging Crankpin Bore

When the crankpin of our ammonia compressor worked loose we decided to remove it, enlarge the hole in the crank and shrink in a new pin.

To do the job cheaply and quickly a 1⅝-in. shaft, 28 in. long, was threaded on one end with 30 threads to the



IMPROVISED BORING BAR

inch. A ⅜-in. hole was drilled through the shaft to carry the cutting tool, the latter being held by a setscrew. Two 4x4-in. wood blocks, each 2 ft. long, were clamped to the crank and each had a bearing for carrying the shaft of the small boring bar. The arrangement is shown herewith.

J. H. CUNNINGHAM.

Grit in the Feed-Water Meter

Recently, the writer experienced considerable trouble with a Kennedy-type water meter. On opening it considerable fine coal grit was found. The puzzle was, how did it get there? The source of supply had not been changed, and this difficulty had never arisen before.

The overflow pipe from the injector had, temporarily, been put to discharge near the coal bin, and this pipe sometimes got covered over with coal when the bunkers were full. In this particular style of injector, a vertical one handling 23,000 pounds of water per hour, unless the correct amount of water is put on to suit the steam, a considerable suction can be felt at the overflow pipe, probably due to the check valve on the combining nozzle not seating tightly, so that it drew quite a little coal dust up the overflow pipe, discharging it into the feed line and meter.

Rochdale, England.

Influence of Ash Content

I read with interest Mr. Ellis' letter, "Influence of Ash Content of Coal," in the Nov. 3 issue.

High ash certainly cuts down furnace efficiency; on that point there is no argument. Mr. Ellis states that "coal apparently follows a straight-line characteristic as regards its value on a basis of its ash content, assuming the same character of coal." If by "same character" Mr. Ellis means any general class such as anthracite, semianthracite, semibituminous or bituminous, I take exception to his statement.

For a given coal I will concede the straight-line characteristic, but I do not see how one characteristic can be applied to all coals of the same character. For instance, in anthracites the heat of combustible or ash-free heating value, as it is sometimes called, varies from 14,400 to 15,200 B.t.u. With 15 per cent. ash, the B.t.u. dry in these limiting conditions is 12,240 and 12,920, respectively, a variation of 680 B.t.u. per lb. On this basis, it would appear to be advisable not only to keep the ash down, but to buy heat and not to accept the absence of ash as an indication of high heat. Low ash may or may not indicate high heat. The calorimeter answers that.

The formula at the end of the letter would, perhaps, have been better understood if an example had been worked out. As it stands, the "value of coal" increases numerically as the ash content increases, which is just the reverse of what Mr. Ellis stated. For instance, take a coal having an ash-free value of 15,000 B.t.u. and assume that two subsequent shipments show 10 per cent. and 20 per cent. ash, respectively. Assume the price delivered to be \$3.50 per ton. The B.t.u. of the first shipment are 13,500 and of the second shipment, 12,000.

The value of the first shipment by the formula is then

$$\frac{350}{13{,}500 - (13{,}500 \times 1.5 \times 0.10)} = \frac{350}{13{,}500 - 2025} = \frac{350}{11{,}475} = 0.0305$$

The second shipment shows a value of

$$\frac{350}{12{,}000 - (12{,}000 \times 1.5 \times 0.20)} = \frac{350}{12{,}000 - 3600} = \frac{350}{8400} = 0.0417$$

From this it appears that the worse the coal, the higher its value, as given by the formula. If it is correct, will Mr. Ellis state how much better he regards the first shipment than the last, based on the figures given by the formula?

Questions for Discussion

Gasoline Engine Run on Natural Gas

We purchased a gasoline engine that was taken out of a wrecked automobile. It is a 5x5-in. six-cylinder engine rated at 60 hp. when running at 1000 r.p.m. We are repairing this motor and intend to connect it through a flexible coupling to a 750-r.p.m., 17½-kw. generator to furnish power for our after-midnight load. The engine will be operated with natural gas and the speed controlled by a flyball governor mounted on the fan shaft and connected with levers and rods to butterfly valves in the air and gas intakes.

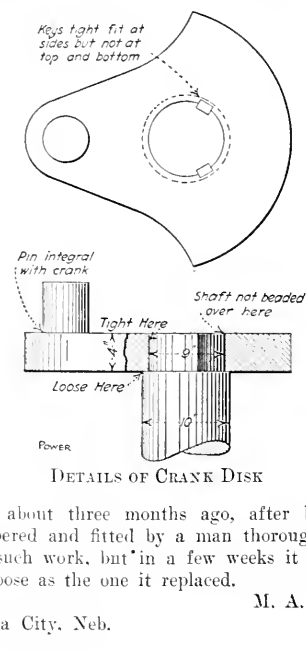
Have any readers of Power had practical experience with this type of engine operated on natural gas? If so, I should be glad to have suggestions as to how they have overcome the speed-governing problem, also as to what proportion of power the engines developed with natural gas in comparison with gasoline.

Erwiss Gawthrop.

Pittsburgh, Penn.

Loose Crank Disk

Can any of the readers of Power suggest some means of tightening a loose crank disk on a large high-speed engine without removing it? The disk was shrunk on the shaft about three months ago, after being carefully calipered and fitted by a man thoroughly experienced in such work, but in a few weeks it was apparently as loose as the one it replaced.



Details of Crank Disk

Nebraska City, Neb.

Inquiries of General Interest

Effect of Inside Lap—What is the effect of adding inside lap to a slide valve?

J. W. D.

By adding inside lap the exhaust port is closed earlier, thereby resulting in higher compression of the exhaust.

Corrosion of Steel Uptake—What would cause our steel stack and uptake to corrode more rapidly than formerly?

N. R.

Other things being equal, more rapid corrosion would take place from use of fuel containing more moisture or more sulphur, or from introduction of more moisture with the air supply to the furnace.

Slope for Drainage of Boiler to Blowoff—How much should the rear end of a return-tubular boiler be set lower than the front end for drainage toward the blowoff?

F. W. S.

Sufficient slope for drainage is usually obtainable for boilers 16 to 18 ft. long by setting the blowoff end about 2 in. lower than the front end.

Quality of Boiler-Feed Water—What proportion of scale-forming substances may be contained by a water to be considered as good or poor boiler-feed water?

L. G. N.

Water containing 8 to 10 grains of boiler-incrusting substances per gallon may be considered as good, while those containing 15 to 20 grains or more may be regarded as poor.

U. S. Navy Composition Metal—What is the U. S. Navy composition or steam metal?

J. M. C.

This is a composition metal consisting of 88 per cent. of copper, 10 per cent. of tin and 2 per cent. of zinc. Its tensile strength is about 32,000 lb. per sq.in. and its elongation about 25 per cent. On account of its strength and toughness this composition is considered superior for valves, flanges and other boiler accessories.

Danger to Cylinder from Sudden Overloading—Does overloading a cutoff engine have any tendency to blow out a cylinder head?

G. M. S.

In case of overloading, the higher velocity of steam in the steam pipes and passages has a tendency to suddenly sweep into the cylinder any accumulations of condensation and thereby endanger the cylinder and its head to rupture from presence of water in the cylinder.

Receiver of Returns Should Be Vented—Where a low-pressure heating system is supplied with live steam passed through a reducing valve and there is no vacuum pump on the returns, is it necessary to discharge the returns either to an open tank or into the atmosphere?

M. J. N.

Where the piping is properly arranged for drainage the returns may be collected in a closed receiver with an automatic air-relief valve, though it is better to supply the receiver with an air vent that is always in communication with the atmosphere.

Omission of Low-Down Tubes in Return-Tubular Boilers—In return-tubular boilers, why is not the space generally utilized for tubes on each side of manholes and handholes in the lower part of the flue sheets?

L. G. J.

Tubes placed low down in the flue sheets are not favorably located for receiving the flow of the gases from the combustion chamber and are thus of little value as heating surfaces. By their presence in the lower part of the boiler they not only displace a substantial amount of water which should be present to absorb the direct heat of the fire, but also impede circulation in a part of the boiler where it is most needed.

U. S. Navy Standard Boiler Compound—What is the composition of U. S. Navy standard boiler compound?

A. N. I.

This compound consists of calcined sodium carbonate, trisodium phosphate, dextrine or starch, and a tannin compound such as mangrove bark, cutch or catechu. These materials are intimately united by thorough digestion, dried, finely powdered, well mixed and readily soluble in water. The compound must show on analysis at least 76 per cent. of anhydrous sodium carbonate (Na_2CO_3), 10 per cent. of trisodium phosphate ($Na_3PO_4 12H_2O$), 1 per cent. of starch, and sufficient cutch to yield 2 per cent. of tannic acid, the remainder consisting of water and such impurities as are common to the ingredients.

Use of Iron in Place of Copper Feed-Water Tubes—A closed feed-water heater now fitted with copper tubes is capable of warming a uniform supply of boiler-feed water from 50 to 190 deg. F. To what temperature would the feed water be heated, using the same number and size of iron tubes?

J. H. B.

By the use of iron in place of copper tubes the rate of heat transmission would be about two-thirds as great as with copper tubes and the temperature of the water would be raised to about

$$50 + \tfrac{2}{3} \text{ of } (190 - 50)$$

or approximately to 143 deg. F.

Saving from Higher Evaporation per Pound of Coal—What percentage of fuel is saved with an equivalent evaporation of 9.5 lb. of water from and at 212 deg. F. per lb. of coal over an equivalent evaporation of 8 lb. of water per lb. of coal?

L. S. F.

With an evaporation of 9.5 lb. of water per pound of coal each pound of water requires $\frac{1}{9.5}$ of a pound of coal. With an evaporation of 8 lb. of water per pound of coal each pound of water requires $\frac{1}{8}$ of a pound of coal. Therefore, when the evaporation is at the rate of 9.5 of water per pound of coal, $\frac{1}{8}$ lb. $-$ $\frac{1}{9.5}$ lb. of coal is saved for each pound of water evaporated and the saving amounts to

$$\left\{\frac{\frac{1}{8} - \frac{1}{9.5}}{\frac{1}{8}}\right\} \times 100 = 15.78 \text{ per cent.}$$

Size of Safety Valve for Compressed-Air Tank—What size of pop safety valve should be used for a compressed-air tank supplied from a compressor having a rated maximum capacity of 130 cu.ft. of free air per min. compressed to 100 lb. per sq.in. gage pressure?

P. E. C.

The safety-valve capacity should be 25 per cent. in excess of the rated maximum capacity of the compressor, or

130 + 25 per cent. of 130 = 162.5 cu.ft. per min.

and the size of valve required may be determined from the formula,

$$Q = 28\ PDl, \text{ or } D = \frac{Q}{28\ P\ l}$$

in which

Q = Discharging capacity of the valve in cubic feet of free air per minute = 162.5 cu.ft.;

D = Size of valve in inches;

P = Absolute pressure of air relieved by the valve = 100 + 14.7 or 114.7;

l = Lift of valve, which for standard pop valves may be taken as $\frac{1}{31}$ of D.

By substituting in the formula and solving for D,

$$D = \frac{162.5}{28 \times 114.7 \times \frac{1}{31} D} = 1.25$$

that is, a $1\tfrac{1}{4}$-in. safety valve should be used.

The Electric Traction Elevator*

Elevators may be classified first according to the driving power employed, which gives three principal classes, namely, steam-driven, hydraulic and electric elevators.

The first class is now practically obsolete. There are, of course, a few of them still running, but there are no new installations.

Hydraulic elevators may be divided into several groups, depending upon the method in which the hydraulic power is applied. Some of these types are: The horizontal, rope geared; the vertical, rope geared; and the plunger, which is direct connected. The plunger type practically superseded other types of hydraulic elevators during the period of 1904 to 1907, but has itself been almost entirely superseded by the 1 to 1 gearless electric-traction type.

Without considering in detail the technical features of the plunger elevator, the principal reasons for this change may be summarized in its comparison with the gearless traction type as follows:

1. Higher initial cost of plunger installation.
2. Larger amount of total space in the building occupied by the machinery.
3. Lower car mileage and consequently more elevators required for the same service.
4. Higher power consumption.

As to the location of the electric elevator, this is preferably directly over the hatchway, an arrangement which gives the best traction, least amount of ropes, minimum space required, longer rope life and higher efficiency.

The roping is extremely simple, usually six ropes of ⅝-in. diameter being used. The material is soft steel and in actual installations there is generally a safety factor of not less than 12. Each rope is provided with a self-adjusting rope hitch of the ball-and-socket type, which, owing to gradual creeping, prevents any excessive twisting stress and relieves the usual bending stresses at the hitch, caused by vibration.

A traction machine is arranged so that in case of overrun at the terminals either the car or the counterweight strikes an oil buffer, thereby reducing the traction sufficiently to prevent further motion of the car, even if the motor keeps on running. The car buffer is of the spring-return type and is mounted in the bottom of the pit.

The counterweight equals the weight of the car and usually about 40 per cent. of the maximum load. If we consider an elevator of 2500 lb. lifting capacity, 40 per cent. of this equals 1000 lb. (the overbalance) and this represents about six or seven persons. With such a condition of loading it is apparent that there is no net load to be lifted and, therefore, the only power required is for acceleration and to overcome friction and electrical losses.

ROPE COMPENSATION

It is obvious that with a high-rise elevator the variation in the net load on the elevator machine due to the shifting of the weight of the hoisting ropes from one side to the other as the car moves up and down would be excessive if this was not compensated for. This compensation is usually obtained by means of chains or ropes attached to the car and counterweight and running down the hatch in a loop. The weight per foot of these compensating ropes is such that, together with the electric cables that lead to the car, they compensate fully the weight of the hoisting ropes for all positions of the car.

For all high-speed, high-rise elevators compensating ropes are used and in the pit a tension device is provided for the compensating ropes. For moderate rises and comparatively low speeds, chains are used instead of ropes.

DRIVING MOTOR

The motor is of the slow-speed type, generally having six poles and provided with a shunt field only. The armature is series wound with conductors of rectangular cross-section in order to get in the maximum amount of copper. With a 36-in. driving sheave, a car speed of 600 ft. per min. corresponds to 63.5 r.p.m. of the motor armature.

For a considerable time it was considered that such a slow-speed motor delivering around 35 hp. would have an exceedingly low efficiency, but this is not the case. On the contrary, it has been demonstrated that a motor with this low speed can be designed to have just as high efficiencies as any high-speed motor.

Passing now to the different parts of the hoisting engine, the driving sheave is mostly 36 in. diameter, is cast integral with the brake wheel, and is bolted to the armature sleeve or spider. Circular rope grooves are employed. The magnet brake is of the shoe type, usually provided with a series winding for quick release and a shunt winding for holding. The brake shoes are lined with fabricated asbestos. The gradual and soft application of the brake is obtained by magnetic retardation of the magnet cores. The brake shoes used to be lined with leather, but after exhaustive tests of a number of different braking materials it was found that a certain kind of fabricated asbestos was the most suitable, its particular characteristics being that the friction between the lining and the brake wheel is constant at all times.

Elevators of the gearless traction type have been for some time equipped with ball or roller bearings. These are used for both the main motor and the rope sheaves. This was done primarily to gain space, because it is readily apparent that these anti-friction bearings take up much less room than the plain solid bearings. Personally I consider ball bearings superior to roller bearings for elevator machines. With roller bearings slightly out of alignment, even though this be insufficient to set up destructive strains, the friction will be increased materially. As a matter of fact, actual tests have shown that friction induced in this manner can readily be in excess of the friction in a plain bearing. Ball bearings are capable of resisting a certain amount of end thrust, which in the case of these traction machines is sufficient to take care of the "float" of the armature, caused partly from magnetic action and partly by the action of the hoisting ropes. Roller bearings will permit of no end thrust at all, and therefore, when they are used additional means must be provided to take care of this.

It is necessary, of course, to provide some lubrication in a ball bearing so as to prevent cutting, particularly of the cage; therefore, grease is provided, which will stay in the bearing. Furthermore, grease is most efficient in ball bearings for elevator machinery to prevent corrosion of the balls and races. A little rusty speck on either the race or a ball will soon destroy the bearing; hence these bearings must be usually well protected. If the grease is wiped out and the bearings run perfectly dry, the apparent friction losses will have been reduced to about one-fifth of that with lubrication.

SPEED CONTROL

Speed variation is obtained partly by field regulation and partly by series and bypass resistance in the armature circuit. The field regulation is usually capable of reducing the speed down to 60 or 40 per cent. of full speed, and further reduction is obtained by resistance control, as previously mentioned.

The combination of both methods is necessary to obtain sufficiently slow speed—about 60 ft. per min. This slow-speed car is required to make accurate stops both at intermediate and terminal landings and also in order to be able to make a very short travel or to "inch up or down to the landing."

In connection with the regular operating features of the control apparatus, there are also a number of other features introduced for safety. Some of these are:

1. Automatic return of car switch to off position.
2. Automatic stopping switch on car for stopping at terminal landings.
3. Final cutout limit switches in hatchway, operating independently of the automatic stopping switch.
4. Automatic stopping of elevator in case of over-speed by means of an electric contact operated by a centrifugal governor which will apply the electromechanical-brake and dynamo-brake effect on the armature, and, finally, the electric safety on the car.
5. Oil buffers, as previously mentioned, are capable of independently stopping the fully loaded car when descending at 50 per cent. excess speed without discomfort to the passengers.
6. Regulation of the shunt field by centrifugal governor to maintain constant full speed with variable loads.
7. For high-rise elevators the use of a retarding and latching device.

LOADS AND SPEEDS

Gearless traction machines utilizing 1 to 1 or 2 to 1 roping have been built for loads varying from 2000 lb. up to 11,000 lb. at car speeds from 350 to 700 ft. per min. Of these duties the most generally used for the modern high office building, utilizing 1 to 1 roping, is about 2500 lb. at 600 or 700 ft. per min., although in many instances a load of 2500 lb. at 500 or 550 ft. per min. is suitable. The high rise elevators in the Woolworth Building run at a speed of 700 ft. per min. In the new Equitable Building certain of the elevators are arranged to run a portion of their travel on express service at a speed of 650 ft. per min., and the remainder of their travel on local service at 550 ft. per min. The change in car speed is automatically accomplished at the point where the service changes.

*Excerpts from an address of David Linquist, chief engineer of the Otis Elevator Co., before the New York Section of the American Society of Mechanical Engineers.

For more moderate speeds and also for the heavier loads 2 to 1 roping is utilized, which retains the same safety features and general characteristics as in the 1 to 1.

The traction principle is also applicable to elevator machines employing moderately high-speed motors with some form of gearing between the motor and the driving sheave. This type of machine is most suitable where lighter capacities are involved or where the service conditions are not so severe. Under these conditions the power consumed will be comparatively light on account of the small mileage, and hence the more expensive gearless machine with its reduced power consumption may not be necessary.

Two types of geared machines have been developed—one employing worm gear and the other herring-bone gear reduction. Of these the worm gear is suitable for the slow or more moderate speeds and is extensively used for this purpose. The machine with herring-bone gear reduction is not suitable for slow car speeds on account of the difficulty in obtaining sufficient speed reduction. It is undoubtedly more efficient than worm gearing, and it has been used with some success in connection with quite high-speed elevators. The fact that the herring-bone gear has been used for these high speeds does not mean that it is to be considered equal to the gearless machine, with which it cannot compare as to operating features and power consumption. The worm gear has inherently the least tendency to vibrate, but the herring-bone gear is generally more efficient.

The maximum efficiency of the high-speed motor used in connection with the geared machine may be practically as high as that of the gearless, but the efficiency at lighter loads, which is the most prevalent running condition, is lower; hence, the high-speed motor is at a disadvantage. Equal amounts of field regulation may be applied to both types.

For high speeds it may be taken that under the best conditions the gearing has a loss of about 10 per cent.

ELECTRO-MECHANICAL SAFETY DEVICES

1. The safety should be so arranged that the application of a predetermined but definite light retarding force will stop the car and net load without shock in case the hoisting ropes are intact.

2. The safety device should be so arranged that the application of a predetermined definite strong retarding force will gradually bring the car and maximum load to rest in the case of a free falling car.

3. The light retarding force should be immediately applied, preferably by means of a centrifugal governor, in case the car should attain excessive speed in either direction.

4. It should be possible to immediately apply the light retarding force from within the car when desired.

5. The light retarding force should be applied automatically in case of overrun at the upper or lower terminals, and be arranged not to interfere with the starting of the car in the opposite direction.

6. The strong retarding force should start to apply the instant the hoist ropes part, independent of the speed of the car and counterweight. In safe lifts a strong retarding force should be automatically applied independent of the parting of the hoisting ropes at a definite speed which should be higher than the speed at which the light retarding force is applied.

7. A tripping governor should not be necessary to apply the strong retarding force.

8. The releasing carrier, even though improperly adjusted, should not prevent the application of a strong retarding force to the car in case the ropes parted.

9. The principal actuating parts of the safety should be made to move automatically at frequent intervals, in order to prevent them from clogging up or corroding together. This motion of the actuating parts need only be very small to give the desired results, but some motion is necessary to secure dependable action of the safety.

The light retarding force is obtained by one helical steel spring forcing the curved wedges between the rollers of the safety jaw. When the car is in service this spring is held under compression by means of an electromagnet.

DISCUSSION

Some questions were asked with reference to the rope strains. In reply Mr. Linquist stated that under ordinary conditions the apparent safety factor with the load at rest was never less than 12. This did not take into account the additional stress due to acceleration and bending of the rope, which would make the real safety factor hardly over 8.

As to whether anything had been done with reference to the employment of alternating current in electric elevator service, the speaker replied that, up to the present time no alternating-current elevators have been put on the market of the direct-connected or gearless traction type. Those in use are of the geared type, for speeds up to 350 ft. per min. approximately. For 250 to 300 ft., two motors are employed, with a speed variation of from 1 to 3 down to 1 to 4; in other words, the reduction of speed is to ⅓ or ¼. The change in speed is obtained by rearranging the connections of the motor in such way as to change from a small number of poles giving the high speed to a large number of poles giving the slow speed.

With reference to the smooth application of the brake, no known method has been used for magnetically retarding an alternating-current brake. There dashpot retardation has to be employed, and in the majority of cases the brake-magnet parts are inclosed in coil-type casings and the brake-magnet cores are formed partly for plungers to act as dashpots.

Going back to the question whether anything has been attempted in the line of gearless alternating-current traction machines, Mr. Linquist stated that last year he had built such a machine. Half of the outfit consisted of an alternating-current motor, and at the same time it acted as a motor it also acted as a converter. The other half of the machine consisted practically of a direct-current motor with a revolving field with unusually large speed variation and speed regulation. The machine was built and tested, and so far as the speed control was concerned it was perfect. There was field regulation from no speed up to full speed, and it was possible to obtain any desired speed without resorting to resistance control. On the other hand, the losses were comparatively high and the efficiency was not very good. As far as operation was concerned it was successful, but considering the cost of operation and first cost, it was hardly a commercial proposition, because as good results and perhaps better could be obtained by changing the alternating current by means of converters or motor-generator sets into direct current and operating direct-current elevators.

Electric Ship Propulsion

Before a joint meeting of the Western Society of Engineers and the American Institute of Electrical Engineers, W. L. R. Emmet, of the General Electric Co., gave an interesting talk on the above subject on the evening of Apr. 26. The development of the high-speed turbine paved the way for electric ship propulsion. Its application in this field had been long foreseen. Mr. Curtis had worked for two or three years on the problem, and since 1900 Mr. Emmet had spent much of his time on the turbine. About six years ago he had first approached the Navy with a view to equipping battleships for electric drive, but at about the same time the question of reduction gearing had been brought to the front and the Navy had been impressed to the extent that the collier "Neptune" was equipped with turbines and reducing gears. The excellent results obtained aroused interest in the general question of reducing the speed between the turbine and the propeller, and as a result Mr. Emmet secured the contract to equip the "Jupiter" electrically. During the two years this ship has been in service it has made a wonderful record. Results 20 per cent. better than from any ship afloat have been obtained, and the equipment is as good as new. The turbines run regularly on a water rate of 11 lb. per shaft hp.-hr., which may be compared to 14 lb., the best obtainable from a triple-expansion-engine-driven vessel. Naturally, electric propulsion gained in favor, and about a year ago it began to be thought of seriously for battleships. As the advantages of the electric drive increase with the power required, Mr. Emmet had been particularly anxious to equip a battleship, and only within the last few days the contract for the "California" had been closed. An estimate on the cost of installing electric drive showed that a saving of $160,000 would be effected over the cost of the turbine equipment that had been previously planned. In these large powers all sorts of complications arise when the turbines drive the propellers directly or through reduction gearing. With the latter the power must be divided up between a large number of units, as there is a limit to the size and capacity of individual gears beyond which it would not be safe to pass. In ships where the turbines drive the propellers directly there must be a compromise in speed. The turns made by the propellers are much too high, and the turbine runs at about a tenth of the speed it ought to have to give the best results. Besides, there is great complication of piping for high- and low-pressure turbines, and as the pressure in some of this piping is below the atmosphere, air leaks are liable to develop and lower the efficiency by reducing the vacuum. On the other hand, with the modern electric drive the loss cannot exceed 8 per cent. The apparatus is designed so that practically a constant water rate is maintained for all loads.

In the "Lusitania," with a speed of 180 r.p.m. the propeller efficiency is 62 per cent. The turbines for the "California" will have a speed of 2200 r.p.m. and deliver to the generator 75 per cent. of the available energy in the steam. In the latter the turbines will be simple, compact machines, while those of the "Lusitania" are enormous. By dropping the propeller speed of the "Pennsylvania" from 222 to 160 r.p.m., the efficiency would be increased 8 per cent., which would just counterbalance the loss by electric propulsion. Comparing the present equipment with an electrically propelled "Pennsylvania," the efficiencies would bear a ratio of about 63 to 73 per cent.

Investigating the possibilities of reduction gearing held back electric propulsion. Parsons had condemned the latter and favored gears. Reduction gearing has proven successful on small ships running at moderate speeds. As the speed of the vessel increases, however, the ratio of reduction between turbine and propeller speeds becomes greater and the gear problem is more difficult. The General Electric Co. had become interested in gearing and developed a system which was installed on three freighters equipped with turbines. These gears may be applied to cases where electric propulsion is barred, but in the favorable cases the speaker could not imagine any arrangement of gears which would be anywhere near as good as electric drive.

Electric propulsion is to have a wide field of application. The company had recently figured on two large Russian cruisers and on a number for our own navy. Mr. Emmet stated that he could reëquip the "Lusitania" and save $150,000 per year in the cost of coal. Electric drive for liners so far exceeds engines that the equipment would pay for itself in one or two years.

Slides were thrown on the screen showing the 20,000-ton collier "Jupiter" and its power-plant equipment. At 15 knots the vessel requires 7000 hp. The generator is of simple and rugged construction and is not restricted as to voltage or frequency. It has a capacity very little greater than required by the motors, so that even a short circuit would not result in much injury. The motors are of the three-phase induction type, the stator having bar windings and the rotor a definite wound design provided with external resistance to be used when reversing. The governor is designed much like a tachometer with a system of fulcrums which can be moved in and out and varied through a wide range of speed.

For the "California" each turbine will have a maximum capacity of 18,000 shaft horsepower and on maximum load will require 170,000 lb. of steam per hour. The vessel has a displacement of 30,000 tons and a maximum speed of 22 knots, and yet each of the two turbines driving it is only 14 ft. long. The motors are 12 ft. in diameter by 11 ft. wide. Consequently, the entire equipment occupies comparatively little space, and the first impression would be that it was designed for a tugboat or at least a vessel much smaller than the "California." Even the auxiliaries will be electric driven, and the only steam piping entering the engine room will be the two leads for the main turbines.

The two turbines will develop a maximum of 36,000 hp., which is required to force the vessel to 22 knots. At 14 knots 7000 hp. is required. Performance charts showed that the water rates will remain practically constant over a wide range of speed. At 14 and 21 knots it was 10¾ lb. per shaft hp.-hr., and for the range in speed between these two points it remained between 10 and 11 lb. At a speed of 15 knots, 28½ in. of vacuum, no superheat and 190-lb. gage pressure, the "Jupiter" showed a performance of 11 lb. per shaft hp.-hr. These figures are exceptional and can be obtained only when both the turbine and the propeller are running at their most efficient speeds. By diminishing the excitation with the speed the efficiency is maintained and at the same time the torque is not reduced beyond that which is required. It is simply a case of diminishing the excitation until the propellers are turned at the right speed with the minimum amount of steam. One of the big problems is reversing, but it has been met by using high excitation while the change in direction is taking place.

With the reduction gear the great problem has been to equally distribute the load over the entire face of the gear. With a rigid gear most of the load is applied near the ends of the teeth. In the General Electric design this difficulty has been overcome by a gear made up of separate disks which will give sidewise and distribute the load over the surface.

A number of charts comparing the relative economy of engine-driven vessels, geared turbines and electric propulsion showed the following water rates per shaft horsepower-hour. For the "Vespasian," with triple-expansion engines, the water rate was 19 lb.; with geared turbines, 16 lb.; and with electric drive, 12.7 lb. The "Cairngowan," with triple-expansion engines, developed a shaft horsepower-hour on 17.3 lb. of steam, and the "Cairnross," a sister ship with geared turbines, on 14 lb. It was estimated that either vessel equipped with electric drive would develop a shaft horsepower-hour on 11.77 lb. of steam. The above figures tend to prove the assertion made by Mr. Emmet that electric drive over triple-expansion engines will reduce the water rate about one-third.

In the discussion it was brought out that as induction motors cannot run above synchronous speed, the propellers cannot race. Even in a heavy sea, with the propellers entirely out of water there is no vibration or any indication of a change in speed. As to the proper fields for reduction gearing and electric drive, Mr. Emmet made the general statement that in all ships requiring above 15,000 to 20,000 hp., gearing would make a poor comparison. In vessels requiring 10,000 hp. and less and running at a low speed, reduction gearing would perhaps make the best showing. The field for electric drive is in large merchant ships and all battleships with the exception of torpedo boats and destroyers, where restrictions in weight prohibit its use.

Recent Court Decisions

Digested by A. L. H. STREET

Duty to Guard Ash Piles—When the owner of a power plant has knowingly permitted children to play about a pile upon which hot ashes from the boilers are deposited, he is under a legal duty to either maintain a guard or give suitable warning to prevent injury to such children, according to a decision of the United States Circuit Court of Appeals, for the Sixth Circuit, in the case of O'Donnell vs. Escanaba Manufacturing Co., 212 "Federal Reporter," 648. In this case judgment was affirmed in favor of a ten-year old girl who was burned in undertaking to walk over a pile of hot ashes.

A Mandatory Statute—A law enacted by the Oregon Legislature in 1911, to promote the safety of electricians, requires dangerous wires to be completely insulated, prohibits intermingling of dead and live wires, requires the supports of live wires to be so designated that the presence of such wires shall be instantly apparent, and requires such wires to be so strung as not to endanger repairmen working near them, etc. Applying this law to an action for the death of a lineman who was electrocuted while working on a pole which supported uninsulated wires, the Oregon Supreme Court lately decided, in the case of McClaugherty vs. Rogue River Electric Co., 140 "Pacific Reporter," 64, that an employing electric company cannot excuse liability for failing to comply with such statutory requirements, by installing switches in such a location that electric current can be shut off while work is being done. The court says: "The requirements of the statute as to the safeguards enumerated are positive and mandatory. There are no alternatives."

Right to Enjoin Construction of Dam—That suit does not lie to enjoin the construction of a power dam when it is being erected under legislative authority is the gist of the decision of the North Carolina Supreme Court in the case of Tucker & Carter Rope Co. vs. Southern Aluminum Co., 81 "Southeastern Reporter," 771. The court said: "The defendant's dam is being constructed under express legislative authority, and is a lawful structure per se, and cannot be restrained as a public or private nuisance. If, in the course of its lawful operation, it may inflict injury upon the plaintiff, it is amply able to respond in damages. Whether the relief to which the plaintiff shall be entitled will be the recovery of damages or the abatement of the height of the dam is a matter which will arise when the facts are found; but certainly the courts will not stop the construction of the dam more than 18 months before its completion upon the allegation of the plaintiff, which is denied in the answer, that it will injure its property if built to the height that is proposed."

Effect of Washington Public Service Commission Law—As construed by the Washington Supreme Court in the recent case of Tacoma Railway & Power Co. vs. City of Tacoma, 140 "Pacific Reporter," 565, the Public Service Commission law of that state "deals only with the questions of safety, efficiency, rates and equality of public service. The power to grant a limited franchise is still in the city. No power was given to the public-service commission to grant, modify, or abrogate franchises or contracts arising out of franchises, except in regard to rates and the regulation of service in respect to its safety, efficiency and equality. It was not the purpose of the act to enlarge franchises, or to require the performance of acts being exercised under a franchise which could not be legally exercised, or for a longer period than such acts could be legally exercised." Hence, it is found that the law did not abrogate a condition in an electric franchise previously granted by the City of Tacoma to an electric company, providing that it should not furnish electricity for lighting purposes.

Cause of Turbine Failure

The "Journal of Electricity, Power and Gas" of Apr. 17 contains the finding of the board which investigated the recent turbine failures at the Fruitville plant of the Southern Pacific Co.

It appears that the trouble began by one of the turbines losing six blades of the impulse element. The load was shifted to the other turbine, but on the following day practically all the intermediate blading of the second machine let go. The first machine being open and under repair at this time, the service was crippled for several hours. Investigation showed the cause of the blade failure in the second machine to have been the rusting of the metal in which the blades are secured. This permitted some of the blades to come out and in turn rip out others, until the entire intermediate stage had been destroyed. It is believed that the rusting resulted from leakage of steam past the throttle when the machine was stationary. It is very difficult to keep the throttles absolutely tight, but arrangements have been made so that in the future this leakage will exhaust to the atmosphere instead of into the turbine casing. Moreover, rusting will be prevented by the introduction of brass lining strips, which the makers are now recommending with this type of turbine.

Ice Plants Not Immune from Accidents

The fact that the refrigerating industry in which chemicals and highly compressed gases are used in connection with tanks, piping and moving machinery is not immune from accidents is attracting the attention of municipal authorities to such an extent that regulations for installing and operating the plants have been drawn up and put into effect in many localities. No doubt, these regulations will have to be revised as experience is gained in their application, and in this respect they may be expected to have a history similar to that of analogous regulations applying to steam boilers. As in almost every other industry, the majority of the accidents that occur are avoidable, provided sound engineering principles are followed in the design, installation and operation of the plants. It follows, then, that the engineer who designs the plant and the man who supervises the installation should bear in mind the question of safety, and it is equally important to place competent men in charge of the operation of the plants, because the judgment and ability of the men are exceedingly important factors in preventing accidents.—"Travelers Standard."

Testing a Refrigerating System with Air

It is customary to test a refrigerating system with air pressure before charging with ammonia. This should be carefully done by experienced men to avoid an explosion by the ignition of the vapor from the lubricating oil, caused by the heat of compression.

A thin coating of lard oil should first be applied by hand to the walls of the compressor cylinders and the compressor allowed to run until the pressure reaches 100 lb. or more. It should then be stopped long enough to cool down, then started up again and operated until forty or fifty pounds of additional pressure is obtained, then stopped again. When sufficiently cooled it should once more be started, but at reduced speed, and stopped whenever the discharge pipe becomes hot enough to be uncomfortable to the hand. If these precautions are taken there is little chance of an explosion from internal causes during the test. The men should be kept away from the apparatus as much as possible, however, as there is always a possibility that an accident may occur through the failure of an imperfect joint or from unforeseen weakness in some other part.

Some Precautions Ice-Plant Engineers Should Observe

The operating engineer of a refrigerating plant should remember that he is subject to many of the hazards that are to be found in the ordinary power plant and also to some additional ones. For example, in compressing air he should never use a machine that has recently been used to compress ammonia, and in opening gage-cocks he should stand at the side rather than in front of the gage-glasses. Such precautions as standing at the side rather than in front of cylinders or compressors and refraining from calking pipes or tightening up fittings while they are under pressure are generally understood, but often disregarded. It is particularly dangerous to calk joints or tighten nuts or fittings under pressure. Many fatal accidents have been caused in this way.

However carefully a system is designed and installed, a certain amount of liquid is likely to accumulate, and its presence in the compressor is always a source of danger. The obvious remedy is to provide a properly located relief valve of sufficient capacity to permit the discharge of practically all the liquid present before the piston reaches the end of its stroke. There are cases where considerable difficulty may be experienced in equipping compressors with such devices, but the greater safety gained is well worth the trouble.

Every steam engine should be provided with a safety stop wholly independent of the ordinary governor. In case the governor fails to work properly and the engine starts to "race," the independent safety stop is supposed to operate as soon as the speed exceeds a predetermined limit, shutting off the steam, bringing the engine to a standstill, and preventing the bursting of the flywheel and other serious consequences.

Piston rings formerly caused considerable trouble, but ordinary snap rings are now used with satisfactory results, so far as accidents from this cause are concerned.—"Travelers Standard."

Ice-Making Plants in the United States

There are in the United States over 12,500 ice-making plants, having an aggregate annual output of about twenty million tons. This does not include the thousands of private refrigerating plants in small restaurants, meat markets, grocery stores and private dwellings. The principles of artificial refrigeration are being applied in more than 150 different industries, including among others mining, paper making, woolen and silk manufacturing, laundering, and tobacco manufacturing.

OBITUARY

JOSEPH G. GANNON

Joseph Charles Gannon, chief engineer of the Greenpoint Hospital, Brooklyn, N. Y., died Apr. 17 from pneumonia. He was 47 years of age and had long been a member of the National Association of Stationary Engineers.

ANDREW J. WILSON

Andrew Joseph Wilson, manager of the Lynn Canadian Refrigeration Co., and a consulting engineer, died Apr. 18, from heart failure. He was 39 years of age and had spent twenty years in Toronto, Can., where his death took place.

PERSONALS

John Sabin, who likes to recall that he is the man who sold the first Bundy trap something more than a quarter of a century ago, has been appointed general manager of the Nashua Machine Co., the manufacturer of the trap

ENGINEERING AFFAIRS

The American Boiler Manufacturers' Association will hold its 1915 convention at the Lawrence Hotel, Erie, Penn., on June 21, 22 and 23. Among other matters the convention will consider the standardization of a uniform cost system and of material, workmanship and terms of payment clauses in specifications. The committee on the A. S. M. E. Boiler Code will report and ways and means will be discussed for securing the adoption of the code in the several states. The attendance of all boiler manufacturers in the United States and Canada is requested. Those expecting to be present should notify the secretary, J. D. Farasey, East 37th St. and Erie Railroad, Cleveland, Ohio.

The National District Heating Association will hold its seventh annual convention on June 1, 2 and 3 at the Hotel Sherman, Chicago. The following papers will be presented: "Commercial End of the Heating Business," by C. F. Oehlman.

Denver Gas & Electric Co.; "Operating Experience with Bleeder Type Turbines," by F. W. Laas, chief engineer, Iowa Railway & Light Co., Cedar Rapids, Iowa; "The Hot Water Heating System at the Grand Central Terminal," by W. G. Carlton, New York City; "A Pressure Study of a Steam Distribution System," by C. C. Wilcox, engineer, Hodenpyl Hardy Co., Jackson, Mich.; and "Exhaust Steam vs. Live Steam for Heating," by George W. Martin, New York Service Co., New York City.

NEW PUBLICATIONS

ELEMENTARY ELECTRICITY AND MAGNETISM. By W. S. Franklin and Barry MacNutt. Published by the MacMillan Co., New York, 1914. Size, 4½x7½ in; 174 pages; illustrated. Price, $1.25 net.

A simple and well-illustrated presentation of the principles of electricity, studied from its effects rather than from the theoretical standpoint. The pump analogy is used to advantage in describing electromotive force and resistance. While the book is intended primarily for the student, its usefulness to the practical man might have been enhanced had more of the illustrations been selected from modern commercial apparatus.

HEAT ENGINEERING. By Arthur M. Greene, Jr., Professor of Mechanical Engineering, Rensselaer Polytechnic Institute. Published by the McGraw-Hill Book Co., Inc., New York. Cloth; 462 pages; 6x9 in.; 198 illustrations. Price, $4.

This volume is announced as a textbook of applied thermodynamics for engineers and technical students. The first chapter contains a brief review of the theory of thermodynamics. Chapters follow on heat transmission, air compressors, the steam engine, the steam turbine, condensing apparatus, internal-combustion engines and refrigeration. Each chapter is concluded by a series of topics and problems. The topics consist of a series of questions relating to the text and the problems (without answers) illustrate its use. The book is decidedly unusual in its treatment of the steam boiler. The combustion of fuel in boilers is briefly described in the section relating to internal-combustion engines, but otherwise a consideration of the steam boiler, its theory, design and performance, is missing. As half of the book applies to apparatus using steam, the omission seems unexplainable. With this exception the book appears to present a useful outline of applied thermodynamics.

ENGINEERING ECONOMICS. By John C. L. Fish, Professor of Railroad Engineering, Leland Stanford, Jr., University. Published by the McGraw-Hill Book Co., Inc., New York. Cloth; 217 pages; 6x9 in. Price, $2.

The title of a book is sometimes descriptive of its contents. Professor Fish's treatise, in spite of its title, does not attempt to set forth laws of wealth peculiar to engineering, but it does explain the factors on which depend the long-run least cost of engineering structures. The book deals mainly with the economic selection of the means of accomplishing engineering ends, and this selection is defined as the choice based on the long-run least cost. The opening chapters are devoted to the derivation of formulas for calculating simple and compound interest and to an explanation of sinking funds, capitalized value and other relevant financial terms. The essential components of first cost, such as investigation, promotion and construction expenses, are next outlined; and scrap value, depreciation and amortization are defined. The application of these terms is shown in a chapter on the elements of yearly cost of service. The method of figuring amortization and interest charges is clearly and completely handled, but the attention paid to operation and maintenance expenses seems inadequately brief. No doubt, the author emphasized the financial and accounting problems, believing that the engineer needed no information on material and labor expenditures. The elements described are illustrated by fifteen numerical examples, four of which apply to the power plant. A useful feature is the list of depreciation rates accepted by various legal authorities, in which apear a number of items of power-plant equipment. There are also a number of references to published cost data and to estimating methods used in designing engineering structures. While the book seems to have been written chiefly for the designing, it should prove useful to any engineer requiring a working knowledge of the principles underlying cost-of-operation calculations.

ENGINEERING EXPERIMENT STATION BULLETIN

Volume 10 of the "Bulletins of the Engineering Experiment Station," University of Illinois, has recently come from the press, bound in half-leather and containing reports of the work at the experiment station from September, 1913, to April, 1914. The subjects covered are: The Strength of I-beams in Flexure, by H. F. Moore; Coal Washing in Illinois, by F. C. Lincoln; The Mortar-Making Qualities of Illinois Sands, by C. C. Wiley; Tests of Bond between Concrete and Steel, by D. A. Abrams; Magnetic and Other Properties of Electrolytic Iron Melted in Vacuo, by T. D. Yensen; Acoustics of Auditoriums, by F. R. Watson; and the Tractive Resistance of a 28-Ton Electric Car, by H. H. Dunn.

BUSINESS ITEMS

The M. W. Kellogg Co., New York, has moved its offices into larger quarters at 90 West St.

E. G. Calles Co., Chicago, Ill., has been appointed agent for the S-C Regulator Co., Fostoria, Ohio, for the Chicago territory.

The McClave-Brooks Co., Scranton, Penn., has opened a Boston office in the Equitable Building, No. 202, in charge of S. C. Smith, manager.

The Pittsburgh branch office of the Bristol Co., Waterbury, Conn., has been moved from 1670 Frick Annex into better quarters at 832 Frick Building. R. B. Anthony is district manager.

The Wilson-Snyder Manufacturing Co. and the Wilson-Snyder Centrifugal Pump Co., of Pittsburgh, Penn., have opened a branch office at 52 Vanderbilt Ave., New York City, in charge of A. H. Sherwood.

The general sales department of the Nashua Machine Co. will hereafter be located in the principal office of the company, in Nashua, N. H. A Boston office will be maintained for New England business, in charge of E. M. Stevens, who has been associated with the business for many years.

M. N. MacLaren, New York manager of the Nordberg Manufacturing Co., of Milwaukee, Wis., builder of Corliss engines, uniflow engines, poppet-valve engines, high-compression oil engines, air compressors, hoisting engines, blowing engines, electric hoists, pumping engines, steam stamps, etc., announces the removal on Apr. 26 of the New York office from 42 Broadway to the new Equitable Building, 120 Broadway.

The C. W. Hunt Co., Inc., owing to increasing business, has moved its New York office from 45 Broadway, where it has been for 28 years, to the new building of the Adams Express Co., 61 Broadway. It will occupy a suite of offices on the 11th floor, which will give it much better facilities for transacting business. The company is a large manufacturer of coal-handling machinery, conveying machinery and small motor trucks.

The Wright Manufacturing Co. (alarm water columns, Emergency and Victor steam traps, Cyclone exhaust heads), the Austin Separator Co. (steam and oil separators), the Murray Specialty Mfg. Co. (Murray automatic boiler-feed regulators) have moved from 55-59 Woodbridge St., West, to larger and better quarters at 97-101 Woodbridge St., West, Detroit, Mich. The Murray Co. has just issued an attractive catalog, which can be had on application to the new address.

The Bruce-Macbeth Engine Co., Cleveland, Ohio, has recently made the following shipments: One 100-hp. natural-gas engine to the Fedders Manufacturing Co., Buffalo, N. Y.; one 350-hp. natural-gas engine and Steam Process to the Mansfield Milling Co., Mansfield, Ohio; one 150-hp. natural-gas engine to the Galion Iron Works & Manufacturing Co., Galion, Ohio; one 125-hp. natural-gas engine to the Setter Brothers Co., Cattaraugus, N. Y.; one 150-hp. natural-gas engine to the Dunn-Taft Co., Columbus, Ohio; one 150-hp. natural-gas engine to the Fostoria Glass Co., Moundsville, W. Va.; two 90-hp. natural-gas engines to the Brookville Glass & Tile Co., Brookville, Penn.

Kerr Turbine Co., Wellsville, N. Y., is distributing Bulletin No. 51, "Economy Geared Turbines," which explains the great advantages often obtained by interposing gears between turbine and driven generator, pump, blower or pulley, and also explains the new method by which Economy turbine gears are so accurately hobbed that no grinding or polishing is necessary for finish. A copy of this bulletin will be sent on request. Recent sales made by the Kerr Turbine Co. include the following: City of Atlantic City, N. J., 18,000,000-gal. Economy turbo-pump; City of Baltimore, 500-kw. Economy turbo-generator; City of Williamsport, Penn., 425 hp. turbine for driving a pump; City of Youngstown, Ohio, two 250-kw. turbo-alternators; dredge "Columbia," Port of Portland, Ore., two 1000-hp. geared turbines; Swift & Co., Chicago, 3 turbine units; Christian Moerlein Brewing Co., Cincinnati, 300-kw. turbo-generator; Carnegie Steel Co., Farrell, Penn., 125-hp. turbine; Jones & Laughlin Steel Co., Woodlawn, Penn., 325-hp. turbine; National Tube Co., Christy Park Works, McKeesport, Penn., 350-hp. turbine. Export orders include East Hull Gas Co., Groves, England; Corporation Gas Works, Birkenhead, England; and Armour de la Plata, Argentine.

✕

The Flow of Steam from one vessel to another through an orifice with parallel sides increases as the pressure difference increases, down to 58 per cent. of the absolute initial pressure. A greater pressure difference does not affect the velocity, even though discharging into a perfect vacuum. For example, steam at 100 lb. pressure will increase in velocity as the pressure against which it discharges diminishes down to 58 lb., then the velocity of the flow will remain constant no matter how much the receiver pressure may be reduced—even to a perfect vacuum. Therefore, steam at approximately 25⅓ lb. discharging into the atmosphere has attained the maximum velocity possible in such a nozzle, which is 1470 ft. per sec., because 58 per cent. of 25⅓ equals 14.7, or ordinary atmospheric pressure.

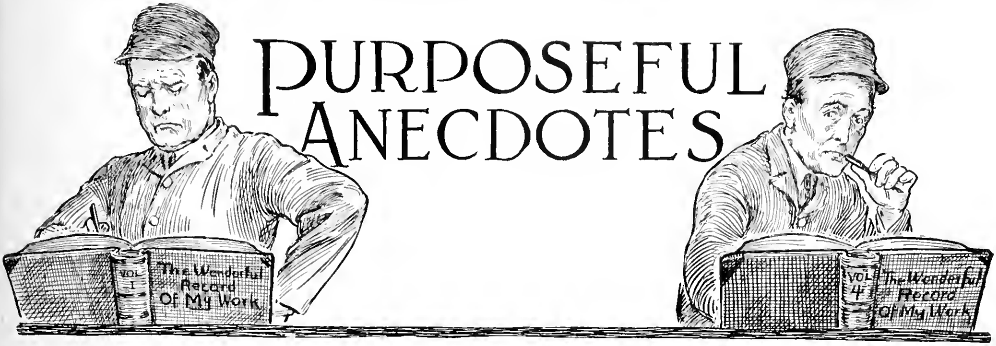
POWER GENERATION AND TRANSMISSION

POWER

ONE OF THE HILL ENGINEERING WEEKLIES

Vol. 41 NEW YORK, MAY 18, 1915 No. 20

PURPOSEFUL ANECDOTES



How I Earned My Raise

AFTER my first year in charge of our power plant I was told by the owner that my work was satisfactory—that I would be retained at the same salary.

The news, however, did not please me much. I had hoped for a raise. Why didn't I get it? Would I have to work another year at the same salary?

The more I thought about it, the more peevish I became, until I finally decided on a unique plan for throwing up my job. I would revenge myself by "heaping coals" of fire on the head of the owner. I would prove that I'm "game."

I began by working up a written "process system" that would enable my successor to pick up the plant where I left off, without difficulty.

I put down in black and white the peculiarities of our grates, boilers, draft, etc., and the method of firing that I believed to be best—

Position of ash doors, rate of feed of stokers, speed of fans, method of cutting out boilers, when to do it, method of cleaning, dangers—And other points that had given me trouble during my year in charge.

But I found that my grouch was beginning to leave. Writing about my plant made me THINK. I began to wonder if, after all, my methods were BEST. My interest increased. I studied. I experimented. And as a result, I learned that my old methods were NOT best, and I began putting BETTER methods in force.

I continued writing my process system, altering it wherever improvements in operation were made, and at the end of six months I had covered the entire plant. But I realized by this time that it was not yet at its best—that even better overall economy was possible and should be attained. I saw that we needed a little additional equipment and I could PROVE it with actual figures.

So, instead of resigning, as I first intended to do, I handed my process system to the owner, told him what I had done and what I had learned. I told him what was needed and why, and I won my point.

I did not have to wait the year out for my raise. TRY IT.

Boiler Plant of Union Brewery

By Thomas Wilson

SYNOPSIS—An isolated boiler plant of 1500-hp. rating equipped with complete coal- and ash-handling systems. Boilers have the new marine settings, and special precautions have been taken to insure a minimum loss of draft between the stack and furnace.

An uptodate boiler plant, unusually complete for its size and containing the latest features in boiler-room design, has recently been completed by the Otto F. Stifel Union Brewing Co., in St. Louis. The commercial life of the old boiler plant was rapidly drawing to a close, and the early intention of enlarging the brewery made the new plant imperative. As a starter only the boiler house was erected, across the street from the brewery. It is the intention to erect an engine room adjoining, but at present the old equipment, consisting of three engine-driven ammonia compressors and two generating units, is supplied with steam at 150 lb. pressure from the new boiler house. The pipe supplying steam for the above machines and for industrial uses in the brewery passes through a tunnel under the street. At the delivery end the supply is controlled by an electrically operated valve.

The new building is of fireproof construction throughout, as it is made up of brick walls, concrete floor, tile and concrete roof, steel sash and ventilators, and no wood except the doors. The interior dimensions are 47x64 ft., and the height from the floor to the roof trusses is 38 ft. It is equipped with three 500-hp. vertical water-tube boilers, and there is space for one more of the same size. The boilers, shown in Fig. 1, now carry a pressure of 150 lb. gage, but eventually will supply steam at 175 lb. pressure to the equipment of the new engine room. A feature of the boilers is the marine-type setting recently adopted in stationary work to reduce the radiation and eliminate infiltration of air. It is made up of 4½ in. of "circle" firebrick and 3 in. of asbestos fiber covered by steel plate. The exterior furnace walls, made up of 9 in. of firebrick and 12 in. of common brick, are protected by ¼-in. asbestos board and the steel-plate covering. This construction prevents leakage from the sides, and as the stoker works under a ledge it is easy to block off the air from the front.

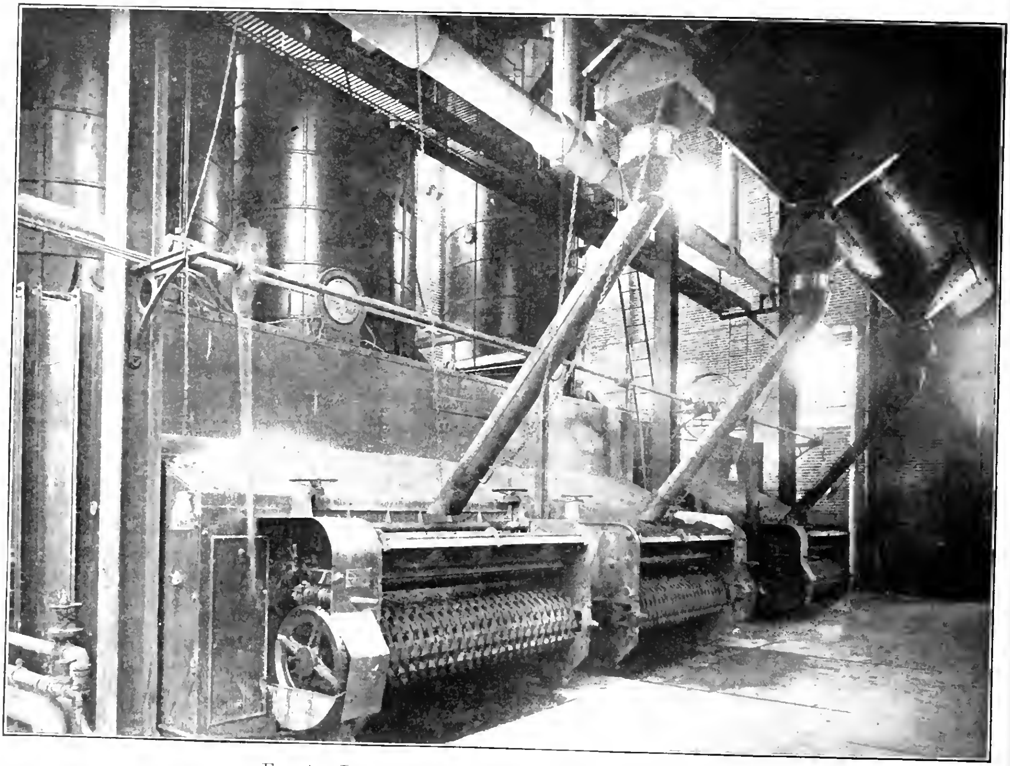


Fig. 1. Boiler House of the Union Brewing Co.

Stokers of the chain-grate type were installed, having an active width of 7 ft. 6 in., a length of 11 ft. 7 in. and an area of 87 sq.ft. To the 5000 sq.ft. of heating surface contained in each boiler, the above area bears a ratio of

1 to 57.5. This is somewhat higher than the usual 50 to 1, but in this particular case the grate surface was made less than the average for the following reasons: As fuel had to be carted eight blocks, it was decided in the interests of economy to use a high grade of Illinois

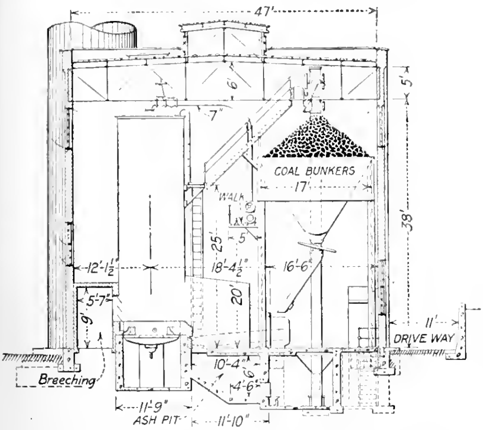

FIG. 2. TRANSVERSE SECTION OF BOILER PLANT

reduction of grate area was desirable and its installation an evidence of good engineering.

An inspection of the drawings will show that special precautions were taken to reduce to a minimum the loss of draft between the stack and the furnace. In the first place, under average conditions a boiler of the type installed shows a draft loss approximately only 0.2. This is from the boiler side of the damper to the entrance from the furnace. The low drop is partly due to the static effect of the hot gases rising in the first pass and dropping in the second pass after being cooled by coming in contact with the heating surface. Through three-wing dampers the gases discharge directly to a rectangular breeching built up from the floors and running straight to the stack. The breeching tapers toward the farthest boiler, but at the stack is 5 ft. 7 in. wide and 9 ft. high, giving an area of 50 sq.ft. in round numbers. It is made of tile, firebrick lined, and has a run of 57 ft.

The stack is one of the finest for its size in St. Louis. It rises 185 ft. above the boiler-room floor and has an internal diameter of 7 ft. 6 in. The shell is made of a special radial tile filled with reinforced concrete, and for a height of 70 ft. is lined with firebrick. An air space of 3 in., unfilled, separates the lining from the shell. For a gas temperature ranging around 500 deg. and allowing 100 lb. of gas per horsepower, the stack is figured to

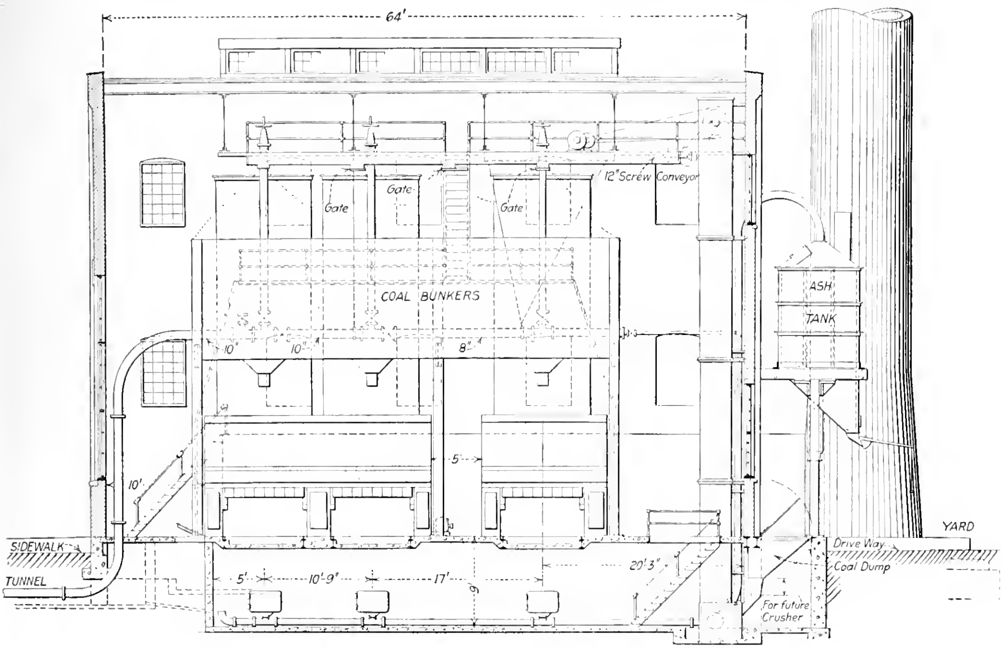

FIG. 3. LONGITUDINAL SECTION SHOWING GENERAL ARRANGEMENT

washed coal. This quality of coal requires less grate surface than an inferior grade as it contains less impurities, and as it is high in volatile more of it can be burned per square foot of grate than coals containing more ash or higher in fixed carbon. For these reasons and because an excellent stack had been provided, which is capable of producing a strong draft over the fire, a

produce a draft of 1 in. of water at the base for the four boilers and 1.1 for the three boilers now installed. For higher temperatures the draft will be slightly greater. While clean, the breeching should not cause a drop of more than 0.1 in. and the return from the breeching into the stack 0.05 in. Taking the boiler farthest from the stack, interference by the gases from the two other boilers will cause a drop of 0.1 in.—0.05 for each boiler. The right-angle turn of the gases in the breeching at the outlet of the boiler will cause a loss of 0.05 in., the damper [illegible] 0.05 in., the boiler 0.2 in. and the right-

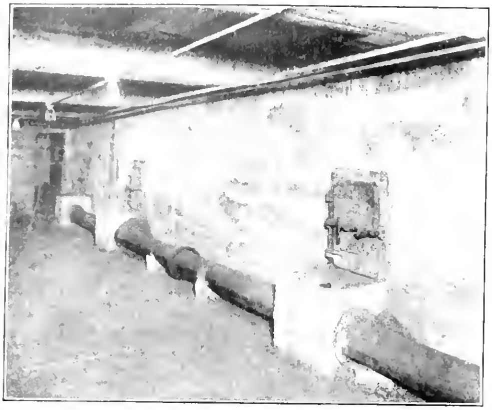

Fig. 4. Part of Ash-Removal System in Front of Ashpits

boilers approaching the stack the draft over the fire will be slightly higher, but with the three-wing dampers the intensity can of course be varied to suit the load conditions, thickness of fuel bed and the character of the coal.

It may be of interest to check the relative areas of stack, breeching and grate, and these will be compared on the basis of three boilers, as the fourth, when installed, will in all probability be held as a reserve unit. With an internal diameter of 7.5 ft., the stack has an area of 44.2 sq.ft., while the breeching, as previously stated, has 50 sq.ft. The breeching, then, is a trifle larger than the stack, as it should be, and its area bears a ratio to the connected grate surface of 1 to 5. This conforms with the average ratio adopted in recent practice. Each square foot of sectional area in the stack is intended to serve 5.9, or nearly 6, sq.ft. of grate, and each square foot of breeching 5.2 sq.ft. of grate. Per boiler horsepower, still considering the three units, the stack has an area of 0.0291 sq.ft. and the breeching 0.0333 sq.ft.

Figs. 2 and 3 indicate the arrangement of the plant, the layout and size of the steam piping, and the provisions made for handling coal and ashes. A feature worthy of notice is the walks, giving ready access to the top of the boilers, the steam header and the screw conveyor over the

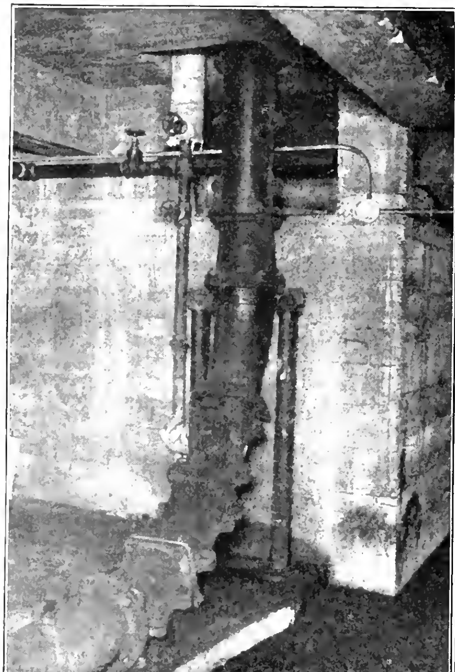

Fig. 5. Bend at Which Steam Nozzle Is Introduced

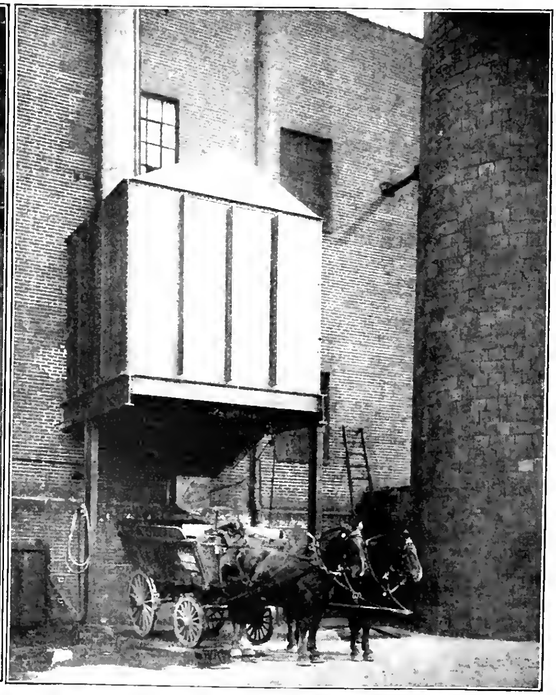

Fig. 6. The Receiving Tank for the Ashes

angle turn from the furnace up into the boiler, 0.05 in. The various drops total 0.6 in., and deducting this loss from 1.1 in. leaves a draft of 0.5 in. over the fire for the farthest boiler. With the fourth boiler installed the above draft would be reduced to about 0.35 in. For the

bunkers. As previously stated, coal is carted to the plant and dumped from the yard into a hopper shown at the right in Fig. 3. Provision has been made here for a coal crusher, which may be installed at a future date. From the hopper the coal slides into the boot of a bucket elevator and may be hoisted at the rate of 30 tons per hour. At the top of the boiler room the coal is transferred to a screw conveyor and may be dumped through any one of three gates into a suspended steel bunker of 175 tons' capacity. A separate spout for each boiler carries the coal to the hoppers of the stokers. All three stokers are eccentric driven from a shaft turned by a 5½-hp. motor.

Ashes are removed by a vacuum system using a steam nozzle to supply the motive power. As shown in Figs. 4, 5 and 6, this consists of about 100 ft. of 8-in. chilled cast-iron pipe having walls 1 in. thick, a steam nozzle and a tank to receive the ashes. The horizontal run in front of the ashpits is close to 50 ft. and the rise about 43 ft. The nozzle is located in the basement at the point where the pipe turns upward. Its location is shown in Fig. 5. The photograph was taken before the steam pipe leading to the nozzle had been fully covered. The far end of the ash pipe is left open, and when steam is turned on, air is pulled through the pipe at high velocity. Ashes raked from the pits into the pipe are carried along with the current of air, and when they pass the nozzle, are positively forced up into the tank by the jet of steam. Through a gate at the bottom of this tank the ashes are loaded into wagons and carted away.

The system was designed to handle 200 lb. of ashes per minute, or 6 tons per hour, with a steam pressure of 114 lb. at the nozzle. The nozzle is ⅝ in. diameter, and at the above rate will discharge against atmospheric pressure about 2000 lb. of steam per hour. Charging 22c. per 1000 lb. for steam, the cost for steam only per ton of ashes removed would be 6.4c. In a plant of this size additional labor should not be required to operate the system. The charge to add per ton for depreciation, interest on investment, etc., cannot be determined without knowing the amount of ashes removed per year or the life of the equipment, but at a rough estimate the total cost should not exceed 10 to 12c. per ton.

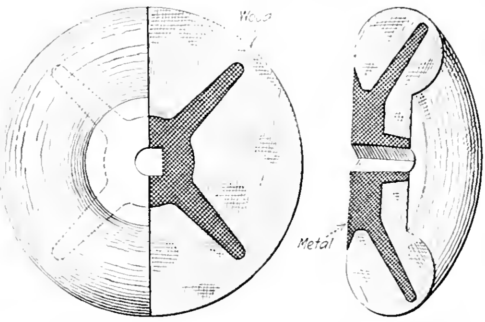
Feed water for the boilers comes from a 1000-hp. open heater in the old plant. It flows by gravity to the pumps, one of which is a 10x6x10-in duplex and the other a 12x7x12-in. simplex taken from the old equipment. The water lines are arranged to feed the boilers at either top or bottom, and for the present the water is fed at both points, with a view to reducing pulsations set up by the single pump. There is also a duplication of feed mains so that one pump may supply cold water for washing one or more boilers while the other is supplying the hot feed water as usual.

At present means for measuring water and weighing coal have not been provided. It is the intention, however, to install at an early date a water meter, coal scales below the bunker, a damper regulator and CO_2 apparatus. With these refinements so necessary for the keeping of accurate records, the plant, for its capacity, will be one of the finest in the country. Including building, stack, the fourth boiler and all equipment now installed, the total cost will reduce to $10 per boiler horsepower.

Ruebel & Wells, consulting engineers, of St. Louis, designed and erected the plant under the direction of Phillip Scheuerman, general manager of the brewery.

"Kantsplit" Valve Handle

One of the annoyances in a steam plant is the cracking and working loose from their metal seats of wooden valve handles such as commonly used on water-column



Showing How the "Kantsplit" Valve Wheel Is Made

cocks and the like. This trouble renders the handles useless and wooden handles have in many cases been replaced by metal, which, when used with steam, becomes hot and disagreeable to handle.

The "Kantsplit" handle seems to be so constructed as to prevent splitting and working loose from its bottom plate. The illustration shows how it is made. The handle is of birch or maple wood, which is used as a mold into which is cast a metal wheel, the spokes of which bind the fibers of the wood together and prevent it from splitting.

As the metal "freezes" to, and engages projections of, the top and bottom plate so as to make the finished handle one piece, the bottom plate cannot easily work loose.

The handle is inexpensive and is made by the Holton-Abbott Manufacturing Co., 61 Gorham St., West Somerville, Mass.

PRINCIPAL EQUIPMENT OF STIFEL BREWERY PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
3	Boilers	Vertical water-tube	500-hp.	Generate steam	150-lb. pressure, natural draft, stokers	Wickes Boiler Co.
3	Stokers	Chain grate	87-sq.ft	Serve boilers	Motor driven	Laclede-Christy Clay Products Co.
1	Motor	Direct-current	5½-hp.	Drive stoker shaft	110 volt, 1000 r.p.m.	Sprague Electric Co.
1	Ash removal system	Vacuum	8-in. pipe, ⅝-in. nozzle	Convey ashes from pits to tank	Steam pressure 114 lb. at nozzle, capacity 200 lb. per min.	Girtanner-Daviess Engineering & Contracting Co.
1	Coal handling system	Bucket elevator and screw conveyor	30 tons per hour	Transfer coal to bunker	Geared to motor, ratio 7 to 1	Stephens-Adamson Mfg. Co.
1	Stack	Radial tile	185-ft. high, 7½ ft. dia.	Serve boilers	1 in. draft at base	Wiederholdt Construction Co.
1	Pump	Duplex	10x6x10-in.	Boiler feed	150-lb. steam pressure	Epping-Carpenter Co.
1	Pump	Simplex "Hooker"	12x7x12-in.	Boiler feed	150-lb. steam pressure	Reliance Machine & Tool Works
2	Lubricators	Force feed		Serve boiler feed pumps		Hills-McCanna Co.
1	Heater	Open	1000-hp.	Heat boiler feed water	Exhaust steam	Harrison Safety Boiler Works

Figures on the cost of generation in small municipal plants are always interesting. The following are taken from the annual report of the 500-kw. municipal plant at Topeka, Kan., and include depreciation at 5 per cent., interest at 4 per cent. and taxes at 1.725 per cent.

Net cost per kw.-hr. at switchboard	$0.0165
Net transmission cost per kw.-hr.	0.00784
Gross cost per kw.-hr. at lamps, including all operating, overhead and fixed charges	0.0427
Net cost per arc lamp per year	24.31
Net cost per 100-watt series tungsten lamp per year	14.66

Interior Wiring for Lighting and Power Service--III

By A. L. Cook

SYNOPSIS—How to figure the sizes of branch circuits and feeders in lighting service for both direct- and alternating-current systems. The next installment will take up power circuits.

Two-Wire System

The two-wire system, previously described, is the simplest arrangement of lighting circuits. In laying out this or any other arrangement the voltage drop for the circuits must first be calculated. For direct-current circuits the drop can be calculated from the formula,

$$e = \frac{21.4 \times D \times I}{circ.mils}$$

where

e = Total drop in the two wires;

D = Distance in feet between the feeding point and the load; in other words, the distance one way;

I = Current in amperes.

To determine the size of wire for a given loss in volts the formula may be transposed to

$$Circ.mils = \frac{21.4 \times D \times I}{e}$$

The number 22 is sometimes used instead of 21.4 but the latter is satisfactory unless the wires are to be located in a very warm place. An example of the use of these formulas may be helpful. Suppose the feeder is No. 00 B. & S. (133,100 circ.mils.), the length of run 150 ft., and the load 50 amp.

$$e = \frac{21.4 \times 150 \times 50}{133,100} = 1.2 \ volts$$

If it is required to find the size of wire for this circuit with a loss of 1.5 volts,

$$Circ.mils = \frac{21.4 \times 150 \times 50}{1.5} = 107,000$$

Referring to Table 7 (page 642, May 11 issue) it will be seen that the nearest size is No. 0, which is slightly smaller than required.

While any direct-current two-wire circuit can be calculated by means of these formulas, it is more convenient to use some form of chart. The one printed in Fig. 7 is based upon the formula already given and is a modification of a chart devised by R. W. Stovel and N. A. Carle (see *The Electric Journal*, June, 1908). If it is desired to find the drop for the feeder already calculated, start at 50 amp. on the lower left-hand side and follow vertically until this line crosses that for 00 wire; then pass horizontally to the right to the line marked 150 ft. and follow down vertically and read 1.2 volts.

To determine the size of wire as in the second problem, start with 1.5 volts at the lower right-hand side and follow up vertically to the 150-ft. line; then horizontally to the left to the line for 50 amp., which also crosses the No. 0 line at this point.

Suppose it is desired to find the drop when 6 amp. is carried by a No. 12 wire for a distance of 100 ft. The chart does not give a value for 6 amp., but the drop can be figured for 12 amp. and then divided by 2, since it will be half as great as for 12 amp. Using the chart, we obtain 4 volts, so the drop for 6 amp. would be 2 volts.

If it is desired to find the drop for 125 amp. carried on a 300,000-circ.mil cable a distance of 200 ft., the position of the 125-amp. line will have to be estimated between the 100- and the 150-amp. lines. Carrying this up to the 300,000-circ.mil line and then across to the right and down as before will show a drop of 1.8 volts.

Returning to the original problem, compare the size of wire required for 240 volts with that for 120. If the load is 50 amp. at 120 volts, this is $50 \times 120 = 6000$ watts. With the same load at 240 volts, the current would be $6000 \div 240 = 25$ amp., or one-half that for the lower voltage. Hence, the same percentage drop can be allowed for the higher voltage; that is, if 1.2 volts are allowed in the first case, 2.4 in the second will give satisfactory operation. From the chart it will be found that the size of wire required is No. 5. For 120 volts, therefore, No. 00 wire having 133,100 circ.mils is required, and for 240 volts to transmit the same power, only 33,100 circ.mils, or ¼ the size. No. 5 wire is a size not ordinarily used, so that No. 4 would probably be employed, but the saving due to the higher voltage is apparent.

If the load consists entirely of incandescent lamps the current can be determined either by dividing the total watts on the feeder by the voltage of the lamps or by multiplying the current per lamp (see Table 1, page 602, May 4 issue) by the number of lamps. With arc lamps it is best to multiply the current taken by each lamp by the number of lamps. For alternating-current circuits, the same chart may be used if the two wires of a circuit are run in the same conduit and the load consists of incandescent lamps. Alternating-current arc lamps have a power factor of about 0.70 or 0.65, and if a large load of these were to be carried on a feeder the drop would be greater than for direct-current and the method employed for calculating motor circuits, as described later, should be used. For wires not larger than No. 4 the chart can be used without modification for circuits carrying alternating-current arc lamps. For exposed work, where the wires are separated several inches, the drop on the circuits would be greater than for direct current. In the case of branch circuits No. 10 or smaller, the increased drop is small even with arc lamps; consequently, the direct-current chart can be used. For the feeders, however, the drop should be calculated by the method used for motor circuits. If a feeder carries both arc and incandescent lamps, it is not correct to add the two circuits together. This is because of the power factor.

Branch Circuits

The wiring of an electric-light installation is divided into branch circuits, to which the individual lights are connected, and the feeders which supply the branches.

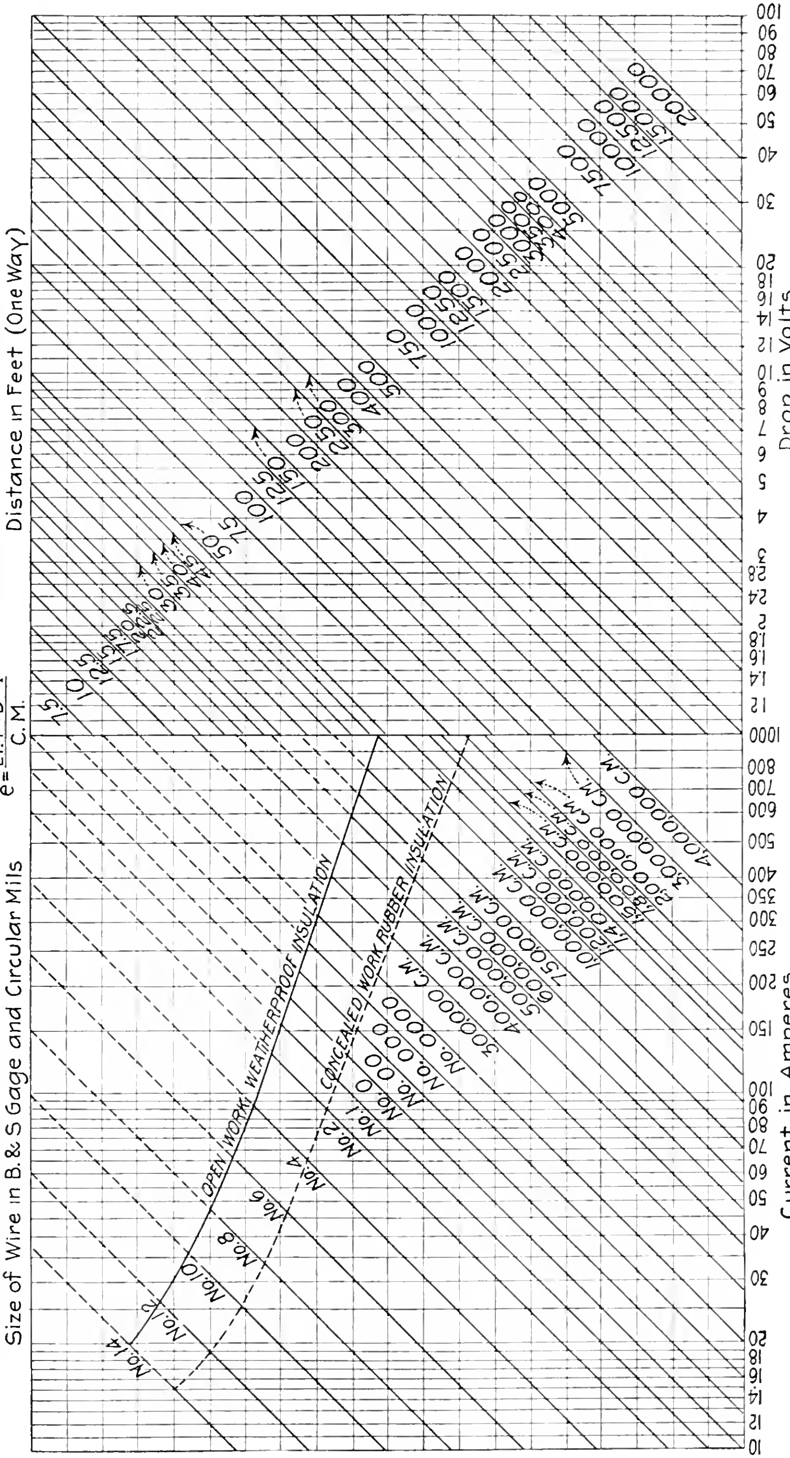


Fig. 7. Stovel-Cable Wiring Chart for Direct-Current Circuits

Sometimes, a feeder supplies more than one group of branch circuits, in which case there are feeders and sub-feeders, or mains, feeding the individual groups. The arrangement of circuits varies to suit conditions. Fig. 8-a shows a scheme sometimes used in mills where the cost must be kept down. Here, mains are run the length of the room and the lights tapped directly from them through individual fuses in the rosettes, no branch cir-

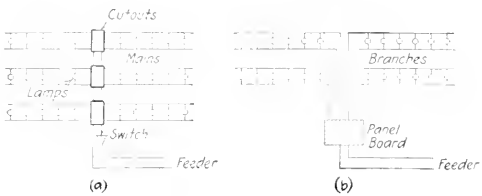

Fig. 8. Arrangement of Branch Circuits

cuits being used. Its principal objections are lack of control of the individual circuits and variation in voltage at the lights, as those nearest the fuse blocks may have a voltage 2 or 3 per cent. higher than those at the extreme end. A modification of this arrangement is shown in Fig. 8-b. Here the lamps are arranged in groups taking not more than 660 or 1320 watts, depending on the kind of outlet, and each group is wired separately to a panel-board. This has the advantage of individual control of the groups of lamps and while more expensive is used extensively, particularly with large-sized lighting units.

Fig. 9 shows an arrangement frequently used for small office buildings and sometimes for factories. Here there is a panel-board on each floor, from which the branch circuits are run. This has some of the objections found in Fig. 8-a since the drop to the panel on the top floor will be greater than that to the first floor. However, it is fairly satisfactory for buildings of four stories or less, particularly if the load on each panel is relatively small. In Fig. 10 is shown a modification of this arrangement which results in much better voltage regulation, since the drop to each panel can be made about the same. A further modification would provide one feeder for each panel, but this is justified only when the load on the panel is very large. As a rule, not more than three panels should be placed on one feeder.

It is assumed that the number, size and location of the outlets have been settled as previously described. If control switches are to be provided, they should be located carefully. For offices and similar places they should be placed about 4 ft. from the floor, near the entrance door on the lock side, so as not to be hidden when the door is open. In factories they may be located on columns or side walls and should be grouped as much as possible, to save wiring. When the tenants are supplied with meters they should be placed near the panel-board if possible, or in the various offices. Meters are not commonly used, owing to the cost, the usual method being to charge each tenant a flat rate for lighting. The panel-board should be as near the center of the load which it is to supply as possible, as this results in more uniform voltage on all the lamps. For office buildings the best location is in the halls, the panels being, as far as possible, at corresponding points on the various floors, so as to give direct vertical runs for the feeders. For factories they should be near the center of the room, if feasible, and for very large areas the room may be divided into two or more parts and a panel provided near the center of each part. The number and location of panels are fixed by the number of branch circuits and their lengths. It is unwise to use long branch circuits because of the high drop, and for uniformity in wiring it is generally best to settle on one size of wire for all branch circuits irrespective of their lengths.

As a guide in locating the panel, it is convenient to know the length of branch which can be used and not exceed 1.5 per cent. drop. Table 8 gives these values for the sizes of wire ordinarily used for branches, with the maximum load allowable and also with smaller loads. When using this table the distance given is that to the center of the load. For example, if there were 8 outlets of equal size and spaced 10 ft. apart, the center of load would be at the center of the row; that is, a distance of 35 ft. from one end. If from the panel to the first lamp were 20 ft., the distance to be used in calculating the drop would be 55 ft., and it would be assumed that the entire load on the branch was to be carried to that distance. If the units are not all the same size the center of load would shift toward the larger ones. To calculate the center of load in this case multiply the distance from each unit to the panel-board by the number of watts or amperes for that unit, add these values together and divide by the total watts or amperes in the circuit; the result will be the distance to the center of load. With the aid of this table the location of the panel-board may be roughly checked.

The maximum load in watts which may be carried by one branch has already been specified, but it is also necessary to check the number of sockets on each branch. For a 660-watt branch not more than 16 will be allowed, and for a 1320-watt branch 32 is the largest number. These rules apply to the circuits where the lamps do not have individual fuses, but only fuses for the entire group on one branch. These rules would allow the use of sixteen 40-watt lamps in the first case, and thirty-two in the second. Since the lamps are usually larger than this, the number of outlets would generally be less. Sometimes local rules modify these general rules, so it

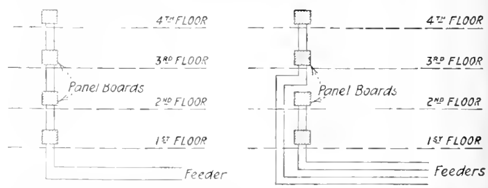

Fig. 9. Arrangement for Small Office Buildings and Factories

Fig. 10 Drop to Each Panel about the Same

is always best to obtain information on this point from all parties interested. In counting the number of sockets, plug outlets for portable lamps must be included. It is important to have each branch circuit fully loaded, as each additional branch which must be provided for on the panel-board makes an additional cost of three or four dollars in the panel; on the other hand, it is frequently necessary to allow for possible extensions of the branch or an increase in the size of the lamps. The extent of this allowance will vary. Thus, an office building, where the lighting requirements might be very different with different tenants, should be more liberally designed than factory lighting, where the requirements are fairly well fixed. For the latter the branches may be loaded to 90 per cent. or more of their capacity, while for the former it is best to allow only 80 to 90 per cent. load.

After the branches have been sketched in, the size of wire should be determined. It is common to use No. 14 for branches, but reference to Table 8 will show that the lengths must be rather short if the allowable drop of 1.5 per cent. is not exceeded. For the usual runs in factories and office buildings No. 12 wire will be found more suitable; and for circuits with 1320 watts, No. 10 may have to be used. It is unnecessary to check all the branch circuits; one or two from each panel, which appear to have the greatest drop, being checked by means of the chart or Table 8. If it is found that the allowable drop is greatly exceeded, a larger wire may be used or a rearrangement of circuits made. If this load is decreased, the number of circuits will be increased, and thus affect the cost of the panel. Therefore, it will generally be preferable to increase the size of wire. In any case the branch circuit should be fused to its maximum capacity as follows:

TABLE 8—BRANCH LIGHTING CIRCUITS

Maximum length of circuit for 1.5 per cent. drop.

Size, B. & S. Gage	Distances in Feet* — 120 Volts — 12 Amp.	10 Amp.	6 Amp.	5 Amp.	240 Volts — 6 Amp.	5 Amp.	3 Amp.	2.5 Amp.
14	29	35	58	70	116	138	232	276
12	46	55	92	110	184	220	360	440
10	73	87	146	174	292	348	...	...
8	116	139	232	278	464	...	...	...

*Note that the distance given is in each case to the center of load and not to the end of the run.

	125 Volts or Less	125 to 250 Volts
660-watt circuit...........	10 amperes	5 amperes
1320-watt circuit..........	20 amperes	10 amperes

Referring to the example given in Table 3 (see page 604, May 4 issue), let us apply these rules to the machine-shop floor. The natural location of the panel would be on one of the columns on the center-line of the room. The column nearest the center would have four bays on one side and five on the other, giving a maximum length of branch circuit of about 112 ft. In this case, it would be best to run the circuit with the length of the room, to facilitate the control, although this compels crossing the beams forming the bays. There would be a maximum of 10 lamps in one row on one side of the panel-board, the distance to the first unit on the farthest row being about 35 ft. and that between end units 67.5 ft.; hence, the distance to the center of the load is $\frac{67.5}{2} + 35 = 68$ ft. 9 in. The load is $\frac{10 \times 100}{120} = 8.3$ amp.

TABLE 9—LOADS ON PANELS

Floor	A Panel No.	B Circuits in Use	C Total Circuits Provided	D Load in Watts	E Amperes Load at 120 Volts	F Maximum Amperes
Basement .	1	4	6	2,160	18	30
First floor.	2	12	16	10,800	90	160
Second floor	2	12	16	10,800	90	160
Third floor.	4	8	10	3,600	30	50
Fourth floor	5	12	16	10,800	90	160
Fifth floor.	6	12	16	10,800	90	160

A No. 12 wire, carrying this load, would give a drop of 1.83 volts, or 1.53 per cent., which is satisfactory. The loads on the panels can now be obtained by adding those on each branch, each plug outlet for a portable light being figured at 50 watts. The size of the panels will be fixed by the number of circuits, plus an allowance for extensions. For panels up to 10 circuits, at least 2 spare circuits should be allowed and for 10 to 20 circuits at least 4 should be provided. These computations, for the example previously discussed, are given in Table 9.

When locating the service connection, or switchboard, care should be taken to place it as nearly central to the load as possible. There is generally little choice, since the board must be located in the basement if the service is underground, and if overhead it must be as close as possible to the point of entrance of the wires. If the supply is from a private power plant the choice of location is influenced by other considerations. The place chosen in any case should be as clean and dry as possible, and provision should be made for preventing access to the board by unauthorized persons.

Feeder Systems

After determining the loads on the panels, it is necessary to plan the feeder system according to the schemes

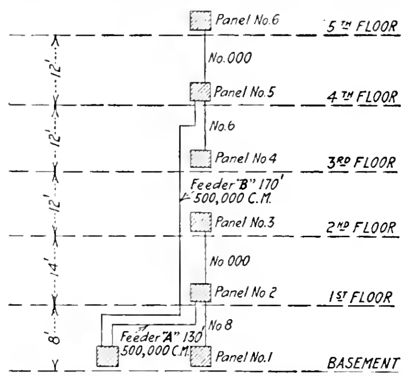

Fig. 11. Riser Diagrams for Factory Building

shown in Figs. 8, 9 or 10. An arrangement similar to Fig. 10 is convenient where it is desirable to provide for cutting off the power from certain sections without interfering with the rest of the lighting. For economy it is desirable to have the load on each feeder as great as possible, but there is a limit to the size of conductor which should be used, particularly where two or three wires are carried in one conduit. For office buildings, particularly, it is difficult to conceal a conduit larger than 2½ in. and to take care of the long-radius bends required for larger conduit. In general, a wire larger than 500,000 circ.mils should not be used. For the system shown in Fig. 9, however, the size may run larger than this, particularly for a two-wire 120-volt system. The feeder system should be planned in a preliminary way, bearing these general statements in mind, a sketch being made showing each panel-board with its load in amperes and the various feeders with their lengths and loads. The load on the feeder should be taken as the total load actually connected to the panels supplied by that feeder. For the example given in Table 9, the actual load in watts is given in column D and the load in amperes is calculated for 120 volts using a two-wire system. Fig. 11 shows the arrangement of feeders supplying the panels.

A reasonable allowance should be made for extensions and for an increase in the lighting load. In any case, the feeder should be sufficient to allow at least 600 watts per branch, or, if the arrangement is such that the larger [illegible] are used 1200 watts per branch may be allowed; this should include the spare circuits. The feeder chosen should then be checked to see that the drop, with the actual load, does not exceed the allowable amount as specified previously. If the drop is too great the feeder must be increased in size.

Column F in Table 9 gives the maximum loads for the example chosen. Referring to Fig. 11, calculate the size of feeder *B*. The length is 170 ft., the maximum load 370 amp. and the actual load 210 amp. This requires a 500,000-circ.mil cable if rubber wire is used. The drop with 210 amp. would be 1.53 volts. The maximum allowable drop, as previously specified, is 1.3 per cent. for a feeder. This is 1.56 volts for a 120-volt system; hence, the size of cable chosen is satisfactory. In this case, since the subfeeders supplying panels 4 and 6 are short, practically all the drop is in the feeder and 2 per cent. could be allowed if necessary. If the drop in the branches is less than 1.5 per cent. it is not satisfactory to add the amount saved in the branch circuit to

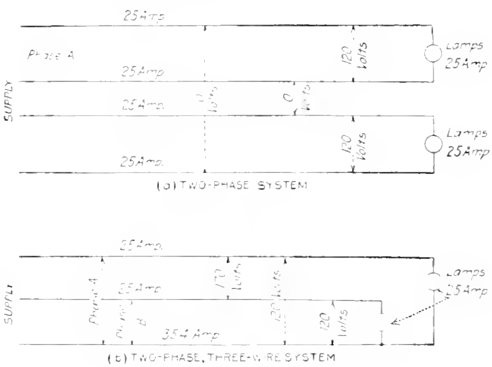

FIG. 12. CURRENT AND VOLTAGE RELATIONS IN TWO-PHASE SYSTEM

the feeder drop, thus making it more than 2 per cent.; instead it should be kept within this limit.

If the total feeder drop exceeds a proper value it must be decreased by increasing the size of feeder or subfeeder. Generally, it is best to increase the main feeder leading to the first panel, as the drop on the subfeeders running to the other panels is usually small. The drop in the subfeeders should be about 0.7 per cent. and in the main feeder 1.3 per cent. When more than one panel-board is carried on a feeder, as in Fig. 10, the subfeeders will be smaller than the main feeders, and would therefore not be protected by the fuses on the latter. To protect these subfeeders, the panel is provided with the necessary fused branch circuits to which they may be connected, these circuits being connected to the main feeder where it enters the panel. With the arrangement of Fig. 9, the size of feeder would be decreased for the panels on the lower floors, the feeder entering the panel-board at the bottom and leaving at the top, and fuses must be provided at the top to protect the subfeeder above. The panel busbars must be large enough to carry the entire current of the panel and the subfeeders connected to it. When the sizes of wires have been checked, the sizes of conduit can be determined by means of Table 6 (see page 641, May 11 issue), bearing in mind that both wires of a circuit must be in the same conduit if alternating current is used.

THREE-WIRE SYSTEM

Calculation of a three-wire system is much the same as that of a two-wire, so that only the points of difference will be discussed. As long as the load is the same on each side of the system there will be no current in the neutral. If, however, the load on the positive side were 20 amp. and on the negative 25, there would be 5 amp. in the neutral. If all the load were removed from the positive side, the current in the neutral would be the same as in the negative wire. Since there is always a chance of the load being different on two sides of a three-wire system, the neutral must be sufficiently large to carry the difference, and is generally made the same size as the outside wires. This is not required by the "National Electric Code," except in certain cases, but it is good practice. If the neutral circuit is opened when the load on each side is the same, there will be no change in the voltage across each group of lamps; but if the negative side, for example, has a larger load than the positive, the lamps on the former would receive less than 120 volts and those on the latter more; hence, these lamps might burn out. Such a case might occur if a fuse in the neutral should blow.

The location of outlets would be the same as for the two-wire system, since the branch circuits are two-wire in any case. The location of panel-boards and switchboards is determined in the same manner, and the arrangement of the circuits may be similar to those shown in Figs. 8, 9 or 10, using three-wire mains and feeders instead of two-wire. The layout of the branch circuits would be made in the manner previously described, and the drop would be limited to about 1.8 volts, since 120 is the voltage for the branches. The branch circuits are so connected to the panels as to give practically half the total load on each side; in other words, to produce a balanced system. The actual load in each outside wire of the feeder would, therefore, be one-half the total for all the lamps supplied from that panel.

The determination of the feeder sizes is governed by the same rules as for the two-wire system. The actual loads in the outside wires would be the sum of the loads for all the panels supplied by that feeder. The maximum load should also be determined by allowing 5 or 10 amp. for each branch connected to either side of the circuit. When these loads have been determined for each main feeder and subfeeder, the size of wire may be chosen by means of Table 7 (see page 642, May 11 issue), using the maximum loads as before. The feeders should then be checked for voltage drop with the actual load. The voltage loss allowable in the feeders is 2 per cent. of the voltage to the neutral, for each side of the system. Thus, if a 120-240 volt system is used the drop for each side of the system may be 2.4 volts. With a balanced load, all of this occurs in the outside wires. If the load were unbalanced, there would be some drop in the neutral, but in any well-designed system this is so small that it may be neglected.

Care should be taken when using the chart, since it gives the drop for a length of wire twice that marked on the various lines, which is the length of run. If the current in the outside wire of a two-wire feeder is used, and the length taken is that for the feeder, then the voltage drop obtained by the chart should be divided by 2 to obtain the drop in a single wire. After the sizes of the outside wires have been determined the neutral may be taken the same, and then the conduit sizes are determined, using one conduit for all three wires if alternating-current is employed.

Referring to the previous example, feeder B would have a maximum load of 185 amp. and an actual load of 105. A drop not exceeding 2.4 volts can be allowed in each of the outside wires, and to carry 185 amp., No. 0000 cable must be used. The drop on a two-wire circuit having a length of run of 170 ft. is 1.8 volts; hence, that for 170 ft. of wire is 0.9 volt, and this is the drop on each of the outside wires of feeder B. The actual voltage loss on the lamps, however, is only 0.9 volt, since they are affected only by the drop in the wires to which they are connected.

Sometimes a three-wire system is arranged so that it can be changed to a two-wire by connecting the outside wires together at the switchboard. This transforms it into a 120-volt two-wire system. If this is to be done, each side should be calculated as a two-wire system with one-half load, the outside wires being made of the size thus determined and the neutral double this size. Sometimes, this type of system is calculated as a three-wire, and then the neutral is made twice the size of the outside wires, but this arrangement results in a higher drop at the lamps than when it is run as a three-wire system.

Three-Phase System

Three-phase systems are sometimes used for lighting, but should be avoided for such service if possible. The three-phase system with three wires takes considerably more copper than the three-wire system, while the four-wire arrangement saves in copper at the expense of added complication in the panel-boards. The branch circuits would be two-wire, as in the previous arrangements.

After the sizes of feeders have been determined from Table 7 by using the maximum load, the drop should be checked by means of the chart. Allowing 2 per cent. drop, this amounts to 2.4 volts across the lamps for a 120-volt system. The allowable drop for each wire is 0.58 times 2.4 volts, or 1.39, and the size should be determined, using the actual load previously found. In using the chart it should be remembered that it gives a drop for a two-wire circuit, so the voltage drop obtained should be divided by 2. The chart can be used if the three wires of a feeder are all in the same conduit; if not, other methods to be described later may have to be used. If the three-phase four-wire system is used, the branch circuits would be divided into three equal parts as before, and connected between the three main wires and a common wire called the neutral. The current in each of the main wires would be the total for all the lamps connected to that wire, and that in the neutral would be zero as long as the current in all the main wires was the same. The actual and maximum currents would be determined as before, using the branches connected to one of the outside wires. If the allowable drop in the feeders is 2 per cent., this applies to each main wire, so the drop in each of these wires for 120 volts across the lamps would be 4.8 volts. The wire size can be obtained in the same manner as before and the neutral made the same size as the other wires.

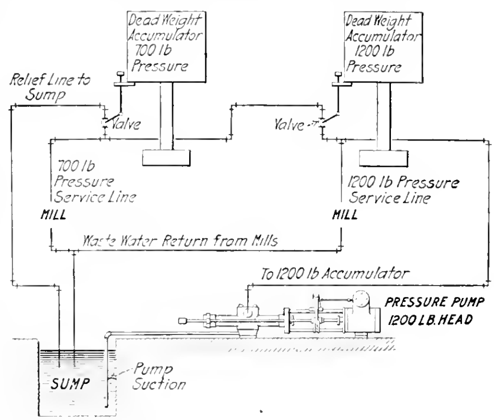
The two-phase system, for use in lighting, is open to the same objections as the three-phase, if all the feeders and subfeeders are made two-phase. Either of the plans shown in Fig. 12 may be used. If the arrangement in *a* is used each phase can be treated independently and figured as a simple two-wire system, but with arrangement *b*, the current in the common wire is obtained by adding together the currents in the two outside wires and multiplying by 0.71. When the load is practically the same on each side, the voltage drop can be computed readily. First calculate the drop in either outside wire with the current previously determined, then the drop in the common wire which would be caused by this same current. Add these together and let the result be represented by A. Then calculate the drop in the common wire due to the current from the other outside wire, and let this be B. The total drop is $\sqrt{A^2 + B^2}$.

In general, the three-phase or the two-phase systems are not well adapted for interior wiring. If either of these systems must be depended upon as a source of supply, it is better to arrange the circuits as a single phase, two-wire or three-wire system.

Two-Pressure Hydraulic Service

By A. D. Williams

Manufacturing operations at the plant of the Firestone Rubber Co., Akron, Ohio, require pressure water at 700 and 1200 lb. per sq.in., and the method adopted to obtain this service is shown in the illustration. Two dead-weight loaded accumulators are used, and the pumping plant is



Arrangement of Accumulator Piping

designed to deliver to the higher-pressure accumulator and to hold it at the highest point of the stroke, delivering water to supply the demand for both pressures. As soon as the high-pressure accumulator rises its full height it opens a valve and a portion of the water flows to the low-pressure accumulator and this, when it reaches the top of its stroke, opens a relief valve, permitting the surplus water to return to the sump or sewer.

To prevent excessive waste of pressure water the steam supply to the pressure pumps is shut off automatically when the low-pressure accumulator rises to a sufficient height to open the relief valve. The pumps are automatically started when either the low- or high-pressure accumulator drops a certain amount. The starting device is so arranged that it will act to start the pump if the high-pressure accumulator drops while the low-pressure accumulator still remains at its highest position. This provision is necessary, as the demand for pressure water is variable upon each of the two pressure systems and a heavy demand might be made on the 1200-lb. line at a time of no demand on the 700-lb. line. In practice the arrangement works out nicely, maintaining full pressure upon both lines and taking care of all service demands.

Pressure water is supplied to the system by three pumps. One is a 13&26x1½x24-in. outside-packed plunger pump with a Corliss cross-compound steam end and flywheel. At present this machine is operating noncondensing, but later is to be connected to a condenser. It will deliver 300 gal. per min. at 50 r.p.m. There are two duplex-compound outside-packed plunger pumps, 12&18x5¾x16 in. These comprised the first hydraulic-service installation, the flywheel pump having been added within the year.

Internal-Combustion Engine Dimensions

By H. L. Watson

SYNOPSIS—A chart for graphically determining the speed, bore and stroke for a given type and size of internal-combustion engine according to average American practice.

During the summer of 1912 there appeared in Power a series of articles by Messrs. Ulbricht and Torrance upon "American Practice in Rating Internal-Combustion Engines."* These represented the results of an extensive thesis made at Cornell University under the direction of Professors Diederich and Hirshfeld, the data being given in the form of curves from which empirical equations were obtained. By means of these equations it is possible to determine the cylinder bore, stroke and revolutions per minute necessary for an engine of any desired type, fuel, and power; four-stroke-cycle stationary engines only being considered. These equations are given in Tables 1 and 2.

It occurred to the writer that these equations might be plotted upon one sheet, thus reducing the work necessary for the solution of a problem. Upon such a chart, herewith shown, all curves denoted by letters refer to the type of engine, and those denoted by Roman numerals refer to the fuel used. To further distinguish them the curves are represented by different kinds of lines.

TABLE 1

Relation of d^2ln and b.hp. for Various Fuels	Remarks
Producer gas $d^2ln = 18{,}500\ (b.hp. + 2)$ $d^2ln = 17{,}900\ (b.hp. + 1)$ $d^2ln = 20{,}600\ (b.hp. + 4)$	Average—all values Single-acting—horizontal and vertical Double-acting—horizontal
Natural gas $d^2ln = 15{,}200\ (b.hp. + 5)$	Average—all arrangements
Illuminating gas $d^2ln = 15{,}700\ (b.hp. + 2)$	Single-acting—horizontal and vertical
Blast-Furnace Gas $d^2ln = 21{,}000\ (b.hp. - 5)$	Double-acting—horizontal
Oils and distillates $d^2ln = 21{,}875\ (b.hp. - 0.75)$	Single-acting—horizontal and vertical
Gasoline $d^2ln = 16{,}400\ (b.hp. - 0.5)$	Single-acting—horizontal and vertical

TABLE 2

Type of Engine	Relation of n to b.hp.	Relation of d to l	Relation of d to d^2l
Vertical Single-acting	$n = \frac{5368}{b.hp. + 14} + 176$	$d = 0.91\ (l) - 0.45$	$d^3 + 0.45d^2 = 0.91\ (d^2l)$
Horizontal single-cylinder Single-acting	Gasoline $n = \frac{3020}{b.hp. + 9} + 128$ Gas $n = \frac{6580}{b.hp. + 21} + 131$	$d = 0.667\ (l) + 0.4$	$d^3 - 0.4d^2 = 0.667\ (d^2l)$
Horizontal tandem Single-acting	$n = \frac{3650}{b.hp. + 4.5} + 156$	$d = 0.772\ (l) + 0.55$	$d^3 - 0.55d^2 = 0.772\ (d^2l)$
Horizontal Double-acting	$n = \frac{9500}{b.hp. + 29} + 72$	Natural Gas $d = 0.533\ (l) + 4$ Producer Gas $d = 0.667\ (l) + 2$	Natural Gas $d^3 - 4d^2 = 0.533\ (d^2l)$ Producer Gas $d^3 - 2d^2 = 0.667\ (d^2l)$

Procedure
1. Assume type of engine, b.hp. and fuel.
2. Obtain (d^2ln) from Table 1.
3. Obtain (n) from Table 2, col. 1.
4. Obtain (d^2l).
5. Obtain (d) from Table 2, col. 3.
6. Obtain (l) from Table 2, col. 2.

In all cases b.hp. = brake horsepower per cylinder end.
d = cylinder diameter in inches.
l = length of stroke in inches.
n = revolutions per minute.

*This series was copyrighted by T. C. Ulbricht and C. E. Torrance.

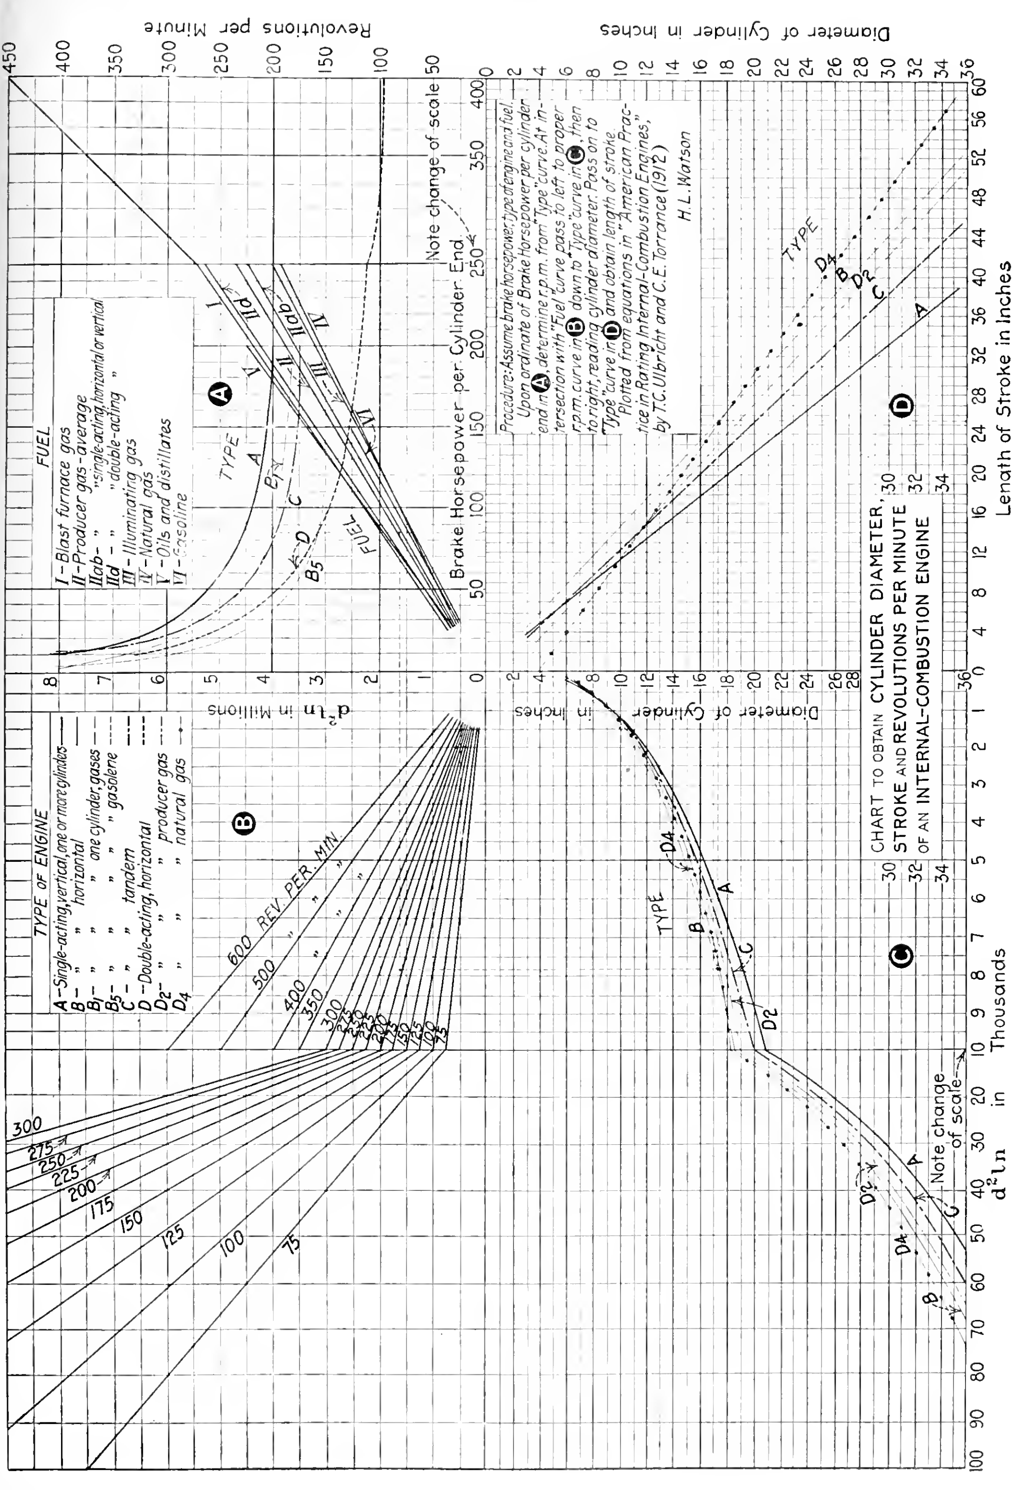


CHART TO OBTAIN CYLINDER DIAMETER, STROKE AND REVOLUTIONS PER MINUTE OF AN INTERNAL-COMBUSTION ENGINE
Procedure: Assume brake horsepower, type of engine and fuel. Upon ordinate of Brake Horsepower per cylinder end in (A), determine r.p.m. from "Type" curve. At intersection with "Fuel" curve pass to left to proper r.p.m. curve in (B) down to "Type" curve in (C), then to right, reading cylinder diameter. Pass on to "Type" curve in (D) and obtain length of stroke. Plotted from equations in "American Practice in Rating Internal-Combustion Engines," by T.C. Ulbricht and C.E. Torrance (1912)

C
D

The expression giving the power of an engine per cylinder end is

$$B.hp. = \frac{PLAN}{33{,}000 \times mechanical\ efficiency}$$

where

P = Mean effective pressure;
L = Stroke in feet;
A = Cross-sectional area of cylinder in square inches;
N = Number of explosions in that cylinder end per minute.

It may thus be said that the power is a function of d^2ln.

where

d = Diameter of cylinder in inches;
l = Stroke in inches;
n = Revolutions per minute.

The equations of the relations between b.hp. per cylinder end and d^2ln for different fuels have been replotted in the upper right-hand section of the chart. The curves between brake horsepower and revolutions per minute for engines of different types have also been plotted in this section, while those showing the relations between bore and stroke for engines of different types have been replotted in section D.

It was necessary to plot curves giving the relations between d^2ln and d. This was done by first drawing in section B a series of curves between d^2ln and d^2l for various r.p.m., and then plotting in section C curves showing the relations between d^2l and d for the different types of engines. The equations of these latter curves were determined as follows:

From Table 2, col. 2 (for a vertical, single-acting engine)

$$d = 0.91\,l - 0.45, \text{ or } l = \frac{d + 0.45}{0.91}$$

whence

$$d^2l = \frac{d^3 + 0.45\,d^2}{0.91}$$

Proceeding in the same manner with the remaining types of engines, the set of equations in column 3 was obtained.

The use of this chart is best illustrated by an example. Let it be desired to determine the revolutions per minute, stroke and bore for a single-acting, horizontal, single-cylinder engine using producer gas and developing 85 b.hp. per cylinder end.

First note the legends in the chart for the curves corresponding to the type of engine and fuel assumed. Upon the 85-b.hp. ordinate in section A note the intersection with the "type" curve, B_1, giving (to the right) the r.p.m. as 200. From the intersection of this same ordinate with the "fuel" curve, H_{ab}, pass horizontally to the left to the intersection with the line in section B representing 200 r.p.m., thence downward to the curve B in section C; from this point pass horizontally to the right, finding the bore of the cylinder to be 17¼ in. By proceeding further to the right to the intersection with curve B in section D, we will find the stroke of the engine to be approximately 25½ in.

It must be remembered that these curves have been drawn through many values plotted and, as such, represent the average size and speed for an engine of the type and power desired, built according to American practice, as set forth in the original article.

Franklin Cylinder Oil "Carburetor"

Engineers have learned by experience that if cylinder oil is fed through a pipe connection that just passes through the shell of a steam pipe, the oil is not well distributed in the engine cylinder to which the pipe is connected. A number of atomizing devices have been

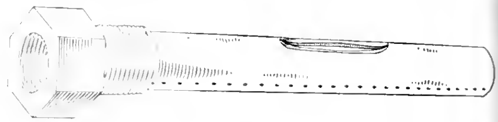

Fig. 1. The Atomizing Tube

used, such as perforated pipes that extend part way across the inside of the steam pipe.

What is known as the Franklin oil "carburetor" is made by the Franklin Oil & Gas Co., Bedford, Ohio. It is designed to atomize the oil so that it will mix with the steam before it enters the cylinder.

The device is made with a nut having a threaded shank with a hollow tube extension that is plugged at the inner end. The top of the tube is slotted and two rows of small holes are drilled in the tubes about one-quarter way around from each side of the top slot. Holes are also drilled in the plugged end. The heated, atomized oil is discharged through the holes. Fig. 1 illustrates the idea.

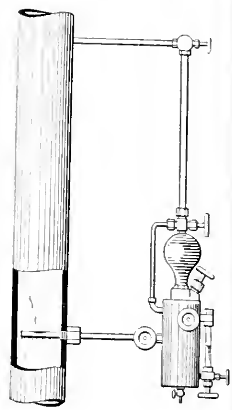

Fig. 2. "Carburetor" as Used with a Lubricator

The "carburetor" is screwed into the steam pipe with the slotted side up when at its permanent position. The lubricator or forced feed pump discharge pipe is screwed to the thread inside the nut which is outside of the steam pipe. Fig. 2. The appliance is made in three sizes—⅜-, ½- and ¾-in. standard pipe threads, and of different lengths to meet the requirements of the steam-line diameter.

Branded Waste

While waste is one of the minor items of power-plant supply, a saving of any considerable percentage of the aggregate amount spent for this commodity in one year would be a very tidy sum. The Royal Manufacturing Co., of Rahway, N. J., extensive dealer in cotton and woolen waste, is making an attempt to standardize the trade. It has divided its wares into twelve branded grades, of which samples are furnished in a folder. The waste is bought by its branded name, and the packages are guaranteed to contain not over a certain amount of tare and to be of accurate weight, so that the payment for a lot of hoops and bagging at waste prices, or the padding of an order 30 to 50 per cent., is avoided.

The Why's of Boiler Draft

By C. F. Hirshfeld*

SYNOPSIS—Draft through a boiler simply explained by comparison with a pipe carrying water under pressure. The stack is considered as a pump and its action explained from this viewpoint.

Despite the fact that much has been written on the subject of draft and its significance in boiler practice, there seem to be many engineers to whom it is more or less mysterious. One of the simplest methods of attacking this problem and one which has the advantage of giving correct viewpoints throughout is to compare the boiler passes, flues and other parts with a pipe or conduit carrying water under pressure.

Measuring Head by Standpipe or Gage

Assume for this purpose the arrangement shown in Fig. 1. A large vessel is fitted with an overflow, and water is supplied constantly through the nozzle shown. If the overflow is large enough, the height of water will remain constant at the level shown. The pipe leading from the bottom of the vessel will, for the time being, be assumed closed at the right-hand end. Under such conditions, the pipe will stand full of water under a head h. If holes are drilled in the horizontal pipe and fitted with standpipes, as shown, the water will rise in each standpipe to the same height as that in the main vessel.

If the end of the horizontal pipe is opened so that a steady flow of water can occur, the water in the vertical pipes stands at successively lower heights as the open end of the pipe is approached. This is shown in Fig. 2. The explanation, as commonly expressed, is that part of the head is used up in overcoming frictional and similar resistances to flow. It is obvious that dynamic conditions (flow occurring) and static conditions (no flow) are different.

Analyzing the case shown in Fig. 2 more closely, the most obvious difference between it and that shown in Fig. 1 is the fact that the water in the former is moving. As water possessses mass, energy is required to give it motion, and this energy can be measured in terms of a head of water. Thus, in the case of Fig. 2 the required head might be that shown by the height h'. This much of the total head h would be used in the large vessel for imparting velocity to the water. The water flowing out of the large vessel encounters resistance where it enters the pipe, and a part of the remaining head h-h' is lost or used in overcoming this resistance. After the water has entered the pipe, flow is continuously resisted by the friction of the walls and more of the remaining head is used in overcoming this frictional resistance.

Thus, just before entering the horizontal pipe the head remaining is h-h', but by the time the water reaches the first standpipe the head has been reduced to h_1. The amount h_1' has been used to overcome resistance to entrance to the pipe and resistance to flow through the pipe up to the point of location of the standpipe. The head h_2' is used in overcoming the resistance offered by friction in the stretch of pipe between the first and second standpipes.

The heads of water used in the discussion above are merely measures of pressures, and pressure gages might have been used instead of standpipes for reading the loss of head or pressure along the length of the pipe. This arrangement is shown in Fig. 3. If gages 1 and 2 are located at the points previously occupied by the corresponding standpipes, the difference between the gage readings will be equal to h_2', if converted into feet of water.

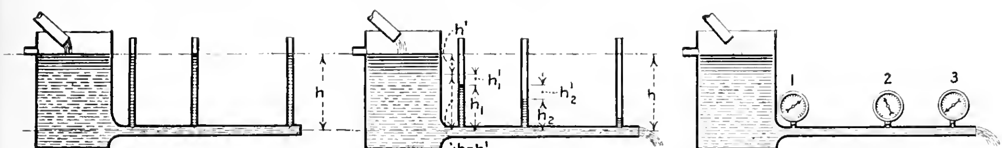

FIG. 1. FIG. 2. FIG. 3.

Illustrating Reduction of Pressure Due to Resistance to Flow

It should be particularly noted that the pressure on the surface of the water in the larger vessel is atmospheric and also that the pressure of the water just as it issues from the end of the horizontal pipe is also atmospheric. That means that the total head h must have been used within the system. Part was used in overcoming resistances, the rest in giving the water velocity; the latter part of the head is represented by the velocity with which the jet of water enters the atmosphere.

If difficulty is experienced in recognizing the fact that the pressure of (or on) the issuing jet is atmospheric, it is only necessary to consider what would happen if it were not. If the pressure of water in the jet were greater than that of the atmosphere, the jet would burst or spread laterally as soon as it issued from the confining walls of the pipe. If the pressure of the water were less than atmospheric, the jet would be compressed by the atmosphere to a smaller diameter than that of the inner surface of the pipe.

Showing Variation in Head Graphically

Referring to Fig. 4, with static conditions (discharge end of pipe closed), the pressure throughout the length of the pipe is the same and equal to that caused by the head h plus that caused by the atmosphere on the liquid. This is shown by the line AB at a height above atmospheric pressure equal to a, which represents a pressure equal to that caused by h feet of water. With dynamic conditions, the case is different. The pressure just inside

*Chief of research department of the Edison Illuminating Co. of Detroit

the entrance to the pipe is shown by the height of A', the distance between A' and A representing the head used in giving the water its velocity and in overcoming resistance to entrance at the inlet. If the pipe is uniform for its length so that the friction loss is the same at all points, the loss of head or pressure will be the same per unit of length at any point along the length and the pressure drop will be as shown by the line $A'B'$. When the end of the pipe is reached, the pressure of the water is equal to that of the atmosphere. This is shown by the location of the point B' on the atmospheric line in Fig. 4.

Pump vs. Fan

For the purpose of getting a case which more nearly parallels the conditions existing in the case of a boiler, the arrangement of apparatus so far considered will be slightly changed. Imagine a vessel connected to a pipe and pump, as shown in Fig. 5. When the pump is not in operation, the water will stand at some height h in the tank and the pipe, and the pressure on the two surfaces of the water will be atmospheric. When the pump is operating, the pipe is filled with water which flows up to the top and into the pump. It is obvious that the water is forced to flow up the pipe by the atmospheric pressure exerted on the surface in the open tank, and if this is true, the pressure within the pipe at the same height must be less than atmospheric. Shown graphically, the case would appear as in Fig. 6. In this figure, the pipe length has been straightened and shown on the horizontal axis as before.

At the point A in Fig. 6, which represents conditions just inside the entrance to the suction pipe, the pressure is equal to that due to atmospheric plus that due to the head h less that lost by conversion to velocity and by resistance to entrance to the pipe. There is then a gradual drop due to friction along the straight part of the pipe to the point B, which represents conditions at the entrance to lower elbow. The loss through the elbow is greater than through the same length of straight pipe, and there is therefore a more rapid drop of pressure from B to C in passing through the elbow. The line representing loss of pressure or head then runs from C to E, the pressure decreasing both because of vertical rise and friction loss. The drop EF represents the loss caused by the upper elbow and by resistances to entry at the pump, so that the pressure which would be shown by a gage connected to a point inside the eye of the pump impeller would be that indicated at F, and obviously lower than atmospheric. In the pump the pressure is raised from that shown at F to that shown at G and then there is a gradual and regular loss of pressure again because of the frictional resistance offered by the discharge pipe.

This case is practically identical with that of a boiler under induced draft, as shown in a simplified way in Fig. 7. The pressure in the ashpit is that of the atmosphere. The air is started in motion and passes through the grate and fuel bed against a certain frictional resistance, so that there is some such drop as that indicated by AB in getting from beneath the grate to the interior of the combustion chamber. Flow from that point to the damper occurs in comparatively large passages offering small frictional resistance, so that the drop from the combustion chamber to the damper is not great. In the region immediately preceding the damper, the gases pass through two right-angles and the drop is therefore more rapid for a given distance traveled than it is in the straight run preceding. This is shown by the increased angularity of the line CD. As shown, the damper is only partly open and this would cause a throttling loss DE. From this point the losses go on as before until the air finally enters the fan wheel with a pressure as shown by F. In passing through the fan, the pressure is raised to a value above atmospheric as shown by G and the excess above atmospheric is then lost in passing through the stack, so that the gases are discharged from the open end of the stack at atmospheric pressure.

A more complicated case is shown in Fig. 8, for which a horizontal return-tubular boiler with induced draft has been assumed. Capital letters on the graph refer to positions indicated by small letters in the diagram above. Up to the point D, the case is similar to that just discussed. Beyond that point there is a rapid drop due to loss in entering the tubes, a gradual drop due to friction along the length of the tubes and a rapid drop due to losses at the exit from the tubes. This results in giving a pressure such as that shown by E just outside the

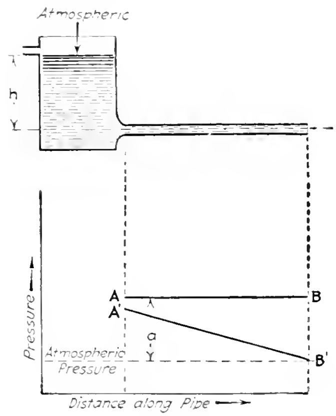

FIG. 4

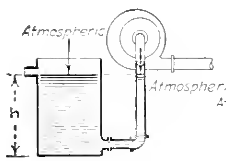

FIG. 5

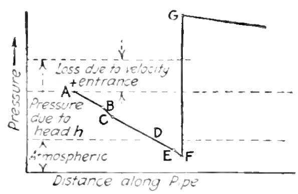

FIG. 6

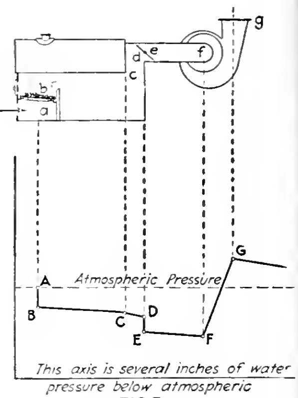

FIG. 7

Showing How the Action of a Centrifugal Pump Is Like That of a Fan tubes in the uptake. From there on the conditions are similar to those previously described.

A more complicated case is illustrated in Fig. 9. A fan draws air from the atmosphere and pumps it into the wind box, raising the pressure from atmospheric to some such value as that shown by A'. The drop through the fuel bed brings the pressure back to atmospheric in the furnace and then the various losses proceed as in previous cases except that the resistance offered by the economizer adds one more complication.

Cases in which induced-draft fans are employed are generally readily understood because it is simple to see that the fan acts as a pump. By lowering the pressure at its own suction it enables the atmosphere to force itself through the boiler and flues toward and into the suction orifice. The fan then raises the pressure of the gases by the amount required to expel them against atmospheric pressure. When a natural-draft stack is substituted for the fan, however, many experience difficulty in appreciating the fact that conditions are not really altered.

mospheric pressure. The weight in pounds supported on a surface one square inch in extent is the pressure in pounds per square inch. The pressure of the atmosphere at a height of several hundred feet above the surface of the earth is therefore less than the pressure of the atmosphere at the earth's surface.

The second fact above stated is easily appreciated by taking the following point of view. Imagine a given weight of gas to occupy a certain volume, say one cubic foot at a certain temperature and pressure. If this gas is heated and allowed to expand so as to maintain a constant pressure, the given weight acquires a larger volume, say one and a fraction cubic feet. Obviously, there is not as great a weight in one cubic foot of space at the higher temperature as there was at the lower temperature; that is, the density, or weight per cubic foot, has decreased during heating.

These principles may now be applied to explain the operation of a stack. Imagine a tube to stand vertical on the surface of the earth, as shown in Fig. 10. The pres-

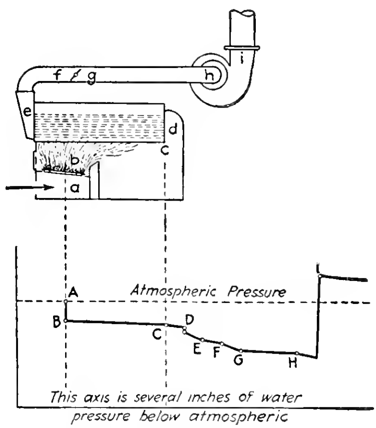

FIG. 8.

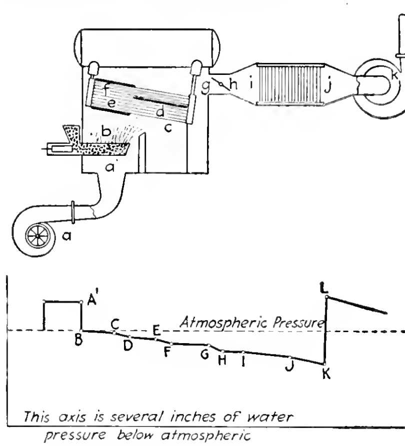

FIG. 9.

DRAFT (PRESSURE) VARIATIONS IN INDUCED- AND FORCED-DRAFT BOILER FURNACES

The stack performs the same functions as a pump in that it lowers the pressure at its suction orifice or base so that air under atmospheric or higher pressure in the ash-pit can force itself through the boiler and flues into the suction orifice. The stack then practically raises the pressure of the gases to such an extent that they can be expelled against the pressure of the atmosphere at its top.

ACTION OF STACK

Two simple facts must be realized to understand the action of a stack: First, the pressure of the atmosphere increases as one passes from a high to a low elevation, and, second, the density or weight per cubic foot of any gas decreases if its temperature is raised while it expands to such an extent that its pressure remains constant.

The first of these facts can be forcibly impressed by regarding the atmosphere as made up of a series of layers like a pile of boards, books or blankets. Obviously, if one could weigh all the layers above a point several hundred feet above the earth's surface, they would weigh less than would all the layers above a point at the earth's surface. The weight thus obtained is what is meant by at-

sure at the height of the top is that caused by the atmosphere above that point; it may be represented by p pounds per square inch. The pressure at the earth's surface, inside or outside of the stack, will be greater and may be represented by P. It will be equal to the sum of the pressure p and the pressure p' due to the weight of air between a point at the height of the stack and a point at the surface of the earth.

If a horizontal chamber be built on the side of the tube near the bottom and be separated from the tube by a diaphragm, as shown in Fig. 11(a), the pressure on opposite sides of the diaphragm will be the same and equal to that of the atmosphere at the height d above the surface of the earth. If now, the air in the tube be heated it will expand, and some of it will leave, so that a smaller weight will remain within the tube. The downward pressure p at the top of the tube will be due to the atmosphere above that point and will obviously be the same at any point in a horizontal plane at that height. The pressure at the center of the diaphragm on the outside will be P as before, as shown in Fig. 11 (b). But the pressure on the tube side of the diaphragm will be P' less than P, because the column of hot air inside the tube weighs less than a column of an equal height of cold air outside of the tube.

If, now, the diaphragm be imagined to be a frictionless and weightless piston, it is obvious that it will move to the right because of the greater pressure on its left-hand side. If the lower end of the tube be imagined to be constructed with an easy bend, the piston would be pushed clear to the top of the tube, because at any lower point the pressure on its lower side would be greater than the pressure on its upper side, as shown in Fig. 12. In this figure P_1' must be less than P_1, because the column of hot air of height a inside the tube weighs less than the column of cold air outside the tube.

A stack or chimney filled with hot air and surrounded with cold air can thus pump the hot air out of itself against the pressure of the atmosphere above. It should be noted in this connection that when the stack is filled with hot gas the pressure within at the base is less than that outside, as shown in connection with Figs. 11(a) and 11(b); that is, the stack "creates a draft." It should also be noted that the pressures outside and inside of the stack are the same at the top, so that the "draft" or "under-pressure" within the stack tapers from a maximum value at the bottom to zero at the top. This is shown diagrammatically in Fig. 13.

It is easy to see that the line representing the pressure within the stack must always lie below (to the right of) the line representing the pressure outside the stack at the same level, from the argument given in connection with Fig. 12. It is also easy to see that it must lie above (to the left of) the line representing atmospheric pressure at the top of the stack, because at any point below the top the pressure inside the stack is equal to the atmospheric pressure above plus that due to the weight of hot air down to the same point.

To convert the model so far considered into an operative stack, it is only necessary to supply a means of continuously heating air as it enters the bottom of the stack, so that the shaft will always be filled with gas at a higher temperature than that outside. This could be done by the use of gas flames playing on the base or by the use of an electrical heater placed within the air at the base. The external cold air would enter at the bottom continuously in an effort to displace the warmer air in the shaft, but as it would be heated as fast as it entered, the process would become nothing more than a gradual sinking of the external atmosphere into the stack and a procession of that same atmosphere up the stack after being heated.

In practice, the air in passing through the fuel causes the latter to burn and liberate heat. Part of this heat is carried in the products of combustion to the base of the stack and serves to maintain the necessary high temperature within the stack. This process is unfortunate in one respect. When the fuel burns, its combustible constituents unite with the oxygen of the air and the weight of gas leaving the fuel bed and traveling up the stack is greater than the weight of air entering by the amount of fuel burned. This means simply that the gases entering the stack would be heavier than the air at the same temperature and they must therefore be heated to a higher temperature than would pure air to give the same "draft" at the base of the stack.

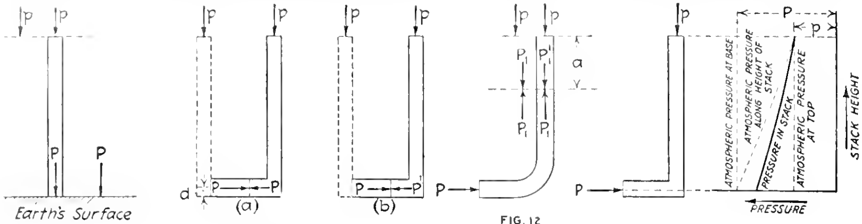

FIG. 10. FIG. 11. FIG. 12 FIG. 13.

ILLUSTRATING WHY A STACK CREATES A DRAFT

STACK AS A PUMP

The stack may now be investigated in connection with a real boiler, considering it a pump, as was done with a blower previously. For this purpose a stoker-fired water-tube boiler supplied with a forced-draft fan has been assumed, as shown in Fig. 14. Capital letters on the graph of pressure variation indicate the same points represented by the corresponding small letters in the diagram. The directions taken by the various parts of the graph should be easily understood from what has preceded.

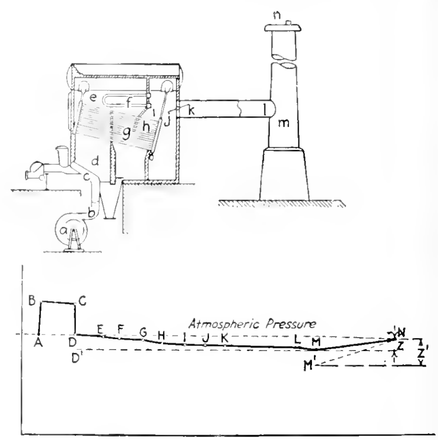

FIG. 14. SHOWING DROP IN PRESSURE IN DIFFERENT PARTS OF BOILER

It is obvious that the drop of pressure from D to M is caused by the various resistances offered to the flow of the gas by the different parts of the boiler and setting. If the same low pressure indicated at M could be maintained while no gas was allowed to flow, there would be no loss of pressure between d and m. The pressure at d would therefore have to be the same as the pressure at m

(neglecting slight differences of elevation) and the graph of pressures between d and m would be a horizontal line as indicated by $D'M$. This is merely another case of the difference between static and dynamic conditions previously discussed; with static conditions there is no loss of head, with dynamic conditions there is such a loss.

But the stack itself is a pipe which carries gases when in operation, and there must be a similar loss of head in it under such conditions. Were one to calculate the pressure at the base of the stack shown in Fig. 14 for a given set of conditions by using the method indicated in connection with Fig. 11, a value such as indicated by the point M', lower than M, would be obtained. The difference between atmospheric pressure and that indicated by M'—that is, the pressure difference Z'—is called the theoretical draft and is the pressure difference which would be available under static conditions. Under conditions of flow, however, part of this pressure difference or driving force is used in the stack, so that only the smaller pressure difference Z remains available for overcoming the resistances in the boiler and flues.

Gas Velocity and Resistance

The frictional and similar losses in such things as pipes, flues and stacks increase approximately with the second power of the velocity of flow through them. Since greater quantities of gas flow through a stack when the boiler is operated at high ratings than when operated at low ratings, the loss in the stack must increase rapidly as the load increases. If no modifying conditions entered the problem, it would be necessary to have such a high stack to get the necessary available or useful draft at high boiler ratings that the damper would have to be nearly closed at moderate ratings. Fortunately, this is not necessary to any such extent as might at first seem probable.

The temperature of the products of combustion rises rapidly with increasing load, so that the density of the column of gases in the stack rapidly decreases. There is, therefore, a tendency toward increased draft as the load increases. This is partly balanced by the fact that increasing temperature and decreasing density mean increasing volume and therefore increasing velocity and loss, but the improvement is sufficient, within ordinary ranges, to more than balance the increased loss.

Again, with a properly operated furnace the excess air used to insure good combustion can often be decreased as the load increases up to a high rating, and this results in the evolution of smaller weight of gas per pound of fuel as the load increases. This would naturally tend to cause a decrease of stack velocity and consequently an improvement in draft.

It is true that in most installations it is necessary to operate with partly closed dampers at light loads and to open the dampers as the load increases. This is not a necessary property of such apparatus, as it is possible to so design the various parts that the available draft is practically self-regulating, and this has been done in several cases.

Wire-Drawn Saturated Steam becomes more or less superheated. Therefore, the apparent loss indicated by the loss of pressure is partly compensated for and the extra pipe friction is the greatest loss. This loss, in turn, is offset to some extent by the fact that the coefficient of friction of superheated is less than that of saturated steam.

Safety in Refrigerating Plants

The special hazards of refrigerating plants have recently received well-deserved discussion in the columns of the technical press, and among those doing good work in this direction is a recent number of the *Travelers Standard*. As every new industry develops, unforeseen causes of accident become apparent, and while the engineer in charge of refrigerating machinery is exposed in such plants to the ordinary dangers of power-station operation, he is also subjected to hazards which need to be specially emphasized on account of their inherent relation to this specialized branch of mechanical service. The growth of the refrigerating industry, employing high-pressure gases with the attendant risk of explosions and other accidents, is attracting the attention of municipal authorities to such an extent that regulations for installing and operating these plants have been drawn up and put into effect in many localities. Experience will, in all probability, show that most of these will have to be revised, and they are likely to have a history paralleling steam-boiler regulations.

As in almost every other industry, the majority of accidents are avoidable. Leaks in gaskets, through cracks in pipes or other defective parts of equipment under pressure, are fertile causes of trouble. Loss of ammonia is often the result of only small leaks, but where large quantities of ammonia escape explosion may result from the mixture of ammonia, hydrogen, oil vapor and other volatile impurities, particularly where open flames are present. Incandescent instead of arc lamps and self-closing doors between the boiler house and rooms where leaks are liable to occur are important safeguards. Provision by which the ammonia supply may be shut off quickly from any one of three or four widely separated points is also a valuable means of protection. In case of a heavy leak the availability of oxygen helmets at convenient places will facilitate temporary repairs and perhaps enable a complete shutdown to be prevented.

Too much care cannot be taken to maintain all valves in operating condition. Many valves in a refrigerating plant are seldom used, and unless tested with reasonable frequency tend to rust in the stuffing-box gland and on the threads of the packing nut. Piston rings in compressors have given less trouble since the snap ring has been used. While the installation of a relief valve in a bypass or in a connection between the discharge side of the compressor in front of the stop valve and the suction side of the compressor in front of the suction stop valve will give protection against excessive pressure in the system, objections against this practice have been voiced, and it is hoped that the investigations into this phase of refrigeration safety now being conducted will result in recommendations applicable without apprehension.

In compressing air the engineer should not use a machine that has recently been used to compress ammonia, and in opening gage-cocks it is safer to stand at the side rather than at the front of the glass. Such precautions as standing at the side rather than the front of compressor cylinders and refraining from calking pipes or tightening nuts and fittings under pressure are generally understood but often disregarded. Valve breakage is the most frequent cause of compressor accidents and is due principally to unnecessary wear, improper cushioning or to deterioration of the metal.

Care in testing initial installations of refrigerating machinery is vitally important. Even though the equipment be tested at the factory and found satisfactory, a further test after assembly should be considered essential. It is customary to lubricate compressor-cylinder walls with oil before starting a test, and more or less oil is forced into the piping by the compressor, with resultant pocketing, heating, vaporization and sometimes an explosion if the temperature rise is extreme. Lubricating oil with a low chill point is desirable for regular use, but a high flash point is more important on account of the increased safety of the latter. Gradual starting followed by cooling of the compressor is a safer practice in testing than immediate operation from stand-still to normal or excessive pressure. The use of butt-welded pipes or of unsupported pipes is considered by many to be undesirable in refrigerating plants.

Water-Tank Controlling Device

The device illustrated herewith is designed to stop a pump when the tank is filled and to start it when the level of the water has fallen to a predetermined point.

The apparatus, Fig. 1, consists of a brass pipe, its length being the distance between high level and low level of the water in the tank. The upper end of this pipe is supplied with a strainer, and a valve and copper float are attached to the lower end. Near the lower end a fitting is provided to which an air reservoir is attached.

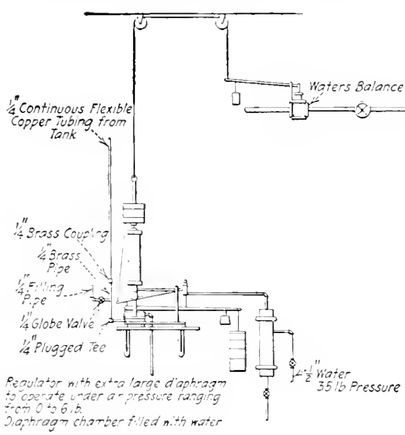

FIG. 2. REGULATOR CONNECTIONS

From the top of this reservoir a pipe is carried to the top of the tank and thence by a flexible copper tube to a damper regulator located near the supply pump. The damper regulator is used to actuate a balanced valve or other device for starting and stopping the supply pump.

The mechanism operates as follows: The water rising in the tank to the top of the pipe overflows into it and compresses the air in the air reservoir. The pressure due to the height of the water in the pipe is transferred through the flexible copper tube to the damper regulator, and it actuates the pump-controlling mechanism and stops the pump. This pressure is held constant until the water in the tank falls to the bottom of the pipe, when the float valve opens and allows the water to escape, relieving the air pressure; and the damper regulator acting in the usual manner actuates the controlling mechanism and starts the pump.

This apparatus has been in operation for four years

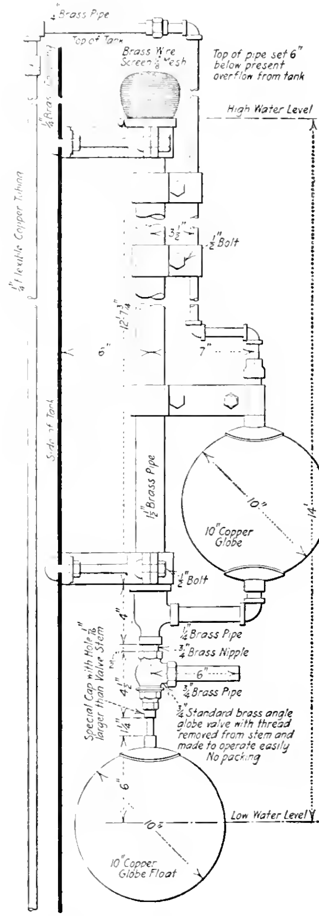

FIG. 1. CONTROLLING APPARATUS IN DETAIL

or more and has proved reliable and satisfactory. It was designed and installed by the Samuel M. Green Co., Springfield, Mass.

Reducing Valves which are too large for the amount of steam they are to pass are usually unsatisfactory. Either they will open and close continually and chatter violently, or will stand in a position nearly closed and become steam cut and leaky. It is more satisfactory to use two small valves in parallel, one set slightly heavier than the other, so that one will supply steam up to its maximum capacity before the other opens. Another way is to use one reducing valve equal to about one-half the maximum demand, and a bypass of about the same capacity with a hand-operated valve in it so that when the reducing valve reaches its capacity the bypass valve may be opened wide and the reducing valve will close down and simply make up the shortage. This, of course, requires that an attendant shall observe the pressure gage occasionally.

Editorials

The Unusual in Engineering Education

Operating engineers of New York City and vicinity have recently had presented to them something worthy of comment in the way of engineering education, yet the character of the presentation is centuries old and the subject is indeed not new, though the proper recognition of its importance is growing.

The subject is the central station versus the isolated plant. The presentation is in the form of a three-act play, with real engineering characters, telephones, charts, records, instruments—everything, in fact, necessary in depicting the problem of how an engineer, his employers and the central station proceed with the business of settling the question of continued isolated-plant service or service purchased from the street.

The curtain goes up on the usual scene of a plant where the engineer has tried to induce the management to buy the instruments and equipment essential to obtaining and recording the data required to show the performance of the plant, but where his requisitions have been repeatedly turned down. The central-station representative, being eminently fair, desires not to take his legitimate advantage of conditions and suggests a call after the plant has operated six months longer to determine what it can do. The issue is forced and the long-lacking equipment is obtained and, which is rather important, *used*.

The end of the trial period sees a proud engineer, an enthusiastic management, and a solicitor who, though regretting his inability to "land" the plant, is frank in his admiration of engineer and management. His little discourse at the close of the last conference should be learned "by heart" by every engineer and vigorously applied. It is the same old sermon about most isolated-plant failures being primarily the fault of the engineer, but a sermon whose value will decrease only as the need of preaching it diminishes.

All things considered, the members of Brooklyn, Number Eight, National Association of Stationary Engineers who conceived and who executed the idea deserve commendation. There are some points which bring forth criticism. But then, these men are not playwrights nor trained actors, neither have they rehearsed or produced sufficiently. Time will supply these needs.

To avoid impressions that impair the value of the play, the members must be extremely careful not to seem to advertise any particular make of apparatus. Some of the slides shown during the consulting engineer's talk to the superintendent do this too plainly, to the dissatisfaction of many in the audience. But that this effect is not intentional is evidenced by the fact that parts of the "lines" which were similarly objectionable have been changed, while the slides are undergoing like treatment. When these features, which excite the critic, are removed, the "company" will, in theatrical parlance, "put it over great."

As a suggestion, we would add that when time permits the evening might be made more valuable by following the play with discussion of the question by audience and players.

Merging Hydro-Electric Interests

The reported plan for merging control and ownership of large hydro-electric and utility corporations in Montana, Washington, Idaho, Utah and Colorado will be urged as an additional reason for the speedy enactment of water-power legislation, when Congress reassembles next winter.

Secretary Lane of the Interior Department, father of the fifty-year leasing plan for the disposal of water-power sites in the public domain which was passed by the House and allowed to die in Senate committee in the last Congress, announced a few days ago that the leasing bill would be reintroduced immediately upon the meeting of Congress in December and expressed the hope that it would pass without further delay. Although the Secretary did not say so, it is understood that the water-power bill will be a part of the Administration's legislative program next winter and that the influence of the President will be used to force the measure to passage.

Consolidations and mergers said to be planned in the states mentioned will place under single corporate control about fifty per cent. of the developed water powers in the Western states. In commenting upon this situation, Secretary Lane said:

"Such a consolidation, involving widely separated power plants, inter- and intrastate transmission lines and Federal questions beyond the scope of state utility commissions, emphasizes the necessity for Federal control and regulation in the interest of the public."

It is reported that the Electric Bond & Share Co., of New York, is the parent of the gigantic merger program. The power which would come under the control of the New York company by the consummation of the several mergers that have been made this year or are in contemplation would aggregate more than 565,000 developed horsepower and about 150,000 horsepower of undeveloped hydro-electric energy.

The Bond & Share Co.'s interest in the merger and control of these Western power sites and plants is represented, according to reports, by a holding company recently formed and known as the National Securities Co. The Bond & Share Co., in turn, is known as a subsidiary of the General Electric Co., and the completion of the merger program will give the General Electric practical control of the hydro-electric field west of Denver.

In the taking over of the Utah Light & Railway Co. by the Utah Power & Light Co. some time ago, all the important water-power plants in Utah were consolidated into a single-headed system. The merger of plants in

Oregon and Idaho now proposed, will similarly unite the hydro-electric plants in these states, heretofore owned by the following companies:

DEVELOPED WATER POWER

	Horsepower
Idaho-Oregon Light & Power Co.	7000
Idaho Railway, Light & Power Co.	14,000
Idaho Power & Light Co.	7500
Great Shoshone & Twin Falls Water Power Co.	9000
Thousand Springs Power Co.	3000
Southern Idaho Water Power Co.	5000

These interests have heretofore been regarded as quite divergent. The Idaho Railway, Light & Power Co., which operates the traction system in Boise, has for some time been seeking a consolidation with the Idaho-Oregon Light & Power Co., which does a commercial business in Boise. The Idaho-Oregon Co. was formerly controlled by the Mainlands, of Oshkosh, Wis., but has been in the hands of a receiver for some time, the receivership being forced primarily by the reduction of power prices from fifteen to nine cents as a result of the entrance into that city of the Idaho Light & Power Co., in competition with the older concern. The Idaho Light & Power Co. has been trying to get into the Twin Falls and Pocatello fields also, and there has been litigation because of the action of the Idaho Public Utilities Commission in permitting the company a "certificate of public necessity" to enter Twin Falls and not Pocatello.

In the Utah merger, by which the water powers of the state came under single control, there were involved plants aggregating 112,850 horsepower of developed energy. The projected acquisition of the Washington Water Power Co. by the same interests will give the General Electric Co. control of the following companies in the Northwest:

DEVELOPED WATER POWER

	Horsepower
Montana Power Co.	184,000
Washington Water Power Co.	156,000
Pacific Power & Light Co.	23,750
Colorado Power Co.	42,250
Utah Power & Light Co.	112,850
Proposed Idaho merger	45,500
Total	564,350

The plan of merger proposes that shares of the older companies shall be exchanged for shares of the new holding company, the National Securities Co., and that all the plants will be operated by a big new company to be organized for this purpose.

Among the power plants involved are those at Oxbow on the Snake River and at Horseshoe Bend on the Payette, owned by the Idaho-Oregon Co. The Idaho Railway, Light & Power Co. owns a power plant at Swan Falls on the Snake River. Other plants included are those at the Shoshone Falls on the Snake River and at American Falls, Idaho. All these power sites were on public land and were the property of the people of the United States until within recent years, and practically all of them passed into private ownership for a nominal consideration and without qualification.

There is no control over water-power companies by state utility commissions in Colorado, Wyoming, Utah or Montana.

Without raising the question of whether the water powers can best be developed by competition or by monopoly, advocates of the Ferris bill urged that the drawing tighter of the lines of private monopoly emphasizes the need for legislation now to protect the public's interests in the power sites still remaining in the public domain.

With half the power of the West under single control, it is urged by Secretary Lane and other advocates of the leasing plan and Federal regulation for power sites in the public domain that the Government should perpetually maintain a controlling hold upon these great natural resources, the value of which is not yet fully apprehended. It is pointed out by these same men that state utility commissions cannot do much in protecting public interests against such a great and powerful monopoly, which would be sufficiently strong to dominate the politics of almost any of the states in which it operates.

A small number of Western senators and congressmen who helped defeat the Ferris bill last winter, urged that a leasing system would retard development, inasmuch as it would discourage investment of capital in water-power enterprises, and that what the West wants is development at any price. In the face of the magnitude of the monopoly that will be created by the mergers now projected, it is not believed that this position can be maintained by this element.

"If the water power sites of the West are allowed to pass into private ownership without restriction," said Secretary Lane, recently, in discussing the matter, "it is apparent that it will be practically impossible to regulate or control monopoly in this important resource or to regulate this product in the interest of the consumer. The possibilities connected with the utilization of the water power of the United States are not at this time realized, nor can anyone predict what changes in the method of development and control will be required by the public interest in the course of fifty or a hundred years from now.

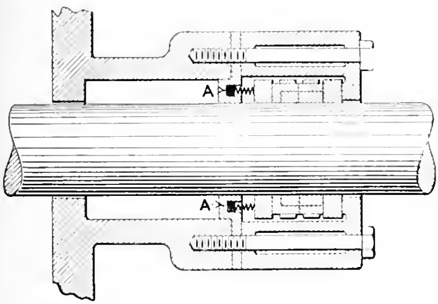
"Only by retaining the fee to these lands and rights in the Federal Government and a measure of control, can the interests of the public, present and future, be properly safeguarded."

Encouraging reports continue to come in showing the favorable attitude of the various states toward the American Society of Mechanical Engineers' Standard Boiler Code. Thomas E. Durban, chairman of the Committee on Uniform Standard Specifications, of the American Boiler Manufacturers' Association and the National Tubular Boiler Makers' Association, has received assurances from J. D. Beck, Industrial Commissioner of Wisconsin, that the State of Wisconsin will "stand by" the recommendations of the committee to the fullest extent and will publish the list of boiler makers who have adopted the Code of the American Society of Mechanical Engineers in the literature of the Commission, in order to encourage the purchase of boilers from such manufacturers. Also an assurance by J. F. Sturgis, superintendent of the Boiler Department of the London Guarantee & Accident Co., Ltd., that all specifications furnished by that company to its assured will conform to the A. S. M. E. Code.

Correspondence

More Spring Tension on Packing

On a 24x48-in. Corliss engine exhausting into a barometric condenser, the vacuum would not go over 22 in. The trouble was located in the metallic piston-rod packing; although it was a good fit on the rod, the tension



Brass Plugs under Springs

was insufficient. Brass plugs the size of the hole and ⅜ in. long were put under the springs at *A* to increase the tension. Now we have no trouble in maintaining a 27-in. vacuum.

Williamstown, Mass.

Quarter-Turn Shaft Coupling

In the Jan. 26 issue, page 117, there is an article on a "Quarter-Turn Rod Coupling," which, it is stated, was invented by C. P. Hall, of Chicago. Such an appliance has been in use many years and is known as the "Hobson" patent.

James McClure.

Fletcher, N. C.

So far from the quarter-turn rod coupling being new, I know it to be at least twenty-five years old. A fisherman in a little town in Nebraska, where I lived when a boy, carried such a contrivance around with him in his pocket. It was made of two wooden spools and four wires applied substantially as shown in Power.

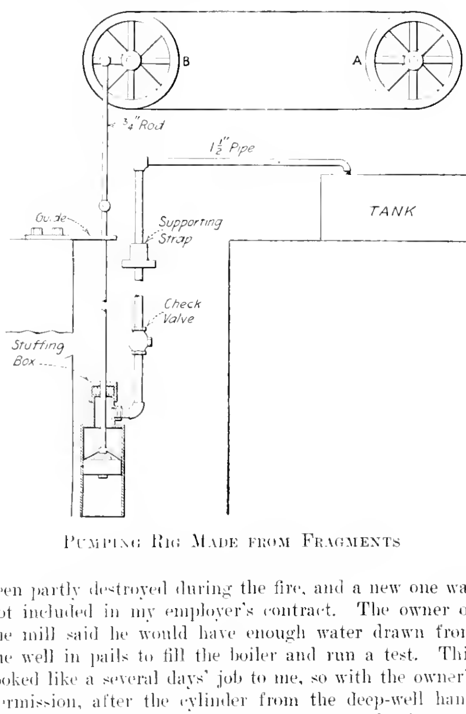
C. O. Sandstrom.

Kansas City, Mo.

[The quarter-turn coupling referred to embraces the idea of the Hobson patent, of which there are at least two kinds. One consists of a number of right-angled rods which move in perforated guide flanges on the ends of shafts and run at right angles, the rods drawing in and out through the flanges as the shafts revolve. A large angle rod serves as a center bearing. Another coupling is made with four angle rods which slide in holes in the shaft coupling. The difference between this coupling and that described in the Jan. 26 issue is that Mr. Hall's coupling consists of six angle rods and the shaft couplings are made longer, so that when the rods are fully extended the end comes at the center of the couplings, and when the rods are at their inner position they come flush with the inner end of the coupling. In the "Hobson" patent, in one coupling the angle rods extend beyond the inner end of the coupling when at their inner position, and in the other design but ⅓ of the shaft coupling has a bearing on the angle rod when extended. In these two respects the Hall coupling is superior to the original patent, as a greater bearing surface is obtained without the necessity of the objectionable protruding angle rods. The principle of the coupling is the same.—Editor.]

Sawmill Engineering

A sawmill was burned down in northern Ontario, fifty miles from a railway, and I was sent out to install a boiler and engine in the new shack called a mill. There was a 55-ft. open well on the property, the water being about 45 ft. from the ground level. The old pumping outfit had



Pumping Rig Made from Fragments

been partly destroyed during the fire, and a new one was not included in my employer's contract. The owner of the mill said he would have enough water drawn from the well in pails to fill the boiler and run a test. This looked like a several days' job to me, so with the owner's permission, after the cylinder from the deep-well hand pump was found, although the bottom cap and valve were missing, I rigged up an outfit as shown.

The bottom of the cylinder extended to within a foot of the bottom of the well, and the pipe was supported by straps placed around it at several places. A shaft extended up to the pump room, on which there was a pulley. Another pulley with a hole drilled in one spoke was put up over the well and connected to the pump as shown. The first tankful was raised by a couple of men pulling on the belt to turn the pulley. The whole thing was put together in about four hours. I have never been back there (for which I am mighty thankful) but I suppose they have a new pump, although that make-shift affair may still be doing its day's work. It was not a noiseless outfit, by long odds.

JAMES E. NOBLE.

Toronto, Ont.

Some Reasons for Different Rates

The comparison of the sale of electricity to that of ice, by C. R. Seed, in the Mar. 16 issue, although meant to justify central-station practice, illustrates, more than anything else, the injustice of the system of rates in most of the principal cities, as well as in the small towns.

To begin with, let us reconsider the example of Jones, the ice man, together with the figures set forth by Mr. Seed.

To harvest ice *A* (for small consumers):

Cost of labor per ton	$1.00
Cost of machinery, house and equipment, per ton	1.50
Total cost per ton of ice	$2.50

To harvest ice *B* (larger consumers):

Cost of labor per ton	$0.85
Cost of machinery, etc.	0.85
Total cost per ton of ice	$1.70

To harvest ice *C* (still larger consumers):

Cost of labor per ton	$0.75
Cost of machinery, etc.	0.60
Total cost per ton of ice	$1.35

To harvest ice *D* (wholesale consumers):

Cost of labor per ton	$0.70
Cost of machinery, etc.	0.45
Total cost per ton of ice	$1.15

Would it not be reasonably fair to all consumers, large and small, if their rates were based upon the average cost of labor, machinery, house and its other equipment? If this were made the basis of rates for all, the total average cost of the ice per ton, leaving out for the present the cost of transportation, would be

$$2.50 + 1.70 + 1.35 + 1.15, \text{ or } 6.70 \div 4 = \$1.675$$

The fairness of this assumption cannot well be disputed. There is no logical reason why the small consumer should be perpetually burdened with the first cost of the icehouse and its equipment. Of course, the cost of transportation will tend to change the rates somewhat, but transporting ice is far different from the transmission of electricity. A given amount of the latter cannot make any more trips in a unit length of time to a few large consumers than it can to several smaller ones. It may be argued that there is an extra outlay for wire in the latter case, but this item in itself is not sufficient excuse for the great difference in the rates to large and small consumers.

Mr. Seed states that the business of the large consumers causes the whole lot to be cheaper. Yes, cheaper for the large consumers. To farther illustrate my point: Suppose that Jones did not cater to the large consumers, but secured several new small customers, which made it necessary to build another story to his icehouse. The cost of ice per ton of lot *A* being $2.50 exclusive of transportation, the cost of lot *B* per ton in this case would be $1.70, which means that the new customers, although not buying any greater quantities than the old ones, are getting their ice for eighty cents less than the original customers, without whom Jones would have had great difficulties in starting in the ice business.

The foregoing does not sound fair, but it is virtually practiced, as Mr. Seed's article proves. If Jones had been a fair-minded business man, instead of having high rates for one set of his customers and low rates for another set, he would lower the rates for the one and raise them for the other until the rates of both were alike; that is, $(2.50 + 1.70) \div 2 = \$2.10$.

Mr. Seed asks, "Which part of the business would Mr. Jones drop?" Let us see. If he drops the small customers *A*, he will transfer the burden of the original cost of the ice plant to the next smallest consumers, or *B*, and will thus raise their rates from $1.70 to $2.50 per ton; he would also have to raise the rates of the consumers *C* and *D*. But he is well aware of the fact that if he juggled with the rates of these large consumers, they would all proceed to install ice and refrigerating machines of their own. He also knows that the small consumers *A* will not install their own refrigerating plants, and that is why Jones goes as far as he likes with these little fellows and why he will not drop that part of his business.

SAMUEL L. ROBINSON.

Providence, R. I.

With no intention of questioning Mr. Seed's entire sincerity in regard to central-station rates, I propose to carry his analogy a little further and present another view of the subject.

Jones cuts 1000 tons of ice at a cost of $2.50 per ton and markets it at a cost of $6.15 per ton, and to make a profit sells at $10 per ton. Smith and Brown, with a new and modern plant, cut 1000 tons of ice at a cost of $1.25 per ton and use it themselves. Jones, seeing a wider field, installs a plant to handle a larger volume of business at a smaller cost per unit of product and proceeds to cut 4000 tons of ice at a cost of $1.15 per ton, and which he markets as follows:

A. Retail 1000 tons, costing $6.15 per ton for delivery, total	$7.30 per ton
B. Retail 1000 tons, costing $4.48 per ton for delivery, total	5.63 per ton
C. Wholesale 1000 tons, costing $1 per ton for delivery, total	2.15 per ton
D. Wholesale 1000 tons, no delivery, to Smith and Brown	1.15 per ton

For the 1000 tons A he charges $8000, or makes a profit of	$700
For the 1000 tons B he charges $6000, or makes a profit of	370
For the 1000 tons C he charges $4000, or makes a profit of	1850
For the 1000 tons D he charges $2000, or makes a profit of	850
Total profits	$3770

Evidently, *B* is the least profitable and *C* the most profitable part of his business, so Jones proceeds to install a new delivery system, so that

A costs $4 a ton for delivery, or a total of	$5.15
B costs $2.50 a ton for delivery, or a total of	3.65
C costs 85c. a ton for delivery, or a total of	2.00
D costs nothing for delivery, or a total of	1.15

But Smith and Brown have now discovered that it is cheaper for them to cut their own ice than to pay $2 per ton for it, and also that some of the class *C* business is attractive and within their reach. Jones, being on his job, proceeds to revise his price list all along the line and then takes for

A. 1000 tons—$7000 (delivery and cutting costs $5150), profit	$1850
B. 1000 tons—$5000 (delivery and cutting costs $3650), profit	1350
C. 1000 tons—$3500 (delivery and cutting costs $2000), profit	1500
D. 1000 tons—$1250 (no delivery and cutting costs $1150), profit	100
Total profits	$4800

and has not only increased his own profit but effectually disposed of any competition by Smith and Brown.

Query: Would Smith and Brown get quite as good rates if it were impossible for them to molest any of the class *C* business?

Would Jones shade the price on class *C* business if Smith and Brown persisted in cutting their own ice, together with a surplus which they offered to class *C* users?

How long would Jones care for Smith and Brown if he did not have the other three classes to produce his revenue?

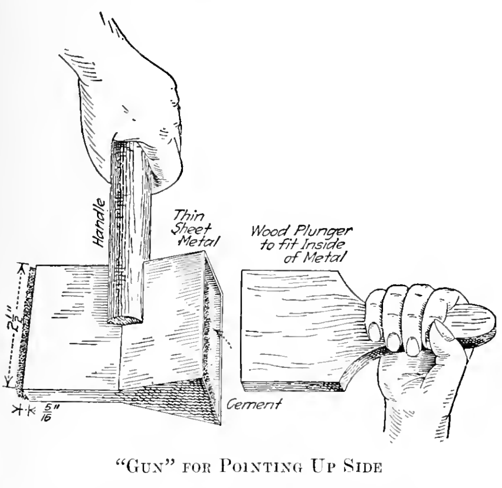
Maynard, Mass.

Boiler-Room Repairs

Most engineers and firemen are not very skillful in laying brick, but there are times when a few minutes spent in pointing up loose brick with cement or fireclay when the fires are out will develop a good job well done.

Getting fireclay or cement in between brick is not always as easy as it might seem. The illustration shows a



"Gun" for Pointing Up Side

sort of a square squirt gun with which you can fill up the most obstinate crack or hole, and you don't have to be a mason to do it, either.

We always keep on hand a little cement, and whenever a crack shows up and needs attention it takes only a few minutes to fix it, and the job is better than that usually done with the time-honored trowel. Our original model was made from a small tin can and a piece of a barrel stave, which was used until worn out, when we had something suitable made by a tinsmith.

Brooklyn, N. Y.

Increased the Capacity of the Plant

In the plant where I am employed low-grade slack coal was originally burned, because it was considered cheaper at $1.35 per ton than screened lump at $1.85. Later on, an increased load compelled the burning of the more expensive coal. About this time the price of fuel oil dropped until it was considered more economical than coal, when the grates were removed and an oil-burning furnace put in. This was satisfactory until the price of oil again became prohibitive. In the meantime the load had increased until it was useless to replace the original coal-burning furnace and expect to pull the load without additional boilers.

The management, realizing conditions, allowed a self-styled smokeless-furnace company to place its furnace under one boiler with the understanding that it would burn the poorest southeastern Kansas slack without smoke or clinker. This furnace produced more smoke from less coal than any other I have ever seen, and I have not yet learned how to burn coal containing 18 to 22 per cent. ash and 5 to 7 per cent. sulphur content without some clinker. The "patented smokeless furnace" did not eliminate any of the natural ash content of the coal and one was all that was needed.

It was necessary, however, to get back to burning coal immediately, and on account of the low-set boilers stokers could not be put in with any assurance of satisfactory operation. Therefore, it was up to us to devise and put in a hand-fired furnace that would deliver sufficient overload capacity to pull our constantly increasing load and at the same time meet modern economic requirements and compete with the central station.

The original layout consisted of four 250-hp. Heine water-tube boilers set 5 ft. above the floor at the front and 3 ft. 6 in. at the rear and baffled with T-tile which exposed the lower half of the bottom row of tubes to the flame. The boilers were connected to a steel-concrete stack, 8 ft. diameter and 172 ft. high, which gave a draft of approximately 0.9 in. of water at the dampers and eliminated the necessity of using forced draft, provided sufficient air opening and grate surface were supplied.

The grate surface was extended from 42 in. in length to 56 in., using a shaking and dumping grate having 48 per cent. air space instead of 42 per cent. The T-tile was replaced with a box-tile baffle which protects the unburned gases from the comparatively cool tubes during a critical stage of combustion, which is completed by the time the gases have passed through the combustion chamber, provided sufficient air is admitted over the grates. This feature was supplied by using a rather large damper on the fire-door, the liner of which was perforated according to common practice, and breaking up the air prevents it from stratifying through the furnace. The ashpits were lowered 6 in., which permitted lowering the back end of the grates 10 in., giving them about the same pitch as the water tubes, and adding several cubic feet to the combustion space.

A small amount of steam admitted under the grates has a cooling effect on the molten ash and dampens that already on the grates, thereby preventing the formation of large clinkers. This makes it possible to clean the fires by shaking the grates moderately at 1½- to 2-hour intervals. This steam is supplied by a bleeder from separators on the power units, which were formerly trapped into a feed-water heater. This trap, however, was almost constantly discharging, and it was believed that, as the feed-water heater was large enough to bring water to the boiling point, the condensation would be worth more in the ashpits than in the heater.

With this furnace we can develop 75 per cent. overrating, with but little smoke, burning slack averaging 10,000 B.t.u. and containing 18 to 22 per cent. ash and cleaning fires once in twelve hours. Lump coal of about 11,000 B.t.u. and 10 to 12 per cent. ash is cheaper at $1.85 per ton than slack at $1.35, and it is possible to carry a heavier overload. The smoke seldom gets darker than No. 2 Ringelman chart, and CO_2 averages 12½ per cent., with no CO.

B. M. Babcock.

Pittsburg, Kan.

Experience in an Isolated Plant

The following experience of a friend was interesting to me and may be to others:

"Eight return-tubular boilers with hand-fired furnaces furnish steam for a manufacturing plant with a load almost uniform throughout the twenty-four hours. Various steam-saving appliances had been employed in the engine and dynamo room, but we had never received any special consideration out in the boiler room.

"A so-called efficiency expert had given the plant at large a general going-over, but about all the effect we felt was to have the force cut down and the consoling news that our department was wasting more money than other plants of this class. Our superintendent was deeply engrossed in what he termed the 'output' end of the business.

"Our chief engineer was well along in years and not very favorable to 'theoretical steam makers!' One day the superintendent came into the boiler room and with him our engineer and a young man who was a stranger. The young man said little, but nothing escaped his scrutiny; dampers, draft, coal, ashes and our methods of firing. I felt quite curious and a little uneasy. Sure enough, the next day we heard that the steam plant was to be shut down and city current used. Our engineer said he was powerless to help us as the central-station representatives had shown that it would be decidedly advantageous to buy current, and that the superintendent had decided to try it. There were 12 men in our crew, who would have to look for new jobs and we were a gloomy bunch.

"Since being put in charge of the boiler room I had been studying up on flue-gas analysis, draft regulation, etc., with but little encouragement from my chief. As it appeared that we were to lose our jobs anyway, I pleaded with the chief to make a last effort with the office for our plant. With courage born of desperation, I told him the plant deserved to be shut down on account of our wasteful habits, and that our methods were crude, etc. He took me with him to the office, where the superintendent received us cordially. The chief said nothing, but simply turned me over to him. With nothing to lose, I made a straight drive for my point—that with the proper instruments and boiler-room methods our plant could produce power cheaper than the central station. The outcome, without the details, was that arrangements were made for a three months' trial for which we were supplied with a set of gas collectors, differential draft gages on all the boilers, a new damper regulator and provision for forced draft. Team work and head work also played a large part.

"The draft was kept at what was found by experiment to produce the best combustion. Different fuel-bed thicknesses were found to require different draft and different ash-pit pressures to get the CO_2 up to the bonus line. We were determined to make a success of it and did. A bonus system was established among the firemen, the charts were gone over each week and a bonus declared in proportion to the percentage of saving. In this way the firemen were made stockholders in this economy enterprise. At the end of three months, the trial period allotted, every fireman had developed into an efficiency expert.

"We never knew what the city-current fellow's figures were, but at the expiration of our three months' test we knew we had won. We found that the greatest source of waste we had to overcome was excessive draft!"

Edward T. Binns.

Philadelphia, Penn.

Electrically Controlled Damper Regulator

In the Apr. 13 issue, page 517, is a letter from Henry W. Geare on this subject. Mr. Geare seems to assume that by some means or other he determines how much air is required to burn a certain kind and quantity of coal per square foot of grate per hour, and then arranges to pass sufficient air through to burn this coal. Of course he does not say how this is determined, and I believe he would find it difficult to determine. If, however, he did determine it once, it would not be the same the next time he tried to do it, as the quality of the coal would vary.

Further on in his letter is the statement: "It will be found that under that close regulation with natural draft a much more uniform and higher average CO_2 can be maintained, and the efficiency of the boilers increased, with the resulting saving in coal." Much more uniform and higher than what? Further on he states that "the results with natural draft are nearly equal to those obtained by a balanced draft system without the use of blowers;" which I assume is intended to be a general statement and rather broad in application. What is a balanced draft system without the use of blowers? He concludes by saying that "a balanced draft system without the use of blowers increased [and now he refers to a particular case] the cost of power required to operate such systems." What systems?

A Prey to the Elements

It is usual to see the bright side of transmission lines illustrated in articles on the subject, but sometimes there is something of value to be derived from their failures.

In the present case all the details of the transmission line were worked out most carefully by government engineers, these were checked up, and then followed the construction, inspection and testing. The towers were put up, tested, and everything done that high-class engineering practice considers desirable. This line ran from the celebrated Roosevelt dam to the neighborhood of the Inspiration Copper Mining Co., in Arizona, and passed over a part of the desert in that vicinity.

The line was in service for some time and no more thought was given to its safety, when suddenly about a year and a half ago there arose in the desert a terrific storm that blew and battled, as storms on the Arizona desert can, and soon showed its disregard for engineering and the government and laid about two miles of

One of the Towers after the Storm

poles or towers to the ground. The condition of one of the towers is seen from the photograph taken shortly after. It will be noted that the tower is clearly buckled and that the rivets and holding parts are still intact. In certain places breaks appear to exist, at first glance, but closer inspection shows that these are the ends of the cross-angles.

Washington, D. C.

Liquid Weigher Improved

A liquid weigher, Fig. 1, failed to operate when the temperature of the feed water became as high as 200 deg. F. The vapors arising from the water evidently formed air pockets in the siphons, causing loss of suction, consequently, the buckets would not drain sufficiently to allow them to turn to the proper position to be refilled.

This difficulty was overcome by making two steel crankshafts $2\frac{1}{2}$ in. diameter, and extending from the center of the weigher through the side walls, and attached to the dashpots on the outside. These crankshafts have a $5\frac{1}{2}$-in. throw and revolve in bronze bearings mounted on the channel beams supporting the bedplate. An arm, or lever, extends from the shaft to the bucket, being fastened between the two short pieces of channels under the bucket, Fig. 2; these channels serve as buffers between the bucket and bedplate. A hole 3 in. diameter was cut in the bottom of the bucket and a special valve, Figs. 3 and 4, made to fit this hole.

After the bucket is filled and tilts the water is turned into the other bucket by the deflector with which the weigher was originally provided, and the valve stem is raised by striking a strip extending across the weigher some distance below the bottom of the buckets. After the water has been emptied into the reservoir the bucket

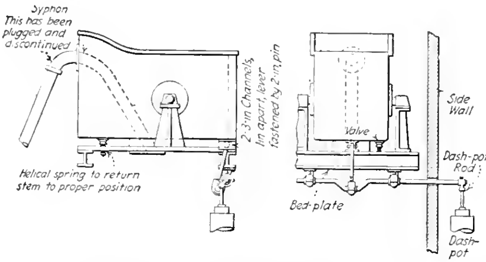

Fig. 1. Section of Weigher Showing the Siphon and Dashpot

returns to its normal position to be refilled, and the valve stem is forced back into its proper position by the helical spring. Should leakage take place through this valve, it can be stopped by increasing the tension of the spring by means of the nuts on the valve stem.

The size of the valve required will, of course, depend upon the time available for one bucket to empty and return to its filling position. The 3-in. valve mentioned allows a bucket containing 485 lb. of water to empty and return to its normal position in from 33 to 37 sec.

Any sort of registering device can be used to count the number of buckets dumped in a given time. An ordinary street-car register can be connected so that each time a bucket is emptied it will be recorded on this register. The amount of water necessary to tilt a bucket can be determined by filling one and allowing it to empty into a barrel mounted on a pair of scales. As the buckets are usually filled through one weir, the total amount of water consumed will be the product of the number of buckets emptied, the pounds of water contained in each bucket, and the number of weirs.

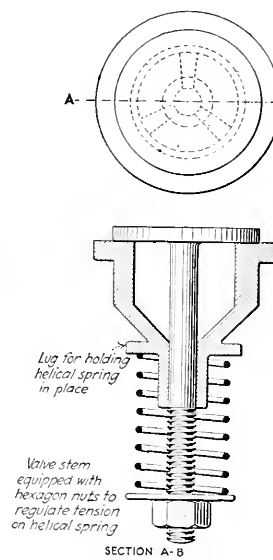

Fig. 2. Section of Valve for Liquid Weigher

After making the above changes the weigher was tested several times before being put into service. The water dumped by the buckets was weighed and the maximum [illegible] differed from the average of a dozen trials [illegible] per cent.

The [illegible] advantage of the weigher (which is a W[illegible] as it is now, over the original one, is that [illegible] no loss of suction on account of the formation of air pockets as there is no siphon effect. The buckets will return to the proper position to be refilled, enabling the operators to keep an accurate record of the total water consumed. Also, the dashspots will give less trouble, as they are no longer submerged.

Effects of Throttled Indicator Cock

During a test on an ammonia compressor a number of diagrams were taken whose areas gave a capacity smaller than the machine should have developed. These diagrams were similar to those shown in Fig. 1. The reexpansion line appears, which would indicate a large amount of gas in the cylinder at the end of the stroke.

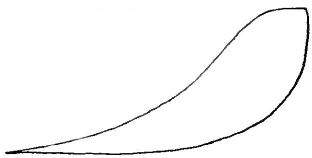

FIG. 1

FIG. 2

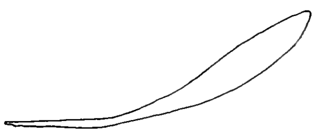

FIG. 3

FIG. 4

DIAGRAMS SHOWING EFFECT OF THROTTLED INDICATOR COCK

In this particular machine the compressor cylinders were single-acting and there was every reason to believe that there should have been a constant pressure line throughout the stroke and a diagram similar to Fig. 2 obtained.

Investigation and experiment showed that if a series of diagrams were taken, one after another, with the indicator cock opened a little more each time, diagrams with widely varying areas could be obtained. Further experiment showed that diagrams varying from that shown in Fig. 4 to that shown in Fig. 2, depending on how much the cock was opened, could be taken. The reason for the cock not being fully opened was that in trying to have the least possible amount of ammonia escape, the operator feared to open it. Instead of getting an intake line at constant pressure, the line obtained would indicate a decrease of pressure as the stroke progressed. This was due to the failure of the indicator mechanism to respond because of the reduced opening through the valve.

Owego, N. Y.

Starting an Old Dynamo

A moving-picture man in a small Western town got hold of an old direct-current dynamo which he wished to use with a traveling motion-picture show, his plan being to drive the machine from a rear wheel of an automobile.

The dynamo had lain around for many years and it was a question whether it was in operating condition. As the "movie" man had had some trouble with the local light plant's electrician, he did not feel like calling on him for advice, so he called in a fellow who posed as being every kind of a mechanic. The latter turned on the power and got the machine up to speed, but could get no sign of electricity from it. He then proceeded to test out with a storage battery, and finally announced that the fields must have been burned out and that it would be an expensive job to put the machine in running order. The movie man hated to give up the project and, as the lighting company's electrician had the reputation of being an expert, he decided to try to get him. The electrician responded reluctantly and after calling for the battery used by the other fellow, made the same field tests, but refused to make a positive statement about the machine.

That evening a friend of the movie man chanced to overhear the electrician say that it would not take him fifteen minutes to get the dynamo to generate. The next day this was repeated to the movie man, who immediately called for the electrician again and told him what he had heard. The electrician confessed to making the statement and agreed to make the trial. He connected six cells of a dry battery in the field circuit for an instant and then brought the machine up to speed, and when the proper connections were made the dynamo lighted up an incandescent lamp nicely.

The machine refused to generate in the first case because it had lost its residual magnetism and the resistance of the fields was so great that the storage battery could not send enough current through them to be noticed or to make a spark. When the electrician made the test he wet his fingers and made and broke the circuit, so that when the circuit was broken through the wires it was complete through his fingers. There was enough inductive kick to be felt and to show that the field circuit was all right, though no spark could be seen. The six dry cells were sufficient to magnetize the fields enough to give the machine a start.

The movie man was greatly pleased, but still had things to learn about electricity. The next day he brought the picture machine around and proceeded to try it out. The dynamo generated nicely until he switched on the arc, when the voltage suddenly died completely. All attempts to get a sign of an arc across the carbons were futile, so once more the light company's electrician was appealed to. Only one question was asked—"Did you use your rheostat the same as when using the company's power?" The answer was, "No."

He was told to do so, with the result that an arc was had without further trouble.

As the dynamo was a plain shunt machine, when the carbons were in contact there was a dead short-circuit across the brushes and nothing to force any current through the field; therefore, the field died and there was no voltage to produce the arc. When the rheostat was in the circuit this resistance prevented the current from flowing through the outside circuit until the voltage was strong enough to build up the field.

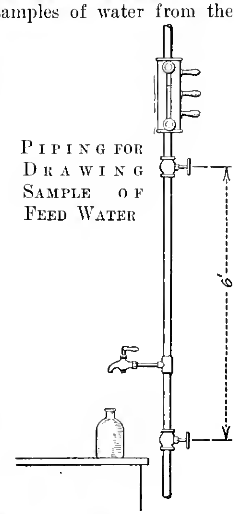
Denver, Colo.

Drawing Feed-Water Samples

For taking representative samples of water from the boilers we have found the following to give best results: Each water-column blowoff pipe has an extra valve near the boiler-room floor, and a pet-cock is connected as shown. To obtain a correct sample the bottom valve is opened first, then the one directly beneath the column is opened to blow out the column.



Piping for Drawing Sample of Feed Water

The bottom valve is closed first, then the top one. After the sample contained in the section between the valves has had time to cool, it may be drawn off at the pet-cock into any convenient receptacle.

Edward T. Binns.
Philadelphia, Penn.

Calking Pipe Leaks

In a certain power plant subjected to a working pressure of 100 lb. the lines have given considerable trouble from leakage in the threads. The flanges on the 10-in. main are extra heavy, with the pipe screwed all the way through and peened. In peening these flanges the erector simply beat down the outer edge of the pipe or, rather, riveted it over, but did not peen the full width of the flange. This does not make a good job and prevents the flanges from being taken off, as it tears the threads. These leaks could be stopped temporarily by calking, which was done in the following manner: A calking tool was made with a bit about 3/8 in. wide, then a small groove was cut in the flange with a narrow chisel and this recess calked full of tinfoil. This would stop the leak for a few days, until it worked around the thread to a new place. Some of them were calked all the way around.

The most troublesome leaks were in some short pieces, which were replaced with new ones.

In making the new pieces a full clean thread was cut long enough to screw in the full width of the flange when tight, and to the same taper as the thread in the flange. No "dope" except machine oil to reduce the friction was used in making up the joint, and the pipe was not peened or beaded in the flange. Several nipples were made up in this way and every one gave entire satisfaction without a leak. Some of the other leaking joints were taken down and the entire surface of the joint peened with a heavy ball-peen hammer, but in a few months they were as bad as ever.

The steam line is level and properly drained, with hangers placed not over 10 ft. apart and adjusted to equalize the load on each, but there is some vibration. Steam is not shut off except at long intervals, and there is ample provision for expansion. The principal cause of the trouble is poor workmanship, as those sections, put in properly, give no trouble.

I believe that for ordinary pressure a flange joint should not be peened, and that no "dope" should be used except good oil, because a metal joint is what is wanted, and this cannot be had if the thread is filled up with pipe compound.

Our experience has demonstrated that a plain screwed joint, properly made up, will hold better than a peened joint.

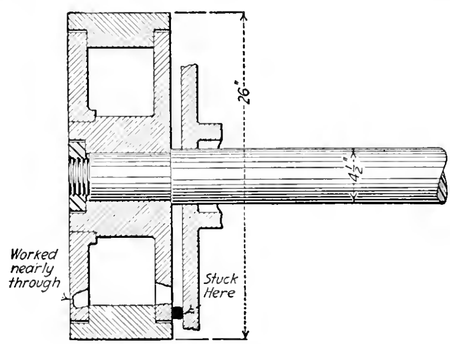
Hyattsville, Md.

Unusual Piston Failure

The piston in our 26x48-in. Corliss engine had a piece of metal of some description left inside when it was plugged up, and after three years of service it worked through the piston on the crank end and was caught between the piston and head, as indicated in the illustration. No damage was done except slightly bending



Piston Wall Worn through

the piston rod. The engine was not shut down for a couple of days, but right after the accident it began pounding badly on the crank end. An indicator diagram was taken, which showed the usual conditions in the head end, but high terminal pressure on the crank end and low compression. It was at first thought that the exhaust-valve stem had twisted, but after studying the diagram it was decided that it would be impossible for the stem to be twisted so that it would lower the compression and raise the terminal pressure. The piston was removed and a hole 1½x1¼ in. was discovered at the bottom of the piston. This was bored out and filled with a 3-in. pipe plug and the diagram was all right.

If any Power reader has had a similar experience I would be pleased to hear from him.

J. W. Dickson.

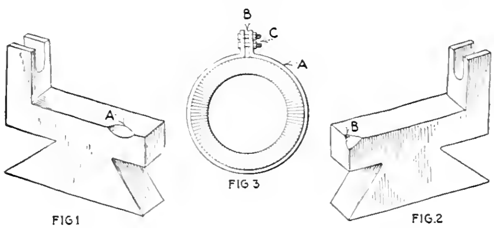
Memphis, Tenn.

Filling Holes in Commutator

The commutator on a 200-kw. generator contained numerous holes which were constantly filling with carbon and copper dust and short-circuiting the segments, with the result that the holes were constantly growing larger. All the well-known methods for filling holes in commutators were tried, but the filling would stay in only a short time, and it did not seem to make any difference what pains were taken to clean the holes before the mixtures were put in; the filling would blow out just the same.

If more time had been available it might have been possible to try something different, but as this was the only source of supply except a storage battery, it could not be shut down for any length of time.

The commutator contained 95 segments, and there was hardly a bar that did not show some kind of hole. They



varied from pin holes to the largest, which covered three-quarters the width of the bar and was ½ in. deep and about ¾ in. long. Some were situated as at *A*, Fig. 1, while others were on the extreme end of the segments, as at *B*, Fig. 2.

While turning the commutator would have helped to a certain extent, as it would have taken out many of the small holes, it was not advisable, as enough could not be turned off to take out all the holes without weakening the commutator; also, it would have been a waste of copper, and there probably would not have been enough carrying capacity left in the segments to take care of the current.

As more load was to be added in a short time, the manager decided to purchase another generator. After wiring the old machine so that it could be run in parallel with the new one, and while waiting for a pulley, it was decided to see what could be done with the commutator. It was thought best to take it apart and put in new mica. Two straps of ¼x1-in. iron were bent around the commutator as at *A*, Fig. 3, a ½-in. space *B* being left at the top. Two bolts *C* were inserted to clamp the strap which, in turn, held the commutator in place after the end-plate had been removed. After taking off the end-plate the bolts were loosened on the straps and the mica between two of the segments was removed and then used as a pattern for cutting the new stock.

Then someone proposed that the holes could be filled with solder, each segment being treated separately, so as not to cause a short-circuit. The question of the commutator becoming hot enough to melt the solder was discussed, but as it had not got hot enough in the past to melt the solder at the leads, little apprehension was felt.

First one, then the other of the straps around the commutator, was moved to the segment that was to be taken out, the opening in the strap coming directly over the segment. After unsoldering the leads the segment was moved to the first strap, and the bolts were taken out to allow the ear of the segment, which was higher than the strap, to pass. The bolts were then put back and tightened, and those of the other strap taken out, so that the segment could be removed.

Where the holes were not too large they were filled with solder, the segment having been heated with a blowtorch. On some of the largest holes the segment was laid down flat and a dam of clay built around the hole. The segment was then heated and the hole tinned, and enough solder melted to fill it. After cooling, it was filed off level so as to conform to the rest of the segment and was put back in the commutator. What is commonly known as "hard solder" was used. About thirty segments were treated.

The new mica was put in where needed, and after the leads were soldered on the segments the end-plate was put on and the straps taken off. The commutator was then turned, as it was out of round and the new mica projected above the bars. It was also the means of removing numerous small holes which were not filled with solder.

The commutator was still running at the end of five years and had given no trouble.

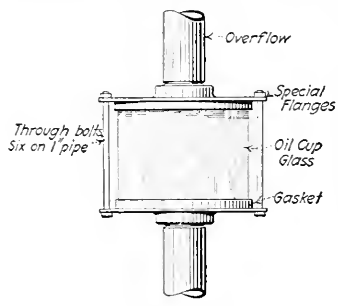
Fairfield, Maine.

Sight Glass in Overflow Pipe

The overflow water from sealing glands, etc., of high-vacuum apparatus should in all cases be so piped as to be visible to the operator, who can then determine the amount required. He can also detect the presence of undue leakage. A lot of work in one instance was required to locate the cause of a drop in vacuum when the



SIGHT GLASS IN PLACE

overflow was not so piped to a feed-water heater, but if there had been a sight glass, the absence of water, indicating the presence of a leak, could have been noted.

When the apparatus is drained by gravity it is a simple matter to place an open funnel in the line, and where the discharge is under pressure a sight glass can be made as shown in the illustration, using special flanges and a glass from a pressure oil cup with gaskets and through bolts.

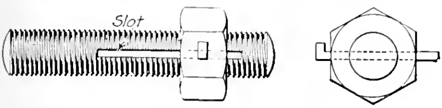
JOHN F. HURST.

Louisville, Ky.

Nut Lock

The nuts on stuffing-box studs sometimes cause quite a lot of annoyance by working off. The illustration shows how I remedied the trouble in a satisfactory manner.

In tightening or loosening the nuts all that is required is to slip the pin out. It is a very easy matter to remove



Slotted Stud for Pin

and replace the pins while the engine is in motion, because it is not necessary to have the hole in the nuts or the slot in the stud so tight that the pin has to be driven in or pulled out with pliers. A flat wire or key is better than a round one. There is no likelihood of the slot closing and allowing the nut to slip over the threads.

New Orleans, La.

Accident to Pump Plunger and How Repaired

A three-million gallon duplex triple-expansion waterworks pump in a near-by pumping station was a "thorn in the flesh" of the chief engineer ever since it was installed—some eight years previous to the accident. After being in service about three months, it developed a mild pound on one side that was finally traced definitely to the water end, but repeated inspections failed to reveal the cause of the trouble.

The water end, which was of the inserted-barrel type, is shown in the illustration. As there are but few parts in the water end, there seemed to be no reason for the trouble, and several inspections showed that the jam-nut was not loose. The noise became more distinct with time, until the fatal day when the studs *B*, Fig. 1, which held the plunger barrel in place, broke off on one side so that

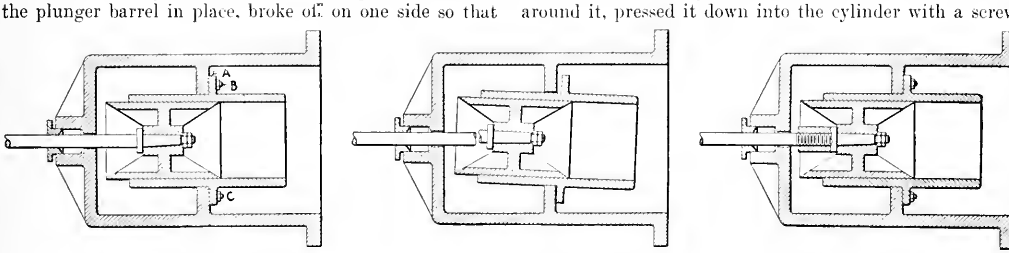

Fig. 1. Original Condition   Fig. 2. Plunger Barrel Displaced and Rod Broken

on the out-stroke the thrust of the rod forced the plunger and barrel off at an angle, as shown (exaggerated) in Fig. 2. This broke the plunger rod off close to the collar.

Upon removing the wreckage the cause of the pound, and also of the accident, was apparent. When the studs *B* were put in at the shop, the threads were not chased down far enough to permit drawing the nuts up against the flange of the plunger barrel, with the exception of three or four which were on one side at *C*. These held the barrel in place for a few months, and then lost motion began to appear at *A*, and grew worse until it had worn in over a quarter of an inch on the flange of the barrel. This continual hammering for several years caused the studs to give way. A new barrel was made and new studs with sufficient thread inserted.

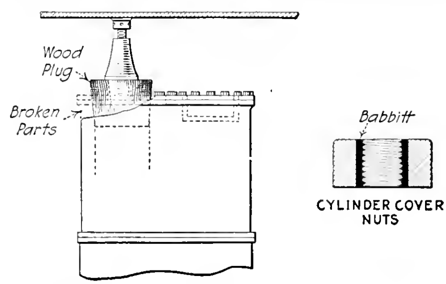
The plunger rod was cut off just inside the collar and threaded. A forging was made which was turned to fit the plunger and looked like a bolt with a large round head bored and threaded to receive the rod, as shown in Fig. 3. A jam-nut was first placed on the rod, as there was enough clearance to accommodate it. The pump now runs better than it did before.

George H. Wallace.

Racine, Wis.

Emergency Cylinder-Head Repair Aboard Ship

On board a Transatlantic steamship we had 8 sets of 8x10-in. fan engines for forced draft. They were located in a hot place over the main boilers. The boilers primed frequently, throwing the water into the steam pipes, and several of the cylinder covers were smashed. In one instance the flange was broken so that a new cover could



Wooden Plug Held in Place with Jackscrew

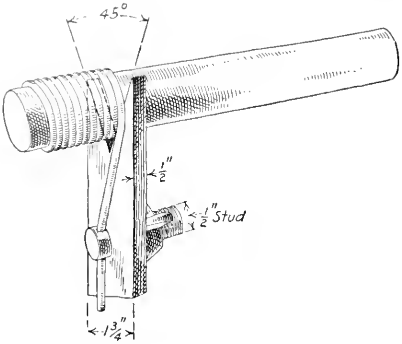
not be bolted on, so we trimmed a block of wood down to fit the bore of the cylinder and, with a sheet of asbestos around it, pressed it down into the cylinder with a screw jack, as shown in the illustration. The engine ran for 10 days, until we reached port, with very little escape of steam.

To prevent the cylinders breaking again we bored out the nuts on the cylinder covers ¼ in. and filled them with babbitt metal, then tapped them out. In case of water in the cylinders it only stripped the soft metal out of the nuts, which were then replaced with new ones and no damage was done We carried a number of these nuts all ready for such emergencies.

New Westminster, B. C. John Dobson.

Spring-Winding Fixture

The illustration shows a spring-winding fixture. Regardless of the diameter of the rod the spring is to be wound on, the tension is adjustable and the strain is taken up by the fixture itself. It is made from a piece of machine steel ½x1¾x14 in. long with a 45-deg. slot in the end, and drilled to receive a ½-in. stud. and a standard



Position of Fixture in Use

½-in. wing-nut. Drill a hole (say ¼ in.) in the stud close up to the head, and the fixture is complete. To wind an open spring the tool is held in the tool post, getting the lead required by the lead screw, the same as for any other purpose. Closed springs are wound with the fixture held in the hand and the wire will give its own lead.

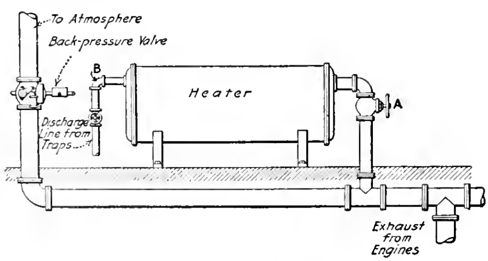
F. L. Young.

Pittsfield, Mass.

Heater Explosions

The illustration shows the arrangement of the exhaust piping, and a heater which was a source of danger that no one had ever noticed until after the head was blown out, resulting in the death of one man.

There were a number of steam traps discharging into



Heater without a Relief Valve

the heater at *B*, and it was customary to partly close valve *A* in case the water became too hot. This valve had an inside screw stem and one could not tell how nearly it was closed except by counting the turns made by the wheel. Just before the accident the feed pumps would not handle the water, so the water tender gave valve *A* a few turns to throttle the exhaust steam. The valve had evidently been left partly closed by the previous watch, so that with the few more turns it was completely closed. As there was then no means of escape for the steam from the traps, an excessive pressure was built up. Some of the traps were out of order and the bypass valves were open, which allowed steam to enter at full boiler pressure. One of the heads was blown out and broken into several pieces. Later, all the heaters were fitted with relief valves.

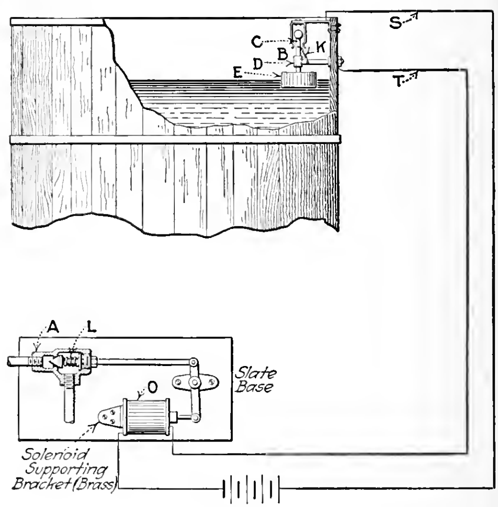
I have seen this same condition in one other plant, which leads me to believe that it may be a common oversight. I think all heaters should be fitted with some form of relief valve.

H. A. Dempsey.

Michigan City, Ind.

Water-Level Control

A mechanism for controlling the water level in tanks is shown. It is adapted to all kinds of water-supply tanks and can be installed at small cost. It consists of a throttle valve *A* operated by the electric solenoid *O*, which is controlled by a float switch *B* in the water tank. This switch consists of a brass spring to which is soldered the wire *S*,



Float and Solenoid Control System

a varnished wood float *E*, in the center of which is fixed a rod *C* with a ball end to make contact with the spring and guided by the arm *D* to which is soldered the wire *T*. Wire *K* is soldered to *C* and *D* to insure a good connection. The solenoid operates the valve through which steam enters to operate the pump.

The operation is as follows: As the water level in the tank lowers, the float *E* descends, closing the electric circuit, throwing the solenoid into operation, opening the steam valve to the water pump; when the pump has raised the water level in the tank to its required height, the float rises, opening the switch releasing the solenoid, and allowing the spring *L* to close the steam valve.

F. B. Hays.

Indianapolis, Ind.

Inquiries of General Interest

Rattling of Exhaust Valves—What causes the rattling noise of the exhaust valves of a noncondensing Corliss engine when running light or when coming to rest after the throttle valve is closed?

R. H.

Under the conditions stated the initial volume and pressure of steam or air in the cylinder may be so small that expansion occurs below atmospheric pressure, and the valves thus become unseated by the pressure of the atmosphere.

Clearance—What is the difference between piston clearance and cylinder clearance?

J. W.

Piston clearance is the distance the piston would have to be moved beyond the end of its stroke to strike the head of the cylinder, and is usually expressed in linear inches, while cylinder clearance is the volume of all the space between the piston at the end of its stroke and the valve face, and is usually expressed as a percentage of the volume displaced by the piston in one stroke.

Obtaining Same Point of Cutoff with Increase of Speed—After increasing the operating speed of an engine, how would the same point of cutoff be obtained for the same load?

C. H. M.

Increasing the speed would require less mean effective pressure, and as with the same point of cutoff there would be the same average pressure per pound of initial, then the increase of speed for the same load and point of cutoff would require a reduction of the initial pressure, obtained either by throttling or by reduction of the boiler pressure.

Determining Brake Power with Indicator—How can the brake horsepower of an engine be determined by use of an indicator and without applying a prony brake?

E. R. M.

The friction of an engine is practically constant for all loads, and as the brake horsepower is the net power developed by the engine, then for all practical purposes the brake power of the engine could be ascertained by determining the highest indicated power it would develop with any kind of load and deducting the power indicated when the engine is doing no other work than overcoming its own friction.

Operation of Automatic Cylinder Lubricator—In ordinary forms of automatic sight-feed cylinder lubricators, how is the pressure of the oil increased so as to force it into the engine steam pipe against the same pressure of steam as that received by the lubricator?

A. A. G.

The condensing chamber of the lubricator is connected by a pipe or passage to the lower part of the oil chamber and, in addition to the steam pressure communicated through the condensing chamber connection, the oil pressure is increased by the pressure due to the head of water of condensation which accumulates in the condensing chamber and its connections.

Allowance for Thickness of Plate—What length of ½-in. boiler plate would be required to form a cylindrical shell 66 in. outside diameter, with butt joint?

G. W. T.

In bending the flat plate into cylindrical form the side that is concaved becomes compressed, the side that is convexed becomes extended and the neutral axis is at the center of the sheet. Therefore, the length of the plate will be equal to a circumference whose diameter would be measured at the center of the thickness of the plate. As this is equal to the outside diameter minus the thickness, and as the diameter measured at the center of the plate would be 66 — ½, or 65½ in., the length of ½-in. plate required for 66 in. outside diameter would be

$$65\tfrac{1}{2} \times 3.1416 = 205.7748, \text{ or about } 205\tfrac{25}{32} \text{ in.}$$

Decrease in Weight from Immersion—When a body is immersed in water, why is its weight decreased by the weight of the volume of water displaced?

J. D. W.

Every part of the surface of the submerged body is submitted to a perpendicular pressure which depends on the depth. If we imagine all these pressures resolved into horizontal and vertical pressures, the horizontal pressures are in equilibrium, while the vertical pressures are unequal and will tend to move the body upward, for the vertical pressures are directly in proportion to the depth. The vertical upward pressures passing through any point in the body will exceed the vertical downward pressure by the weight due to the height of the column of water which is displaced. It follows, therefore, that the total upward pressure will exceed the total downward pressure by the weight of total volume of water which is displaced.

Water Horsepower of Pump—A triplex pump, having plungers 10¼ in. diameter by 24-in. stroke and taking its suction at atmospheric pressure, made 32,200 revolutions during 10 hours' run, pumping against 130 lb. gage pressure per sq.in. What was the average water horsepower and the number of horsepower hours?

F. D.

With three plungers and 32,200 revolutions, during 10 hours' run there would be

$$3 \times \frac{32{,}200}{10 \times 60} = 161 \text{ strokes per minute.}$$

The cross-sectional area of each plunger would be

$$10.25 \times 10.25 \times 0.7854 = 82.516 \text{ sq.in.}$$

and each plunger making 2-ft. stroke and pumping against 130 lb. per sq.in. the water horsepower, without allowance for slippage, would be found by substituting in the usual formula,

$$\text{Hp} = \frac{P \times L \times A \times N}{33{,}000}$$

the values P = 130, L = 2 ft., A = 82.516, N = 161; that is,

$$\text{Hp.} = \frac{130 \times 2 \times 82.516 \times 161}{33{,}000} = 104.67 \text{ hp.}$$

This must be "discounted" by the percentage of slippage, which can only be known by actual test. Allowing 5 per cent. slippage, the average water-horsepower would be

$$104.67 \times (1.00 - 0.05) = 99.436$$

or for the 10 hours' run, 994.36 water-horsepower hours.

Height to Which Water Can Be Forced by Steam Pump—To what height can water be forced by a direct-acting steam pump where the steam piston is 8 in. diameter, the water piston 5 in. diameter and the steam pressure 80 lb. per sq.in.?

F. J. B.

In estimating the height due allowance must be made for back pressure of the exhaust and the loss of total effective pressure of the steam in overcoming friction of moving parts of the pump, difference of atmospheric pressure exerted on the suction and discharge sides of the water piston, and pressure required for overcoming friction of the water, depending on its velocity through the pump, pipes and passages. These losses depend on the design, construction, adjustment and operating conditions. Assuming that 20 per cent. of the steam pressure is employed for overcoming these losses, then 80 per cent. of 80 lb., or 64 lb. per sq.in. of the steam pressure, would be available for operation of the steam piston in overcoming the static pressure due to the height to which the water is forced. As the area of the steam piston is

$$8 \times 8 \times 0.7854 = 50.2656 \text{ sq.in.}$$

the total pressure available for this purpose would be

$$64 \times 50.2656 = 3216.9984 \text{ lb.}$$

and as the area of the water piston is

$$5 \times 5 \times 0.7854 = 19.635 \text{ sq.in.}$$

the static pressure pumped against could be

$$3216.998 \div 19.635 = 163.84 \text{ lb. per sq.in.}$$

At the ordinary temperatures of water, each pound pressure per square inch would be equivalent to the pressure created by a column of water about 2.3 ft. high, and therefore, for the conditions assumed, the pump would force the water to a height of

$$163.84 \times 2.3 = 376.83 \text{ ft.}$$

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Fink Lubricating Oil Frauds Still Alive

[The following is taken in its entirety from the pages of the *American Machinist* in the hope that it may come to the attention of some intended victim before he is separated from any real money.—EDITOR.]

Those who remember the exposure long years ago, in 1884 to be exact, by the "American Machinist" of the alleged lubricant put out by Henry (sometimes known as John) Fink are likely to be surprised to learn that he is neither dead nor sleeping, but is still on the job, although his field of endeavor has been removed to the Southwest and the Pacific coast. Nor has his method changed particularly, as was discovered in a recent visit to one of his railroad victims.

Taking care to keep away from the mechanical department, he approached the executive offices with a fine collection of alleged testimonials handsomely bound in morocco covers. These and his winning ways, backed by the apparent evidence, secured the cash.

In this particular instance, the mechanical superintendent was an old reader of the "American Machinist" and also possessed of an excellent memory. As soon as the recipe, which had already been bought and paid for by the executive department, was sent to him, he recognized it as an old friend—or enemy. Making a few extracts from the "American Machinist" of 1884-5, he sent them to the executive offices to show how badly they had been stung. The formula is practically identical with the one purchased and is given below.

Since then he has answered a number of inquiries from railroad and other shops along the Pacific coast as to the value—or rather, the lack of value—of the lubricant, for as soon as Fink secures a victim he immediately turns him into a club to force others into line.

GUARDING AGAINST SIMILAR ATTACKS

For the information of those who do not remember the original exposure and who wish to be thoroughly armed against being victimized, we refer to the bound volumes of the "American Machinist" for 1884-5-6. The original article will be found on page 7 of the Mar. 22, 1884, issue; the others following on page 57, Apr. 12; page 4, May 10; page 7, July 12, and page 8, Dec. 27.

The following year tells of his Canadian exploits, his indictments, and the inability to find him when suits were attempted.

He was written to regarding the compound before the first article appeared, but instead of proving his claims, he answered: "We hereby notify you that any item your paper may publish which will injure us in any way we shall most certainly hold your paper responsible for."

The best-known firms in the country fell victims to his wiles, paying from $100 to $700 for the recipe. After being bitten themselves, they came forward with letters relating their experiences, instead of allowing others to become victims owing to ignorance in the matter. Publicity is the best safeguard against such methods, and we shall be glad to hear from all recent victims, in order that the fame of Fink may precede him and make his efforts unprofitable, if nothing more.

DIRECTIONS FOR MANUFACTURING FINK'S PATENT LUBRICATING OIL MIXTURE

To make 48 or 50 gal. of the mixture, take 15 to 17 lb. best lump lime, 22 oz. pulverized french chalk, 20 oz. carbonate potash, 16 oz. calcine magnesia, and 20 oz. pulverized borax. Put these ingredients into a barrel with the head out and add three or four buckets of hot water. After all are dissolved, fill the barrel with cold water, stir the mixture thoroughly and let it settle for about seven hours. After it is perfectly settled and clear, mix the clear water of the mixture with the oils you now use, in the following proportions.

For engines and cylinders take 17 gal. of lard or cylinder oil, 3 gal. of castor or machine oil, 20 gal. of clear mixture, or 40 gal. clear mixture to give it more body. To lard oil or any animal oil or greases: Light oil, mix one-half oil and one-half clear mixture. Heavy oil, mix one-third oil and two-thirds clear mixture.

To mix any kind of machine or black oil, take 15 gal. of any kind of machine or black oil, 5 gal. of lard or animal oil or cheap grease, 20 gal. of clear mixture, or 40 gal. of clear mixture to give it more body.

These proportions may be varied or changed according to the oils or greases used, the climate, or for various reasons to suit the machinery where oils or greases are used.

Put these ingredients into a barrel with the head out and stir them with a paddle. Do not stir the mixture more than once. Use nothing but clear mixture to mix with oil.

If not strong enough add more ingredients to the barrel of mixture. Rinse the barrel before making a new quantity of mixture. Throw away the settlings in the bottom of the barrel of mixture before making a new quantity. Use the best lump lime and the softest water that can be procured in the manufacture of the mixture.

For paint oil or paint would advise the use of one-half linseed or paint oil and one-half mixture. Then use same as pure oil for painting. For wood oil use same as lard or animal oil in same proportions.

The oils or greases can be used with this mixture to suit any class of machinery or climate, from the very finest and lightest machinery to the heaviest, by using more or less of the mixture. The more of the mixture you add to the oil or grease, the heavier it is.

Perhaps this may sound familiar to some of the victims of long ago.

Recent Court Decisions

Digested by A. L. H. STREET

Child Labor in Alabama—Under a law enacted at the present session of the Alabama legislature, and approved by the governor Feb. 24, 1915, it becomes unlawful to employ any person under 16 years of age in operating or assisting in operating any steam boiler or dangerous machinery.

Use of Streams for Power Purposes—A power company authorized to condemn private property in the conduct of the company's business is not entitled to interfere with the navigable capacity of any of the navigable waters of a state unless such interference is authorized by statute. But it may take the private rights of property of a riparian owner upon complying with the constitutional and statutory provisions relating to the condemnation of private property. (Minnesota Supreme Court, in re Otter Tail Power Co., 151 "Northwestern Reporter," 198.)

Duty to Safeguard Power Machinery—Under the Iowa statute that requires every employer to safeguard dangerous machinery when that is practicable, a stationary engineer cannot be deemed to assume the risk of his employer's failure to safeguard setscrews on revolving shafts connected with pumping machinery. But where an employee relies upon failure to provide guards, he has the burden of establishing the fact of their absence. Then the burden shifts to the employer to show that it was impracticable to safeguard the machinery in the particular instance. (Iowa Supreme Court, Winn vs. Town of Anthon, 150 "Northwestern Reporter" 1036.)

OBITUARY

FRANK W. BALFOUR

Frank W. Balfour, district manager of the Southern California Edison Co., died Apr. 25, at Pomona, Calif. Mr. Balfour came to this country from England in 1886 and was employed in the city engineer's office in Los Angeles. He had been with the Edison company for fifteen years and was its first district manager.

GEORGE L. BAULDRY

George L. Bauldry, chief engineer of the plant of Walter Baker & Co., Dorchester, Mass., died at his home on May 4 after a week's illness with pneumonia. Mr. Bauldry was born 53 years ago at Bourne, Mass., and learned the machinist's trade in New Bedford. Later, he was a member of the Hartford, Conn., fire department. In 1899, after a varied experience, including service with the New York, New Haven & Hartford R.R., he entered the Walter Baker plant as a fireman. By hard study in night school he worked his way upward and in eight years he became chief engineer of the company. In addition to his engineering duties, Mr. Bauldry bore important resposibilities as a citizen. He was a member of the Milton Warrant Committee for two years, and also recently on the committee charged with motorizing the local fire department. A few days before his death he was appointed a member of the board of fire engineers. He was affiliated with various Masonic and engineering organizations and is survived by his widow, a brother and a sister.

A. R. (DICK) FOLEY

"Dick" Foley is dead. When the "Lusitania" received her fatal blow and plunged into the sea off the Irish Coast, Friday, May 7, she took Dick with her.

Mr. Foley, known to all as Dick, probably had as large a circle of friends among engineers and supplymen, both here and abroad, as any other can claim. For about 15 years he was connected with the Home Rubber Co., which deeply feels the loss of one so influential in building up its business. As his friends know, Mr. Foley had made many trips abroad for that company.

Engineering organizations, especially the National Association of Stationary Engineers, have few friends more loyal and helpful than was Mr. Foley. He was a member of the Trenton, N. J., Association, N. A. S. E., and made his home in that city, at 713 Hamilton Ave. The works of the company he so long served is also in that city. He was one of the

A. R. FOLEY

oldest members of the National Supplymen's Association of the N. A. S. E.

Mr. Foley was in the early 50's. He was born in England, came to this country at the age of 21 and settled in Boston. He is survived by a widow, one son and two daughters. We understand that his body will be shipped to Trenton for burial.

PERSONALS

J. E. Woodwell has removed his office to 8 West Fortieth St., New York City, where he will continue the practice of consulting engineering.

H. S. Collette, secretary of J. G. White & Co., Inc., and The J. G. White Engineering Corporation, has resigned from these companies, and expects to reside permanently in California.

R. J. S. Pigott, formerly mechanical construction engineer, Interborough Rapid Transit Co., New York, has been made power engineer for the Remington Arms-Union Metallic Cartridge Co. at Bridgeport, Conn.

Frank H. Williams has resigned his position with Sperry & Barnes Co., New Haven, Conn., to accept an appointment as chief engineer and master mechanic at John Morrell Company's plant at Sioux Falls, South Dakota.

Prof. W. H. Kavanaugh, head of the Experimental Engineering Department, University of Minnesota, has been appointed a member of the International Jury of Award, Department of Machinery, at the Panama Exposition, San Francisco. He is spending the month of May judging exhibits.

Joseph McNeil, who is well known as a former chairman of the Board of Boiler Rules of Massachusetts, and who recently has had charge of the inspection department of the Boston office of the Hartford Steam Boiler Inspection & Insurance Co., is now stationed in the New York office.

O. L. Remington, general manager, and H. P. McColl, engineer, of the Wm. McLean Co., importers, Melbourne, Australia, are visiting the industrial centers of the country. They are making a study of machinery and apparatus devoted to power uses and have established temporary headquarters at the Hotel La Salle, Chicago.

G. L. Fales has become associated with the Raritan Copper Works, Perth Amboy, N. J. Mr. Fales was formerly superintendent of power, Tennessee Copper Co., Copperhill, Tenn. When he left the latter concern, its employees gave him a fine silver service as a mark of their high esteem and good will. The readers of "Power" will remember him as a contributor of several interesting articles on boiler operation.

ENGINEERING AFFAIRS

The National Association of Cotton Manufacturers held its annual meeting at the Copley-Plaza Hotel, Boston, Apr. 28 and 29. The business sessions were devoted to papers and discussion on concrete construction for cotton mills and on the dyestuff situation as affecting the cotton industry.

A. S. M. E. Legislative Work—At a recent meeting of the Council of the American Society of Mechanical Engineers it was decided that the society's representative on the conference committee of the United Engineering Societies be present at the state constitutional convention and coöperate with the representatives of the other engineering societies in any matters bearing upon their mutual interests. It was also moved that a committee of five be appointed to formulate general principles for the guidance of those who may serve the society in a representative capacity, and particularly when dealing with public questions.

Two Awards by the Franklin Institute—The City of Philadelphia, acting on the recommendation of the Franklin Institute, has awarded the John Scott Legacy Medal and Premium to Herbert Alfred Humphrey, of London, Eng., and to Cav. Ing. Alberto Cerasoli, of Rome, Italy, for the Humphrey pump, a device for raising water by the direct application of the explosive energy of a mixture of combustible gas and air. The Edward Longstreth Medal of Merit has been awarded to the late George A. Wheeler for his escalator (an inclined elevator for transporting persons from one level to another). The basic invention was first disclosed in a patent granted to Mr. Wheeler in 1892, and a number of patents were subsequently issued to him for improvements and developments.

NEW PUBLICATIONS

DIRECT-ACTING STEAM PUMPS. By F. F. Nickel. Published by the McGraw-Hill Book Co., Inc., New York, 1915. Size 6x9 in.; 258 pages; 218 illustrations. Price, $3, net.

This book had its basis in a course of lectures delivered by the author before the students of Columbia University. It is not a treatise on pumping machinery in general, but, as the title implies, is confined exclusively to the direct-acting steam pump. Doctor Nickel's experience, extending over thirty years in this line, not only fits him to speak authoritatively on the subject, but has enabled him to weave into the text much first-hand information concerning the development of this type of pump.

In descriptive matter it is not unlike two or three other books on the subject, although the greater number of illustrations render it, perhaps, more complete in this respect. The treatment of such subjects as the duplex valve motion and compounding are original; the chapter on performance factors, distinguishing between different efficiencies, heads, speeds, etc., is particularly instructive. The text is supplemented by a large number of tables covering pipe-line friction, steam forces and duty, and a chapter on the operation and adjustments of direct-acting pumps will be found useful, especially by the operating man.

JOURNAL OF THE AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

The American Society of Heating and Ventilating Engineers has issued the first number of a quarterly journal. According to the editorial announcement, the new publication is not intended to replace the annual volume of "Proceedings," but rather to present in advance papers to be given before the society. It will also offer a medium for a closer interchange of ideas between members by publishing discussions on the papers, questions asked and answers supplied by the members on any subjects of interest to the organization. The headquarters of the society are at 29 West Thirty-ninth St., New York.

TRADE CATALOGS

Sherwood Mfg. Co., Buffalo, N. Y. Catalog No. 16. Oil pumps, injectors, ejectors, etc. Illustrated, 20 pp., 3½x6 in.

The Deming Co., Salem, Ohio. Catalog J. Power pumps. Illustrated, 190 pp., 7x9 in.

The Jeffrey Mfg. Co., Columbus, Ohio. Bulletin No. 141. Single roll coal crusher. Illustrated, 32 pp., 6x9 in.

The Watson-Stillman Co., 50 Church St., New York. Sectional Catalog No. 92. Hydraulic forcing pumps, etc. Illustrated, 128 pp., 6x9 in.

"Engineering Bulletin No. 10"—The Peterson Power Plant Oil Filter and Accessory Apparatus for Central Oiling Systems is the title of a 32-page catalog recently issued by The Richardson-Phenix Co. of Milwaukee, Wis. This catalog describes the construction and operation of the new Peterson Power Plant Oil Filter, and it is stated that filters of this type having a total capacity of over 1,500,000 gal. are now in operation. Curves are reproduced showing the results of some interesting tests made on oil taken from one of these filters, and a chapter on the necessity of using filters in connection with steam-turbine oiling systems contains much new information. The catalog contains fifty illustrations showing many important installations of Peterson filters and oiling systems. Copy may be had by addressing the company.

BUSINESS ITEMS

John F. Hale, formerly with the Warren-Webster Co. of Camden, N. J., has associated himself with the Consolidated Engineering Co. of Chicago.

To meet the continuously increasing demand for Peerless specialties, the Peerless Rubber Manufacturing Co. has moved into larger quarters at 31 Warren St., New York.

The Jeffrey Manufacturing Co., Columbus, Ohio, has moved its New York Branch from 77 Warren St. to 50 Dey St. George H. Mueller, assistant sales manager of the company, is in charge of this office.

The Richardson-Phenix Co., Milwaukee, Wis., has purchased the patents, good will and manufacturing rights of the Osborne "NoKut" valve and is now carrying a complete line of the various valves in stock. Literature describing the "NoKut" valve is sent on request.

The annual meeting of the stockholders of the Joseph Dixon Crucible Co. was recently held in the company's office in Jersey City. Following are the directors elected: George T. Smith, Robert E. Jennings, George E. Long, E. L. Young, William G. Bumsted, J. H. Schermerhorn, Harry Daily. The officers elected by the Board of Directors are: President, George T. Smith; vice-president, George E. Long; treasurer, J. H. Schermerhorn; secretary, Harry Daily; assistant secretary and assistant treasurer, Albert Norris.

NEW EQUIPMENT

ATLANTIC COAST STATES

The Edison Electric Illuminating Co., of Brockton, Mass., has applied for a permit to build a new substation on Ames St., Brockton. The estimated cost is $3500.

Recent press reports state that the town of Reading, Mass., has decided to extend its municipal electric-light service to Lynnfield, North Reading and Wilmington. The estimated cost of the work is $12,000. Arthur G. Sias, 179 Main St., Reading, is Mgr. and Supt. of the Reading municipal electric-light plant.

The H. B. Ives Co., Artizan St., New Haven, Conn., is having plans prepared for a one-story, brick and steel, 24x44-ft. boiler house, and a 125-ft. stack. R. W. Foote is Arch.

The Eureka Flint & Spar Co., Trenton, N. J., is having plans prepared for the construction of a one-story, 36x85-ft. power house.

The Ebensburg Light, Heat & Power Co., Ebensburg, Penn., is preparing to install one 800-hp. Blake & Knowles open feed-water heater and one Worthington duplex feed pump. E. F. Craver is Gen. Mgr. and Cont. Agt.

The Eastern Pennsylvania Light, Heat & Power Co., Pottsville, Penn., contemplates increasing the output of its plant at Palo Alto, a suburb of Pottsville, by 2000 hp. The estimated cost of the work is $200,000. W. B. Rockwell, Pottsville, is Mgr.

SOUTHERN STATES

Press reports state that the Lynchburg Traction & Light Co., Lynchburg, Va., has appropriated $85,000 for rebuilding its transmission lines. It also contemplates enlarging the Blackwater St. station. J. W. Hancock is Gen. Mgr.

The Parkersburg, Marietta & Interurban R.R. Co. has selected a site in Parkersburg, W. Va., for the location of its new generating station to replace the present power house. The building will be 135x150 ft., and the completed plant is estimated to cost $500,000. Sanderson & Porter, 52 William St., New York, N. Y., is Engr.-in-Charge.

Press reports state that the Baton Rouge Electric Co., Baton Rouge, La., will build a new power plant to cost about $200,000. Donald Stewart is Mgr.

It is reported that the New Orleans Ry. & Light Co., New Orleans, La., will spend about $125,000 in enlarging its power house on Market St.

The Kentucky South-Western Electric Ry., Light & Power Co., Paducah, Ky., will build a new power house in connection with its traction line from Paducah to Murray, Ky. F. M. Smith is Gen. Mgr.

CENTRAL STATES

Bids will be received until noon, May 24, by the Board of Education, City Hall, Cincinnati, Ohio, for the installation of electric-lighting systems in the College Hill School on Maple Ave., College Hill, and the Mt. Airy School, Colerain Pike and Mt. Airy Rd., Cincinnati. C. W. Handman is Business Mgr., Bd. of Education.

The Hilliards Light & Power Co., recently organized at Hilliards, Ohio, with a capital stock of $10,000, will install an electric-light plant to supply the town with electricity. LeRoy Bobyns, T. C. Latham and others are interested.

The Ohio Gas & Electric Co., Lisbon, Ohio, recently organized, plans to establish an electric-light plant in Lisbon. Joseph S. Grayden is interested. Service is now furnished by the New Lisbon Gas Co., which purchases energy from the Youngstown & Ohio River R.R. Co.

(Official)—Bids will be received until noon, May 29, by the Board of Trustees, Miami University, Oxford, Ohio, for alterations and additions to the power plant of the University. The work includes boiler- and engine-room extensions to power building, boiler, feed-water heater, vacuum heating pumps, boiler-feed pumps, power equipment changes and additions. W. L. Tobey, Hamilton, Ohio, is Chn. of Bldg. Com. of Bd. of Trustees. Walter G. Franz, Union Trust Bldg., Cincinnati, is Consult. Engr.

The City Council, Painesville, Ohio, has rejected the terms of the Cleveland, Painesville & Eastern R.R. Co., Willoughby, Ohio, to furnish electricity to the city of Painesville, and has authorized an issue of $35,000 in bonds, the proceeds of which will be used to make improvements and buy new equipment for the municipal electric-light plant.

The City Engineer, Ann Arbor, Mich., has submitted tentative plans to the City Council for the installation of a municipal power plant for lighting the streets and public buildings of the city. The estimated cost is $55,585. Manly Osgood is City Engr.

It is reported that the town of Elizabeth, Ill., is considering the establishment of an electric-lighting system. It is stated that the sum of $8000 has already been subscribed for the purpose.

WEST OF THE MISSISSIPPI

It is reported that a company is being organized to install and operate an electric-lighting system in Ute, Iowa. The estimated cost is $10,000.

The City Council of Hays, Kan., is considering the establishment of a municipal electric-light plant. The estimated cost is $27,000.

Bids are being received by the village of Ceresco, Neb., for the installation of an electric-light plant to cost about $5000. G. Johnson is Village Clk. Grant & Fulton, Lincoln, is Engr.

Bids will be received until May 17 by the Village Clerk of Morrill, Neb., for the installation of a municipal electric-lighting system for the village.

A special election will be held in Tekamah, Neb., on May 18 to vote on the question of issuing $15,000 in bonds for the purpose of establishing an electric-light and power plant. M. S. McGrew is City Clk.

At an election held Apr. 26, the citizens of Victoria, Tex., voted in favor of issuing $40,000 in bonds for the purpose of installing a municipal electric-light plant.

It is reported that the Texas Power & Light Co., Dallas, Tex., has purchased the local electric-light plant at Windom, Tex., and will improve the property. F. R. Slater, Dallas, is Gen. Mgr. of the Texas Power & Light Co.

Bids will be received until May 24 by the City of Montrose, Colo., for the construction of a municipal electric-light plant. It will cost about $6000. E. T. Archer & Co., New England Bldg., Kansas City, Mo., is Engr.-in-Charge.

The Mt. Konocti Light & Power Co., Lakeport, Calif., plans extensions and improvements to its plant to cost about $9000.

The city of Tehachapi, Calif., has voted to issue $8000 in bonds, the proceeds of which will be used for the installation of a municipal electric-light plant.

CANADA

It is reported that the Toronto Electric Commission, Toronto, Ont., will build a new substation at Carlaw Ave. and Gerrard St., at an estimated cost of $65,000.

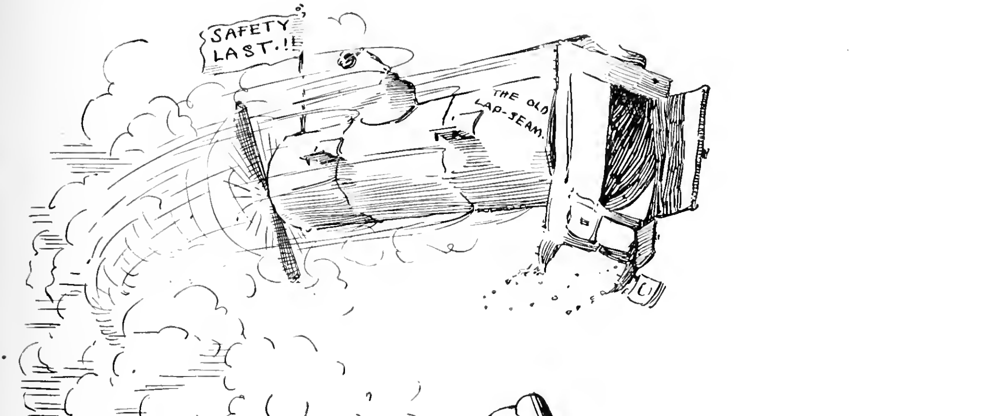
How to Bring Down the Game



In the engineer's warfare against the enemies of safety one of the most effective weapons is legislation

(Suggested by George B. Longstreet, Somerville, Mass.)

Harrisburg, Ill., Railway and Power Plant

By Thomas Wilson

SYNOPSIS—A 2000-kw. condensing turbine plant supplying current for an interurban line, for a number of mines and for lighting. A softener and purifier converts hard, muddy and corrosive water into excellent boiler feed at a cost of 1c. per 1000 gal.

On the middle fork of the Saline River (more commonly known as the Big Muddy), two miles from Harrisburg, Ill., the Southern Illinois Railway & Power Co. built its power plant. It has been in operation more than a year, supplying current at 1200 volts to a single-track interurban line running from Eldorado to Carrier Mills, a distance of 16 miles. The intervening stations are Wasson, Muddy, Harrisburg, Dorrisville and Ledford. The cars are run on hourly schedules, and in the morning and evening hours extra service is given to convey the miners to and from their work. Arrangements have been made with the Illinois Central railroad for interline freight service twice a day, and the coal for the plant is hauled over the company's line.

Three-phase 60-cycle current is generated at 2300 volts, and by motor-generator sets this is transformed into 1200-volt direct current for the railway. Current for power and lighting is stepped up to 33,000 volts through

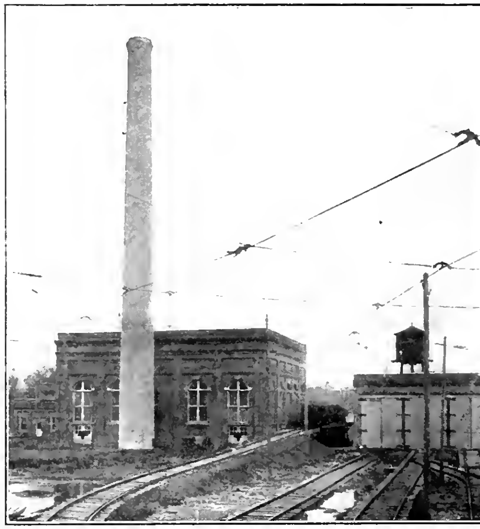


Fig. 1. Harrisburg Plant of Southern Illinois Ry. & Power Co.

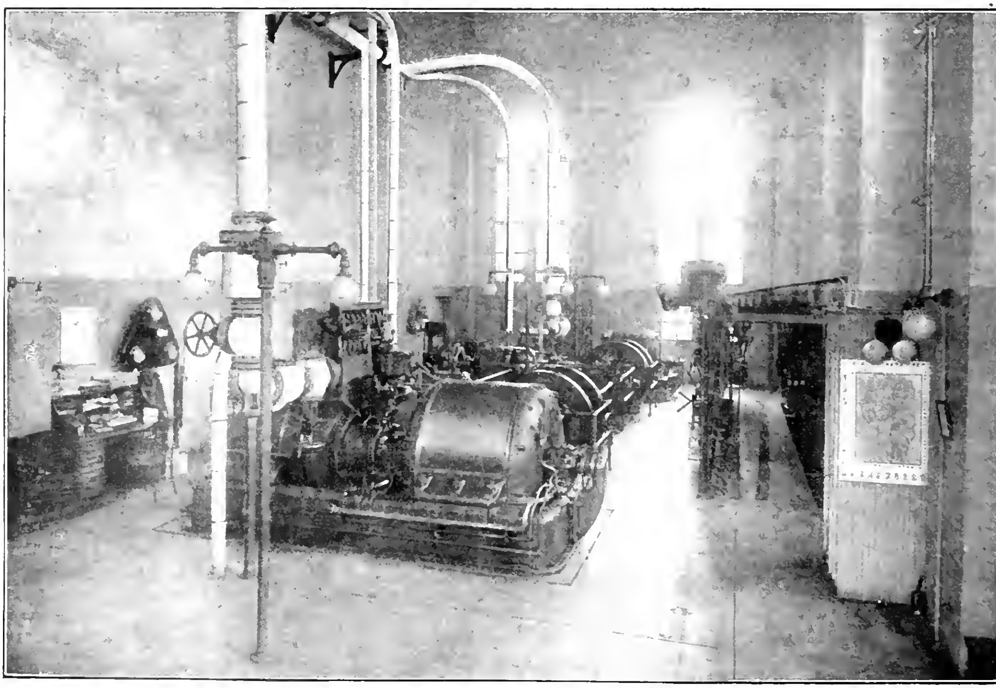

Fig. 2. View in Turbine Room

two banks of three single-phase water-cooled transformers connected in closed delta. At the receiving end it is stepped down to 2300 volts. The Wasson mines, which are electrically equipped, take service. They require direct current at 250 volts for cutting, hauling, etc., and this is obtained through a motor-generator set. Through

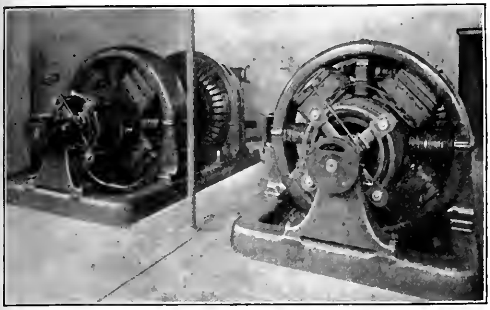

Fig. 3. Motor-Generators Supplying Railway Load

three-phase, 60-cycle, 2300-volt generators at 3600 r.p.m. Condensers are of the surface type, each containing 3600 sq.ft. of surface, or 3.6 sq.ft. per kilowatt of generator rating, and served by a reciprocating dry-vacuum pump, a motor-driven centrifugal pump and a steam-condensate pump. Each circulating pump has a capacity of 3000 gal. per min. The suction of each connects to a 20-in. intake running west from the plant to a crib in the storage reservoir. The latter circles to form a U, so that the discharge from the condensers is received south of the plant at a distance of about one-quarter mile from the inlet. Spray nozzles arranged in clusters of five help to cool the water, and in any event a considerable period of time elapses before the water from the condensers gets back to the intake. The total lift for the pumps is 8 ft. The condensate is pumped to a 1600-hp. open heater, where its temperature is raised for boiler feeding.

It is evident that one generating unit will carry the load, operating at a small overload at the peaks and at a load factor averaging about 40 per cent. the remainder of the time.

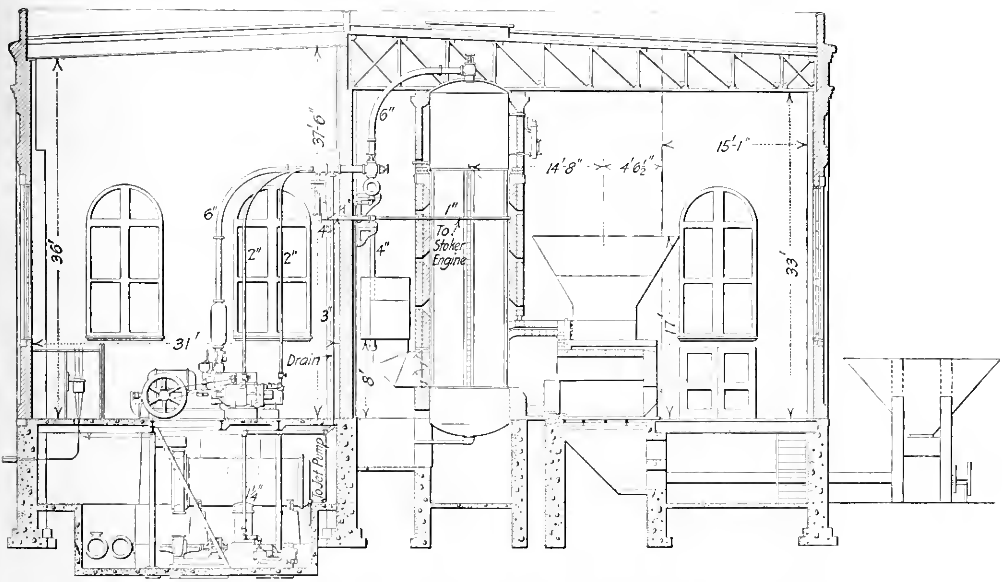

Fig. 4. Sectional Elevation through Engine and Boiler Rooms

a distributing company light and power are furnished to Harrisburg. Carrier Mills is also lighted, and the transmission line has been extended recently to Marion.

Average Load

At present the load will run about 11,000 kw.-hr. a day. At the peak hours the load is about 1200 kw., but owing to the mine and traction loads, it is erratic. From midnight to 4:30 in the morning it will not exceed 500 kw., as the services are reduced to street lighting and mine ventilation.

Generating Capacity

The plant has a capacity of 2500 kv.-a., or, at 80 per cent. power factor, 2000 kw. This is divided into two units consisting of two-stage horizontal turbines driving

Excitation is furnished by two exciters, one driven by a motor and the other by a turbine, although the former is used for the most part. Usually, one of the 300-kw. motor-generator sets carries the railway load, but in the evening it is necessary to use both. The switchboard is fully equipped with modern instruments, hand-operated oil switches for the 2300-volt current and remote control for the high-tension service. Leads from the switchboard are conducted underground in vitrified tile conduit to the transformer building located near the plant.

Boiler Plant

To serve the 2000 kw. in generating capacity there is 1600 hp. in boilers, a ratio of 5 to 4, or one boiler horsepower per 1¼ kw. The boilers are of the vertical water-tube type, contain 3977 sq.ft. of heating surface, and are rated at 400 hp. Dry steam at 160 lb. pressure is supplied to the turbines. Stokers of the top-feed type serve the boilers. Each grate has a projected area of 64 sq.ft., which bears a ratio of 1 to 62 to the boiler

FIG. 5. SPRAY NOZZLES IN ACTION

heating surface. This is high when compared to the average 1 to 50 ratio, but as the grates are set at about 45 deg., the actual area is considerably greater than the 64 sq.ft. given above. The stack rises 155 ft. above the ground, or 135 ft. above the grate level. With a gas

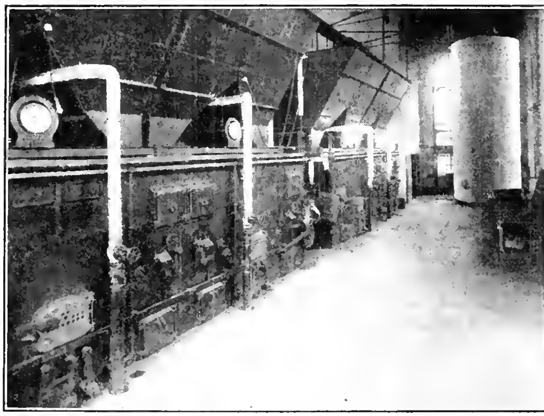

FIG. 6. THE BOILERS AND WATER PURIFIER

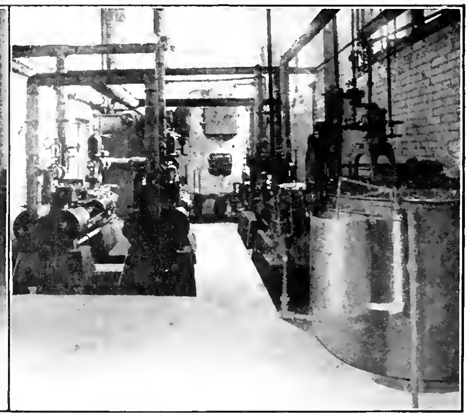

FIG. 7. PUMP ROOM, WITH CHEMICAL TANK OF PURIFIER IN FOREGROUND

temperature of 500 deg., the draft at the stack should be about 0.85 in. of water. Making the usual deductions for drop through breeching and setting, the draft over the fire for the boiler farthest from the stack should be about 0.25 in. and on the first boiler 0.35 in.

The stack, which is of concrete, is lined 50 ft. up. An internal diameter of 8 ft. gives a sectional area of 50 sq.ft. At each boiler the breeching is enlarged until at the stack it reaches a sectional area of 60 sq.ft., the width being 5 ft. and the height 12 ft. For each square foot of stack there are 1.2 sq.ft. of breeching, 5.1 sq.ft. of connected grate surface and 32 boiler horsepower.

COAL-HANDLING FACILITIES

The fuel burned is Saline County screenings. The thickness of the fuel bed is maintained at 3 to 5 in. on the inclined grates and 8 in. on the bottom. By forcing at the peaks one boiler could carry the load, but a second is carried under bank to be ready for emergencies. Under these conditions, combined with the low load factor on the generating units, the operating efficiency is low. From 5 to 6 lb. of coal is required per kilowatt-hour.

The coal is pulled over the company's track from Eldorado. It is dumped into a 30-ton hopper under the siding at the plant. From the hopper it passes through a crusher, which is operated only for lump coal, into a horizontal screw conveyor. A bucket elevator hoists it to the top of the boiler room and a second screw conveyor distributes it to 20-ton bunkers, one on top of each furnace. Ashes are wheeled from the pits to the elevator boot and are delivered to an ash screw at the top, which discharges them onto a temporary platform outside the plant, from which they may be wheeled into the empty coal cars. It is the intention to install a pneumatic system which will convey the ashes directly to the cars or a tank located beside the track.

UNUSABLE WATER TRANSFORMED INTO EXCELLENT BOILER FEED

One of the most serious problems the plant had to contend with was the water-supply. The water is taken from the Big Muddy River, which is well named, as the water retains its yellow, muddy color even in the reservoir, where it has a chance to settle. Besides containing a large amount of suspended matter, at certain seasons it is exceptionally hard and at all times is of a corrosive nature due to the acid drainage from the mines. A short period of operation showed that it would be neces-

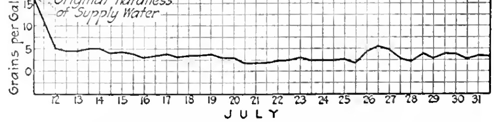

FIG. 8. CHART SHOWING HARDNESS OF WATER AFTER TREATMENT

sary to install a water softener and purifier, and this was done in the spring of 1914. The apparatus has a capacity of 2000 gal. per hr. The water from the reservoir is first pumped to a 25,000-gal. elevated tank, from which it flows to the top of the softening equipment by gravity. Here it is treated with 90 per cent. hydrated lime and 58-test soda ash, the proportions being governed by tests made twice a day. The chemicals neutralize the corrosive and scale-forming ingredients in the water and precipitate them in the form of insoluble matter. After the chemical treatment the water is allowed to settle and is then passed through a gravity quartz filter which is an integral part of the apparatus. Thence it flows by gravity into the feed-water heater and is pumped to the top drum of the boilers, although provision is also made to feed through the blowoff.

It might be stated that the river is one which varies greatly in its flow, depending upon the seasons of the year. For this reason the quality of the water varies widely, and the softener had to be adapted for accommodating the chemical charge to these variations in order to maintain a uniformly treated water. The chart, Fig. 8, shows the amount of hardening ingredients remaining in the treated water during a three-weeks' period in the month of July. The average hardness during the period is practically three grains. The following analyses, made at different periods, show the large variation in the quality of the river water.

	Mar. 4, 1914 Grains per Gal.	June 26, 1914 Grains per Gal.
Calcium carbonate	1.35	9.00
Calcium sulphate	1.97	...
Magnesium carbonate	...	...
Magnesium sulphate	3.29	9.38
Silica	5.30	...
Iron and aluminum oxides	0.75	...
Suspended matter	Undetermined	1.21
Total incrusting solids	12.66	19.59
Sodium sulphate	0.87	...
Sodium chloride	1.60	14.63
Total nonincrusting solids	2.47	14.63
Total solids	15.13	34.22

The following is an average analysis of water delivered during the past summer:

INCRUSTING SOLIDS

	Grains per Gal.
Calcium carbonate	2.10
Magnesium hydrate	1.40
Silica	0.06
Total incrusting solids	3.56

NONINCRUSTING SOLIDS

Sodium sulphate	12.06
Sodium chloride	14.32
Total nonincrusting solids	26.38
Total solids	29.94

The cost for treating the water has averaged about 1c. per 1000 gal. It varies directly with the hardening ingredients in the water, but runs from 1½c. per 1000 gal., which is the maximum, to nothing, as the supply at times contains such a large amount of rain water that it practically has no hardness. During these periods the chemical treatment is eliminated and the water is simply passed through the filter.

In the words of the chief engineer, E. H. Clark, the feed water is now ideal. The condensate from the condensers is returned to the heater and the 15 to 20 per cent. of makeup is the treated water. When the purifier was installed the boilers were thoroughly cleaned and the scale removed. Since then they have been opened up every 30 to 45 days, and washed out. During the nine months the purifier has been in service, there has been practically no scale and no evidence of corrosion.

The W. H. Schott Co., of Chicago, designed the plant and had charge of its erection, but the engineering is now under the direction of C. J. Davidson, of the firm of Woodmansee & Davidson, consulting engineers, of the same city. Under their direction the water softener and spraying nozzles were installed. They report a bright outlook for the plant. As previously stated, Marion has just been added to the list of towns taking service, and other prospects are in view which will increase the load and better the operating efficiency of the plant.

The Advantages of Small, High-Velocity Steam Piping are: Lower first cost for pipe, valves and covering, etc., less erecting and maintenance cost; less weight; less radiation loss; less chance for water to accumulate and less difficulty with valves of smaller size.

To Increase Industrial Prosperity this country needs to export finished rather than crude products and to import raw materials rather than manufactures. Betterment of industrial conditions can come best through expansion of manufacturing. The increase of the element of labor in the product exported will mean that we are not bartering away our heritage of natural resources, but rather that we are using these resources as a basis simply for the expenditure of labor, which renews itself—George Otis Smith, Director, United States Geological Survey.

PRINCIPAL EQUIPMENT OF SOUTHERN ILLINOIS RAILWAY & POWER CO.'S PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
4	Boilers	Vertical water-tube	400 hp.	Generate steam	160-lb. pressure, natural draft, stokers	Wickes Boiler Co.
4	Stokers	Top-feed	Projected area, 64 sq.ft.	Serve boilers	Draft over fire 0 25 to 0 35 in	Murphy Iron Works
1	Stack	Concrete	155 ft. high, 8 ft. diam.	Natural draft for boilers		GeneralConcreteConstructionCo
1	Coal conveyor	Screw-and-bucket	20 tons per hr.	Transfer coal from car to bunker	Driven by 20-hp. induction motor	A. Lucas & Sons
1	Coal crusher		20 tons per hr.	Crush lump coal	Driven by 20-hp. induction motor	A. Lucas & Sons
1	Water softener	Cold process	2000 gal. per hr.	Soften boiler feed		Wm. Graver Tank Works
1	Heater	Open	1600 hp.	Heat boiler feed water	Exhaust from auxiliaries	Platt Iron Works Co.

2	Motor-generator sets	Railway	300-kw.	Railway service	2300-volt synchronous motor, 430 hp., 720 r.p.m., 1200-volt, constant-current generator.	General Electric Co.

Interior Wiring for Lighting and Power Service--IV

By A. L. Cook

SYNOPSIS—The previous articles of the series covered the layout and wiring calculations for lighting systems; the present and succeeding installments cover power circuits, including location of motors and control devices, determination of load, voltage drop and wiring calculations.

It is beyond the scope of this article to discuss the types of motors best suited for various industrial conditions, but the location of motors and the choice of control devices will be considered before taking up the wiring. The location of the motor will be, to a large extent, fixed by that of the driven machine. If there is a choice, however, it should be placed where it can be easily reached for inspection, and also where it will be protected, as far as the surroundings permit, from moisture, dust and accumulations of dirt. It is desirable to avoid where possible the use of entirely inclosed motors because of their greater cost. Control devices also should be selected with regard to where they are to be used and the class of labor which is to operate them. They should be placed in the position most convenient for the operation of the motor and should always include a switch located in sight of the motor, by means of which all wires running to the motor or control device can be disconnected from the supply. This is necessary to facilitate repairs and is a safeguard against operation by unauthorized persons. If the motors are supplied from near-by panel-boards, these switches can be placed on the panels.

The systems of distribution for power include two-wire alternating or direct current, and three-phase or two-phase alternating current. The standard voltages for direct-current motor service have already been specified. A voltage of 115 should be used only where the motors are small and the feeders short. The best voltage for usual conditions is 230, as this gives reasonably small conductors, even for long runs. One advantage of this voltage is that the supply can easily be made three-wire for lighting and two-wire (230 volts) for the motors. A voltage of 550 should be used only where the feeders are very long and the motors large. The panel-boards and control devices will be much larger than for the other voltages, and the cost of maintenance of the system under usual factory conditions will be greater. There is also greater danger of injury to the workmen than with lower voltages. This high voltage is not at all adapted for power supply in an office building and is seldom used for that purpose.

A two-wire alternating-current system (single-phase system) is adapted only to supplying motors up to about 15 hp. With alternating current, either the three-phase or the two-phase system is ordinarily used. The former is best adapted for the usual power supply in factories, the two-phase system being used principally by central stations, where the lighting and motor loads are carried on the same distributing system; in which case the two-phase system is easier to balance than the three-phase. It is possible, however, to operate either system satisfactorily in this way. For an isolated plant, however, the three-phase system is preferable; the lighting load being taken from one or more phases, depending on its relative importance compared with the power load. The choice between 25 and 60 cycles is influenced by the fact that the latter is better for lighting and the cost of the motors is somewhat less. There is also the advantage of a greater number of available speeds in 60-cycle motors for the range usually needed.

Choice of Motors

Alternating-current motors have definite speeds, fixed by the frequency and depending upon the number of poles, whereas direct-current motors have greater flexibility in this respect. The available no-load speeds for alternating-current motors for the usual range are given in Table 10. The highest speed is for the two-pole motor, and the speed can be made as low as required by providing a suitable number of poles. It will be seen by reference to this table that for 25 cycles motors can be built for only three speeds between 500 r.p.m. and the maximum; whereas for 60 cycles there are seven speeds. All of these speeds cannot be obtained from the same motor, which, on the contrary, must be built for a particular speed, and only by special design can it be run at more than one of these speeds; even then the number of available speeds is limited to two.

The alternating-current system is generally better suited for factory power supply than the direct-current, because of the greater reliability and ruggedness of the alternating-current motor. The standard alternating voltages available for general use with either three-phase

TABLE 10—AVAILABLE SPEEDS FOR ALTERNATING-CURRENT MOTORS

Number of Poles	No-Load Speed, R.p.m.— 60 Cycles	25 Cycles
2	3600	1500
4	1800	750
6	1200	500
8	900	375
10	720	300
12	600	250
14	514	214

or two-phase systems are 110, 220, 440 or 550 volts, and for large motors 2200 volts. The ease with which the voltage may be changed to suit conditions allows great flexibility in the choice of a voltage for the motors. Either 220 or 440 volts is commonly used, the lower voltage being preferable for moderate-sized installations, particularly where the supervision may be in relatively unskilled hands. The danger of workmen receiving fatal shocks is greater with alternating than with direct current, and 440 or 550 volts presents a real hazard in this respect; shock from 220 volts is seldom fatal. In establishments of considerable size, particularly with large motors, the great saving in feeder size with 440 or 550 volts results in their frequent use.

More complete protection is permissible with alternating than with direct current, so that with careful planning of the control devices and first-class wiring, these higher-voltage systems can be made fairly safe. Sometimes 1100 or 2200 volts are used for alternating-current motor drive, but as such a high voltage is adapted only for large motors and requires special methods of installation of the wiring and control system to make it safe, these will not be considered in this article.

The common types of direct-current motors are the shunt motor, which is practically constant-speed, and the series motor, which gives variable speed. While the former is called a constant-speed machine, since the speed is practically constant from no load to full load, the speed can be adjusted through a wide range by changing the resistance in either the field or the armature circuit, the former method being preferable. The shunt motor is adapted for any constant-speed service, such as driving machine tools, woodworking machinery, fans, and the like, while the series motor is best adapted for driving cranes, hoists and similar devices. For some purposes a compound motor, which combines the characteristics of the series and shunt, is best; the principal applications of this type being found in the driving of elevators, punch-presses, planers, etc.

The usual type of alternating-current motor is the induction motor, which may be of the squirrel-cage or the wound-rotor type. The former is the most rugged and the simplest kind of motor made, and is cheaper and more satisfactory for general use than the wound-rotor type. A disadvantage is that it cannot start under heavy load without taking a large current from the line, but where the starting load is less than full load and a constant speed is required, the squirrel-cage motor should be used. If the driven machine requires a large starting torque, as for example, a compressor starting under full pressure, or if the speed must be adjusted, then the wound-rotor type must be used. Sometimes it is desirable to use this type of motor for constant-speed service when the size of the motor is large compared with the capacity of the generator supplying the load, because of the great drop in voltage caused by starting a large motor.

The full-load current required by a motor is always marked on the nameplate, but it is frequently necessary to lay out the wiring before the motors have been received. To assist in estimating the load, Tables 11, 12 and 13 have been prepared. The full-load currents given are for direct-current motors and for the usual type of alternating-current induction motors. For the direct-current motors, the "National Electric Code" requires that the size of wires shall be sufficient to carry at least a 25-per cent. overload and the usual motor for continuous service is designed to carry a 25-per cent. overload for two hours.

TABLE 11—CURRENT AND SIZE OF WIRE FOR DIRECT-CURRENT MOTORS

*Allows at least 25 per cent. overload.

The sizes of wire specified in Table 11 are such that the motor can carry from 25 to 30 per cent. overload without exceeding the current rating of the wire in accordance with the "Code" rules. To find the current and size of wire for a motor not given in the table, find the amperes per horsepower for the next smallest motor, and then multiply by the horsepower of the given motor. For example, to find the current for a 65-hp. 550-volt direct-current motor, we find that the current per horsepower is $\frac{89.5}{60} =$ 1.49 amp. The full-load current for a 65-hp. motor is then 1.49 × 65 = 97 amp. Allowing 25 per cent. overload, the current would be 121 amp., and if rubber-covered wire is used the size would be No. 0.

*These motors are thrown directly on the line; all others are provided with auto-starters set to give a starting torque equal to full-load running torque.

The allowance mentioned for overload would be sufficient in the majority of cases; but if the motor is subject to heavy momentary overloads, as for example in the case of a planer drive, a larger overload should be allowed. There is a disadvantage in fusing the motor too high, as it is then not protected against continuous overload which might burn out the motor. For alternating-current motors also, the "Code" requires that the wire shall be sufficient to allow at least 25 per cent. overload. Tables 12 and 13 give data for three-phase and two-phase induction motors, the full-load current values being for modern, high-efficiency motors. These values apply more particularly to the squirrel-cage type; for wound-rotor type of motor the full-load currents would be slightly greater. Squirrel-cage induction motors take very large currents from the line when starting, averaging about 2.9 times the full-load value with a torque equal to full-load running torque. To obtain this starting torque, about 85 per cent. of full-load voltage is applied to the motor. Usually, the load driven by a squirrel-cage motor is such that a voltage of 65 per cent. can be used, and then the starting current will be only about 2.2 times full-load current. A wound-rotor type of induction motor, starting under full load, takes about 25 per cent. more than the full-load current when running.

Because of the heavy starting current required for squirrel-cage induction motors, the rules allow the leads to be selected in accordance with column B of Table 7 (see page 642, May 11 issue) even when rubber-covered wire is used. The sizes specified in Tables 12 and 13 are chosen on this basis. For wires with other insulation the same allowance is not made; that is, according to the "Code," the wire must be chosen in accordance with column B also. However, the inspectors will often allow induction-motor wires when exposed to be fused somewhat higher than the values given in column B. It is apparent that the wires will be adequately protected from injury when fused in accordance with these rules, but the motor will not be properly protected against continuous overloads, which would not cause the fuses to blow, but still would be larger than the motor could safely stand for any length of time. It is customary, therefore, to provide "running fuses" which are not in circuit during starting. The ordinary induction motor is rated to stand a 25-per cent. overload for two hours, but can carry greater loads for short periods. Therefore, the running fuses should have a rating about 50 per cent. greater than the full-load current of the motors.

The rules given for determining the proper size of wire and the fusing of motors apply to motors intended for continuous service, which are designed to carry their rated load continuously or to carry a 25-per cent. overload for two hours. There are certain other kinds of service, such as cranes and elevators, where the load is intermittent and the motor is required to carry heavy momentary loads. The sizes of fuses and wires for this service are chosen somewhat differently, the motors being rated at the load which they will carry for 30 min. without exceeding a safe temperature. Direct-current motors for intermittent service will, however, carry a 50-per cent. overload for short periods without injury and will carry a 100-per cent. overload momentarily without injurious sparking. Alternating-current motors are also rated on a 30-min. basis, and since they have no commutator, will stand for short periods large overloads, amounting to 2 or 2½ times full-load current. Direct-current motors for intermittent service should be provided with fuses allowing at least 50 per cent. overload, and the branch circuits for the motors must therefore be sufficient to carry this current. If rubber-insulated wire is used, column A of Table 7 should be used; for other insulations column B should be employed. In the case of alternating-current motors, the "Code" specifies definitely the current rating for the branch circuits; the values given are as follows:

Service	Percentage of Current Rating of Motor
Operating valves, raising or lowering rolls, tool heads, etc.	200
Hoists, rolls, ore- and coal-handling machines	180
Freight elevators, shop cranes	160
Passenger elevators	140
Rolling tables, pumps	120

This applies to varying-speed alternating-current motors: that is, where the speed changes with varying loads, as in the series direct-current motor, the current referred to being rated for the 30-min. load rating, as previously mentioned. The size of wire must be selected by using either column A or B of Table 7, depending upon the insulation.

In general each feeder will supply a number of motors and in order to calculate its size the probable maximum current to be carried by the feeder must be determined. For usual factory conditions this would be considerably less than the sum of the full-load currents of the motors connected to the feeder. It would seldom occur that all the motors would be carrying full load at the same time. Consequently, a load factor must be assumed, the term load factor meaning the ratio of the maximum to the total connected load. This may vary from 40 to 80 per cent., depending upon the nature of the work and the number and size of motors on the feeder. Where there is a large number of small motors, this factor would be less than where there are a few large motors on the system. For ordinary factory conditions, in the absence of better information, the load factor for the feeders may be taken as 75 per cent. of the rated load of the motors. With alternating current the size of wire should be checked by assuming the largest motor starting and all the others running, allowing 75 per cent. of the full-load current for these motors.

*These motors are thrown directly on the line; all others are provided with auto-starters set to give a starting torque equal to full-load running torque.

†Values of current are for a two-phase, four-wire system; if three wires are used, current in common wire would be 1.42 times value given.

The allowable voltage drop for power circuits can be greater than for lighting circuits, but should not be too large, particularly with induction motors, as they do not operate satisfactorily at voltages greatly below normal. A total of 5 per cent. drop, figured from the motor to the service point or the power-house switchboard, is satisfactory and does not require excessive feeder sizes. This voltage drop should be divided about as follows: Individual motor circuits, 1.75 per cent.; feeders and subfeeders, 3.25 per cent.; total, 5 per cent.

Direct-current motor circuits can be calculated by means of the wiring chart already described (see page 667 May 18 issue). Alternating-current circuits cannot be calculated as easily. This is because of the power factor of the motor circuits, which is generally about 0.80. The effect of this power factor is to make the drop greater than if it were 1.00, as in the case of lighting loads. The extent to which the drop is thus increased depends upon the spacing between wires, the effect being least when the wires are in one conduit and increasing very rapidly when they are separated and run on insulators. When all the wires of a circuit are run in the same conduit the drop is practically the same as for direct current, for wires not greater than No. 0 for 60-cycle circuits and not larger than 300,000 circ.mils for 25 cycles. The wiring chart which was used in lighting calculations can therefore be used for such cases. For larger wires run in conduit and for all wires separated a considerable distance, as in exposed work, the drop must be calculated by other means. The simplest method is to determine the drop in the usual manner, by means of the direct-current chart already explained, and then to determine the additional drop which would be caused by the inductive effect. A method for doing this has been developed by

C. F. Scott and C. P. Fowler and was published in the April, 1907, issue of *The Electric Journal*.

The drop due to inductance depends upon the ratio of reactance to resistance and also upon the power factor. The reactance depends upon the frequency and upon the spacing between wires. We require, then, a table giving this ratio for the particular spacing of the wires and the proper frequency and also a table giving the drop factor corresponding to various values of this ratio. Tables 14 and 15 give these quantities.

An example in the use of these tables will assist in understanding the method employed. Assume a No. 00 wire carrying a single-phase alternating current of 50 amp. a distance of 150 ft. at a frequency of 60 cycles. The drop, if direct current were used, is found by the chart (page 667, May 18 issue) to be 1.2 volts. Assuming the wires are all in the same conduit, it will be seen from Table 14 that the ratio of reactance to resistance is 0.54. Assume that the load consists of incandescent lamps, so that the power factor may be taken as 1.0. Then the drop factor is found from Table 15 to be 1.004. That is, the direct-current drop of 1.2 volts must be multiplied by 1.004, which gives 1.205 volts. Hence the alternating-current drop under these conditions is practically the same as the direct-current drop. If the wires are 6 in. apart the ratio would become 1.04, the drop factor would be 1.044 and the alternating-current drop would be 1.25 volts. If the power factor is 0.8, the drop factor would be 1.42 and the alternating-current drop would be 1.70 volts. It will be seen that for a power factor of 1.0 the alternating-current drop is practically equal to the direct-current drop for ratios up to 0.7, being only 1 per cent. higher for 0.6. For lower power factors, however, the alternating-current drop is, in general, different from, and may be less than, that for direct current. Therefore, it is necessary to estimate this in each case. Table 16 gives the usual values of the power factor for various kinds of loads. The values for induction motors assume that all the motors on a feeder would not be carrying full load at the same time. The power factor of induction motors when carrying full load is in general greater than the values herewith given.

The values refer to the sizes of the individual motors on the feeder. That is, if a feeder carried one 15- and four 10-hp. motors the total connected motor load would be 55 hp., but the power factor on the feeder should be taken as 0.80. By examining Tables 14 and 15 it will be noted that the alternating-current drop increases very rapidly as the size of wire increases. As a rule, wires larger than 300,000 circ.mils should be avoided, except

where the wires are in conduit, when a size of 500,000 circ.mils or larger may be used. If larger wires are required to carry the load two or more can be employed in parallel. For example, find the drop on a 500,000-circ.-mil feeder carrying 300 amp. a distance of 500 ft. The direct-current drop is 6.1 volts. If the frequency is 60 cycles, the power factor 0.8 and the spacing 6 in., the drop factor is 2.88 and the alternating-current drop is 18.4 volts. No. 0000 cable is about one-half the size of 500,000-circ.mil cable; therefore, calculate the drop, using two No. 0000 cables instead of a single wire. The current per cable would be 150 amp., the direct-current drop would be 7.6 volts and the drop factor 1.74. Hence, the alternating-current drop would be only 13.2 volts, which is considerably less than for the single cable. Figuring the size of wire to give the same voltage drop as before (18.4 volts), we find that a No. 00 cable gives an alternating-current drop of 17.2 volts. That is, two No. 00 cables having a total cross-section of 266,200 circ.mils will carry a total load of 300 amp. with less drop than for a single 500,000-circ.mil cable with a great saving in copper. This saving often exceeds the additional cost of running two circuits instead of one, so this point should always be kept in mind when laying out alternating-current circuits. In this connection, it should be stated that wires which are run in multiple, as in the above case, should always be of the same size. For example, if a 500,000- and a 300,000-circ.mil cable were employed to take the place of one of 800,000 circ.mils the smaller wire would take more than its share of the load, and in some cases, might be overheated. This method can also be used for the calculation of three-phase and two-phase circuits by making certain modifications which will be explained later.

Hilliard Rack-and-Pinion Clutch Shifter

An interesting clutch-shifting device for use with the Hilliard clutch and manufactured by the Hilliard Clutch & Machinery Co., Elmira, N. Y., is illustrated in Fig. 2.

While to date this mechanism has been used exclusively in connection with Hilliard clutches, its application is not confined to this particular make, but it is equally adaptable to any clutch which has a sliding member for engaging and in which can be cut the necessary groove to accommodate the clutch-shifter yoke.

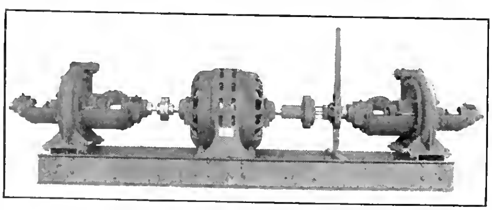

Fig. 1. Shifter on Clutch between Pump and Motor

This device is made either in solid or split form, and the operating mechanism is held in a set position on the shaft by two safety collars; the thrust for engaging the clutch is obtained by means of the rack and pinion. For operating the pinion, several devices may be employed, but preferably a handwheel, which can be attached by a key or a setscrew to the stub pinion shaft or to an extension shaft coupled to the short shaft provided. The device is convenient under certain conditions, say when it is desired to operate a clutch from the opposite side of a brick wall. In one case a 12-ft. extension shaft was attached to the short pinion shaft by a coupling, common pillow blocks being used for a bearing in the wall. On the end of the shaft an ordinary handwheel was attached, and although separated from the shaft by a brick wall, the operator had perfect control of the clutch.

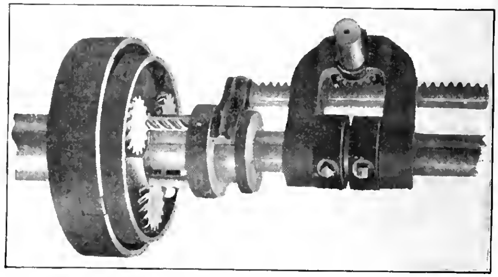

Fig. 2. Rack-and-Pinion Clutch Shifter

There are many places where this device would prove useful. It is manufactured in three sizes. No. 1 size will accommodate a 2-in., No. 2 a 3-in. and No. 3 a $4\frac{7}{16}$-in. shaft. The yoke, suspended from the shaft, is equipped with grease cups which provide ample lubrication, and the device is efficient.

Fig. 1 illustrates an 8½-in. clutch of 7½-hp. capacity and shifter on the shaft of a 15-hp. motor that is used for driving two pumps running at 1200 r.p.m. One pump is coupled to the motor shaft direct, the other by means of the clutch. The convenience of the arrangement is apparent.

The Area of Chimneys should be proportioned to the quantity and quality of the fuel consumed per hour. Isherwood determined by experiments that the stack area should be from one-sixth to one-eighth the area of the grate, modified by the velocity of the gas. This in turn is influenced by the temperature of the gas and the height of the stack.

Safety-Valve Capacity—Below is given the number of square feet of heating surface served by a single 4-in. pop safety valve at 100 lb. gage pressure, under the requirements of the various rules noted. The assumption is made that the ratio between grate surface and heating surface is 1 to 40, and in such rules as require the rate of combustion to be assumed, it has been taken at such rate as would cause the evaporation of 160 lb. of water per square foot of grate surface per hour.

Will Quizz, Jr.

SYNOPSIS—Our observant friend, Will, while reading the advertising section of his technical journal, sees a statement that he cannot verify, so he carries the problem to Chief Teller.

"Say, Chief, I saw a statement last night that has me puzzled."

"What is it, Will?"

"An advertisement which says that a rise of 10 deg. in the temperature of the feed water represents a saving of 1 per cent. in the coal bill. I can't see how they get that ratio."

"Let's see if we can figure it out, Will. Take your steam tables and see what the total heat in steam is at, say atmospheric pressure."

"It is 1150, Chief."

"What does that 1150 mean?"

"It means that it requires 1150 B.t.u. to convert one pound of water from 32 deg. into steam at atmospheric pressure."

"Right, Will! Then 1 per cent. of the total heat would be what? We just had a little percentage the other day."

"One per cent., or one one-hundredth part of 1150, is 11.5, Chief."

"Then each 11.5 B.t.u. added to the feed water to be made into steam at that pressure would represent 1 per cent., would it not?"

"Sure."

"And 11.5 B.t.u. would raise the temperature of the feed about 11.5 deg., so that for this case a rise in temperature of 11.5 instead of 10 deg. would make a saving of 1 per cent., eh?"

"Yes, Chief, but the total heat is not the same for all pressures and that would make the percentage different, I should think."

"Yes, that is true, so look down the column of pressures and you will see that at about 25 lb. pressure, the total heat is 1160 and at 42 lb. it is 1170 and at 71 lb. it is 1180 and at 123 it is 1190, and when the pressure reaches 227 lb. the total heat is an even 1200 B.t.u. In each you simply point off two places, so in the latter case, of course, 12 deg. per lb. of feed water or 12 B.t.u. would represent 1 per cent. That part of the calculation is easy to understand, is it not, Will?"

"But, Chief, the feed water is seldom freezing cold. Wouldn't that change the figures or percentage?"

"It surely would, and that is what brings the figure down from 11.5 or 12 to about 10 for the ordinary case. For example, to change a pound of water at 32 deg. into steam of 100 lb. pressure takes 1186 B.t.u., but if the feed water were 200 deg., there would already be in it 168 B.t.u. more than in water at 32, so that there would have to be added in the boiler only 1186 — 168 = 1018 B.t.u., and the addition of 10.18 B.t.u. per lb., or the raising of the temperature 10.18 deg., would save 1 per cent. So it is true that ten degrees' difference in the temperature of feed water will make a difference of 1 per cent. when the temperature is around 200 deg., and this is where it ought to be, but as the steam tables are based on the total heat in the steam above 32 deg., the calculation must be from that point as a base. All the heat that the water contains above 32 deg., no matter from what source obtained, must be deducted from the original total heat, then the percentage of the remainder calculated as before, since we are interested only in the heat that has to be put into the water at a given temperature to convert it into steam at the desired pressure. The calculation, however, is just as easy as in the first instance, for all that is necessary is to subtract the amount of heat in the water above 32 deg. from the total heat in the steam as shown by the table at the desired pressure, then point off two places, as before. This will show you at once the number of degrees the water must be heated to equal 1 per cent. of the total heat required under these conditions.

"For example: The sun in heating the water in the pond to 78 deg. has contributed 46 B.t.u. per lb. toward converting it into steam which, for atmospheric steam, would be 4 per cent. of the total heat required. Since, as shown, 11.5 B.t.u. equals 1 per cent., then 46 would be 4 per cent. Then to complete the process there will be required 1150 — 46 = 1104 B.t.u. Pointing off two places as before, 11.04 is 1 per cent. of the remaining heat required, so that 11.04 deg. added to the feed water will save 1 per cent. in B.t.u. Now, suppose a small heater contributed 6 per cent. of the remaining 1104 B.t.u. or added 66¼ deg. to the feed water (1% of 1104 = 11.04 and 6% = 66.24), then 46 + 66 = 112 B.t.u. would have been added to the feed water, leaving 1150 — 112 = 1038. Then suppose an economizer in turn contributed 6 per cent. of the remaining 1038 B.t.u., or added 62.3 deg. to the feed water (1 per cent. of 1038 = 10.38 and 6 per cent. = 62.28 or, for easier calculation, 62.3), then 46 + 66 + 62.3 = 174.3 in all have been added, and the total heat the furnace would have to supply would then be 975.7 B.t.u. and the feed water is entering the boiler at a little over 32 + 174.3 = 206.3 deg.

"To sum up this part of the story: In the first calculation 11.5 deg. rise in temperature of the feed water equaled 1 per cent. of the total heat required; in the second, 11.04 deg. equaled 1 per cent. of the remaining heat required; in the third, 10.38 deg. equaled 1 per cent. of the remaining heat required. So you see there is no fixed amount which equals 1 per cent. under varying conditions, even with a 100 per cent. efficient plant."

"The 1 per cent. for ten degrees is only approximate, then?"

"That's all."

"And the saving is in heat units, not in coal?"

"Yes, but what's the difference? You have to burn coal to get heat units, and if you save half of your heat units you ought to save half of your coal."

"But the saving ought to be greater with a poor outfit than with a good one."

"How so?"

"Why, with a boiler of 80 per cent. efficiency I would only have to develop $\frac{1}{0.80}$ (= 1.25) × 10 = 12.5 B.t.u. in the furnace to put 10 B.t.u. into the steam, while with a boiler of only 50 per cent. efficiency I would have to develop 20 B.t.u. in the furnace for each 10 in the steam. If the feed water is 10 deg. hotter it will save only 12.5 B.t.u. per lb. in the case of the 80 per cent. boiler, but 20 in the case of the 50 per cent. boiler."

"That's right. the heating of the feed water for a poor outfit saves more in heat units and in coal, but the same in per cent."

"How can that be?"

"What is 50 per cent. of 5 pounds?"

"Two and a half pounds."

"What is 50 per cent. of 3 pounds?"

"One and a half pounds."

"But it is 50 per cent. in each case."

"Sure."

"Well. with the 80 per cent. boiler you must develop. as you say. 12.5 B.t.u. in the furnace in order to get 10 into the steam. A saving of one B.t.u., or 10 per cent., in making the steam would make a saving of 1.25 B.t.u. in the furnace. With the 50 per cent. boiler you would have to develop 20 B.t.u. in the furnace to get 10 into the steam, and the saving of 1 B.t.u., or 10 per cent., in making the steam would save 2 B.t.u. in the furnace. Do you get me?"

"Yes."

"For the poor boiler the saving is 2 B.t.u. as against 1.25 for the good boiler."

"Yes."

"But 2 is 10 per cent. of 20 and 1.25 is 10 per cent. of 12.5, so that the percentage of saving is the same in both cases, notwithstanding the actual saving is greater in the case of the less efficient boiler. If you save half your coal when you are using 10 tons a day, it will be more tons than it would if you saved half of only six tons a day, but it will be one-half in both cases.

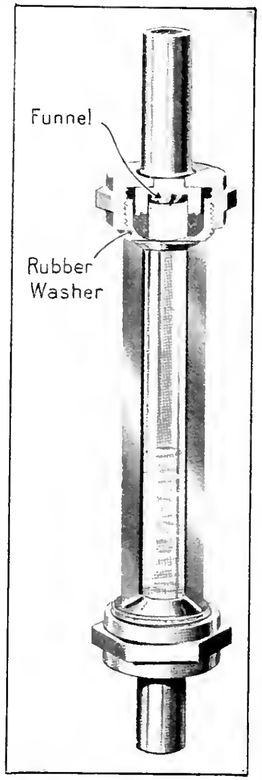
"The next question arises as to how much each B.t.u. is worth in money, which means the cost of the fuel, the labor, etc. If the fuel is cheap the loss, of course, is not so great when heat is wasted, yet the price per ton may be low and still the cost of the B.t.u. it contains or that transferred to the boiler may be high from several causes; low heat value, high cost of labor and unfavorable location being among the things which make it so. Therefore, the calculation must take in the cost of the B.t.u. at different places, by the same course of reasoning. If each B.t.u. in the fuel costs twice as much at one place as at another, then the heat put into the water from some other source is twice as valuable. So you see, Will, only the first general statement can be made which will be universally correct and comprehensive.

"In short the B.t.u. in the water must be considered 100 per cent. It is all there. The efficiency of the B.t.u. in the coal is variable and dependent on the equipment. The cost of the B.t.u. in the coal influences the value of the B.t.u. in the water, and the cost of getting the heat transferred from the coal to the water must be considered for a complete analysis. Does the subject seem clear to you now, Will?"

"Yes, thank you, Chief, and it has given me a better understanding of the necessity of watching the feed-water temperature more closely. I think I'll take more interest in that thermometer on the feed line after what you've told me."

Hill Gage-Glass

The Hill Pump Valve Co., 18 E. Kinzie St., Chicago, Ill., has recently perfected a new gage-glass possessing two distinctive features. It is easy to read and is protected against breakage to an unusual degree. No metal touches the glass. It is held in place by rubber gaskets and is free to expand or contract. Three supporting arms keep the upper and lower connections in alignment and protect the glass against breakage. Should it break, the arms will keep the broken pieces within the inclosure. On the inside the arms are white, so that the glass may be easily read from any angle. To prevent condensation from running down the sides of the glass and making it less transparent, a funnel has been provided and is centered so that the water will drop down through the center of the glass. The rubber gasket and the funnel tend to prevent corrosion at the top of the glass, and the former reduces breakage, which is more or less common when inserting a glass.



Hill Gage-Glass

The Discovery of Oxygen is generally credited to Dr. Joseph Priestly, an English clergyman and scientist. The date, Aug. 1, 1774, is commemorated as the birthday of modern chemistry. At about the same time two others made the same discovery: Scheel, a Swedish apothecary, who called it "fire air"; and Lavoisier, a French chemist, who called it oxygen, meaning "acid former." To Lavoisier is due the credit for the true explanation of combustion.

Development of Switchboards—In the modern electric generating station the protective devices represent the highest class of design and workmanship in the entire installation, while the cost of the switchboard frequently nearly equals that of the plant controlled by it. In the old days, however, says J. Gardner, writing in "Vulcan," few or no protective devices were installed. For instance, in a power station still running there are several 2000-volt 300-kilowatt single-phase generators controlled by open single-pole switches of the simplest type and without even a fuse in circuit; one side of the system is grounded. Everything operates quite satisfactorily until a cable gets grounded or someone makes a mistake; then there is a serious accident. A case of this kind recently occurred. A direct-current generator coupled to a steam engine was being run up in readiness for paralleling with other machines. When the volts were about 100 the attendant closed the main switch of this machine by mistake. Although the fault was discovered immediately, the rush of current into the machine pulled the armature winding partly round the core, and some of the commutator segments were nearly forced out of the V rings. The driving pins in the armature were sheared off and the insulation of the core was damaged. The armature had to be entirely rewound and the commutator rebuilt.

JUST FOR FUN

Failed to Recognize a Thermometer

In our plant we have both steam and hot-water boilers. The chief engineer hired a fireman recently, who had had an engineer's license for over fifteen years and who knew all (?) about engines and boilers. One day the Chief asked me to see if the water was hot enough and to look at the fire, as the demand was heavy. I looked and said, "Yes, it's 160."

After that the fireman, when asked how the fire was, would say, "Fine! I have 160 lb. on it," never realizing that instead of 160 lb. of steam he had 160 deg. It was about three weeks before he "caught on" that it was a hot-water boiler.—*Antoinette Vonasek, New York City.*

"In the Good Old Summer Time"

The retreat from the firing line.

(*From the New York "World"*)

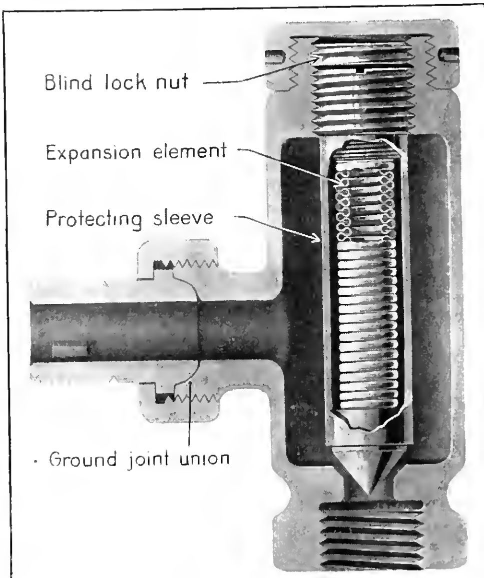
When the Wind Fails

A windmill for pumping water from a mine 60 ft. deep, recently installed and having a wheel mounted on a tower 60 ft. high on the bank of the mine, was an object of interest. Beside the railroad track the section gang during the noon meal discussed the unreliability of power that was available only when the wind was blowing.

The typical section boss, a middle-aged man, had said nothing for some time, but finally he could stand it no longer and he broke in with: "You fellows have bright ideas. Do you think these people are going to wait for wind when they have water to pump? See those cranks, arms and bevel gears. They can put wind on those vanes any time that they have a mind to." This ended the discussion, as no subordinate dared to question the knowledge of his superior.—*T. H. Reardon, Pittsfield, Mass.*

Winn Expansion Trap

The Winn trap shown in section in the accompanying illustration is designed for use on vacuum vapor and modulation systems of heating. It consists of an outer casing made entirely of brass, the valve seat forming an integral part of the casing. A ground-joint union tail piece attaches the trap to the heating unit. In the casing an expansion element, consisting of a seamless corrugated bronze tube which is filled with an expansion liquid, is inserted. The valve head is attached to the tube, and when steam comes in contact with the latter, the liquid



Details of the Winn Expansion Trap

inside expands and pushes the valve head to its seat. As soon as water collects around the tube the liquid contracts and the valve opens, permitting the water to pass through into the return line. A long sleeve guides the valve head to its seat and protects the corrugated element against scale and dirt.

The Winn trap is a modification of the "Welo" trap, which has been on the European market for many years. It is now being built in the United States by the Detroit Steam Specialty Co., Kerr Building, Detroit, Mich.

One of the Effects of Superheat—Superheating steam increases its volume a different percentage for different pressures and temperatures. For example: Steam at 100 lb. pressure superheated 100 deg. expands approximately 16 per cent., while 200 deg. increases its volume 31 per cent., or 15 per cent. for 100 deg., and 300 deg., 45 per cent., or 14 per cent. for 100 deg. For any desired case see the steam tables giving the specific volume of saturated steam, subtract this from the specific volume for the degree of superheat, divide by the specific volume of the saturated steam, and the result will be the percentage of increase in volume. (The same process gives the percentage difference in volume between two different degrees of superheat.) The amount of work steam of a given pressure will do is very nearly in direct proportion to its volume, hence one of the advantages of superheating.

Initial and Operating Costs of Refrigeration Plants

By Robert P. Kehoe

As the figures given by manufacturers to represent first cost, cost of operation, upkeep, etc., are often incomplete, the following tables will be found useful by operators and owners interested in refrigerating and ice-making plants of comparatively small capacity.

Table 1 refers to refrigerating plants. No particular application has been considered and the data may be used for any of the branches of refrigeration, such as general cold storage, markets, hotels, apartment houses, water-cooling plants, fur storage, drygoods stores, and hospitals.

The estimated first costs are necessarily approximate. A refrigerating equipment for a hotel will cost more than a refrigerating plant used solely for cooling water. Again, the same size plant in one hotel may cost more than in another. The figures are a good average, and the comparison between the costs of plants with different drive is quite correct.

Those who now operate plants and know what their equipment cost can use the table to advantage in adding or deducting to the same extent as indicated in the table to determine the difference in cost of other methods of drive. Then by applying the actual costs of labor and fuel, which are known, in the same manner, it may be ascertained how economically each plant is performing and if improvement is possible.

Refrigerating plants of from ten to twenty-five tons' daily capacity are seldom operated by men engaged to do nothing else, but usually by men required for operating other machinery. This has been considered in the table. The figures may be easily corrected to suit local conditions, and the price of fuel also regulated to correspond. The table represents a fair average.

The 60 per cent. yearly load factor assumed should be close to actual conditions in the majority of plants. It will be noted that the labor charge has been carried through the whole year. The 10 per cent. added for depreciation and repairs can be divided about half and half. A 5 per cent. yearly depreciation means complete renewal in fifteen years if the 5 per cent. is calculated as a sinking fund; 5 per cent. yearly for repairs and incidentals should be ample. No building has been taken into consideration because small refrigerating plants are usually located in some part of an existing building.

The advantage of making calculations of operating costs on a yearly basis cannot be doubted. In fact, the daily operating expense alone is misleading, particularly when the yearly load factor is low and a comparatively short period of operation must bear the depreciation and upkeep expense for the year.

The total cost per ton of refrigeration per day is interesting when compared to the cost of using ice for the same purpose. Ice is seldom delivered for less than \$2.50 to \$3 per ton, even in large quantities, and often the price is \$3 to \$4. The table proves that much saving can be accomplished by the refrigerating plant, without considering greater convenience, elimination of slop from melting ice and better preservation of perishable goods under lower temperatures.

TABLE 1 COMPARISON OF INITIAL INVESTMENT, DAILY AND YEARLY COSTS OF OPERATION OF REFRIGERATING PLANTS, WITH DIFFERENT KINDS OF MOTIVE POWER

Refrigerating capacity in tons per day of 24 hours..	10			15			20			25		
Kind of Power	Steam	Electric Motor	Oil Engine	Steam	Electric Motor	Oil Engine	Steam	Electric Motor	Oil Engine	Steam	Electric Motor	Oil Engine

The economy of oil engines as compared with ordinary steam plants and electric motors using central-station current at average rates is quite evident. In the smaller sizes of refrigerating and ice-making plants considered in the tables, the cheaper cost of operation is even more pronounced because small steam plants are not usually economical, while small oil engines perform almost as well as large units.

It may not always be advisable to install an oil engine, on account of local conditions which may favor a steam engine or electric motor. Steam may be required for other purposes. Sometimes the power plant may have to be located in such close quarters that only an electric motor can be used to preserve sanitary conditions. Sometimes it would be inadvisable to place an oil engine or a steam unit in the crowded basement of a hotel, restaurant or hospital where other work is going on and perhaps where foodstuffs are handled. But if the location and requirements do not favor other power, the oil engine will afford a marked saving in the yearly expense.

The table which refers to ice plants is arranged on a basis similar to the table for refrigerating plants. The cost of a special building is included, and the labor is calculated to be used for the ice plant alone. Only half the labor is included during the balance of each year when the plant is shut down or not operated at full capacity. Moreover, special tabulations are given for different yearly load factors. The importance of this factor is indicated by the wide difference in cost of production. For example, the 25-ton oil-engine-driven plant shows a total producing cost of $3.27 per ton when the yearly output is equivalent to three months' full operation, while the same plant producing the equivalent of seven months' full operation reduces the cost per ton to $1.82.

TABLE 2. COMPARISON OF INITIAL INVESTMENT, DAILY AND YEARLY COST OF OPERATION OF ICE PLANTS, WITH DIFFERENT KINDS OF MOTIVE POWER

Capacity in Tons of Ice per Day of 24 Hours	10			15			20			25		
Kind of Power / Type of Plant	Steam, Distilled Water	Electric Motor, Raw Water	Oil Engine, Raw Water	Steam, Distilled Water	Electric Motor, Raw Water	Oil Engine, Raw Water	Steam, Distilled Water	Electric Motor, Raw Water	Oil Engine, Raw Water	Steam, Distilled Water	Electric Motor, Raw Water	Oil Engine, Raw Water
Investment:

Testing and Repairing Pyrometers

By J. Lucas

SYNOPSIS—Describes the fundamental construction of most types of pyrometers, enumerates their faults and shows how their troubles may be corrected. Directions are given for making an accurate pyrometer of material, most of which may be found about the plant.

Types of Pyrometers

The mechanism of most pyrometers on the market is actuated by the expansion and contraction of liquid mercury or metals.

Fig. 1 shows a straight-stem pyrometer, Fig. 2 a high-temperature mercury thermometer, and Fig. 3 a horizontal-face or bake-oven pyrometer. Fig. 4 shows a section of the stem of a straight-stem instrument. A ¾-in. brass pipe acts as a casing for a copper rod *B* welded to a plug *C* screwed into the bottom of the pipe. A collar *D* fastened to the pipe serves as a guide for the rod. The top end of the copper rod is countersunk to receive the end of a lever which transmits the movement of the rod under expansion or contraction to a hand on a dial. The length of the copper rod varies according to the temperature range it is desired to register. Some straight-stem instruments use a copper pipe on the lower end of a brass rod. Other pyrometers have a stem made of a piece of graphite on which is mounted a brass rod, as shown in Fig. 5. The dial, its mechanism and the case are fastened to the end of the pyrometer stem so that the expanding and contracting element is held between two points, one at the lower end of the pipe, the other at the pointer-operating lever. The coefficient of expansion of the stem tube and that of the rod are different, and the rod always expands or contracts more than the pipe, its movement being multiplied by levers in the dial casing.

Fig. 6 shows the interior of a vertical-face instrument. When the rod *A* in the stem expands it transmits its movement to the pivoted pin *B* and to the lever *C*, which carries a rack operating a pinion to which the pointer is attached. The spring *D* fastened to the lever exerts a constant pull on the pivoted pin and holds it in its position.

The dial end of a horizontal-face instrument is shown in Fig. 7. The movement of the expanding element is transmitted by a pivoted pin, as in Fig. 6.

Fig. 8 shows a mercury pyrometer. A heavy, seamless steel tube with a $\frac{1}{16}$-in. hole at *A* holds the mercury. The spring *B* is welded to the cap of the tube, the other end connecting with a lever, as shown. The tube and spring are filled with mercury by holding both upside down; before they are filled the end of the tube is welded and sealed. The movement of the spring is not usually allowed to exceed ¼ in. When it does, mercury is let out of it by unscrewing the stem at *C* until the expansion is ¼ in. One should make sure that the tube is screwed in tight again, as this joint will sometimes leak mercury when it is supposed to be tight.

Pyrometer Troubles

Sometimes the pointer on the dial will move in jumps instead of slowly. This indicates that there are loose joints somewhere. The bottom plug may be loose or dirt may have collected around the guide collar (*D*, Fig. 4), preventing free movement of the rod. When this happens the rod will bend as indicated by the dotted lines (Fig. 4), and of course the instrument cannot indicate correctly. To remedy this take the case off the stem (pipe), unscrew the bottom plug and wash the stem and rod with gasoline. The rod must be straightened before the instrument is reassembled. Now put the stem in a pail or vessel of boiling water for a few minutes and set the pointer on the 212-deg. F. mark. Whenever there is no movement of the pointer for variations in temperature the usual cause is that the pivoted pin has fallen from its bearing.

Troubles Caused by Graphite Rod

The graphite-rod pyrometer is subject to a peculiar trouble. After long service the rod seems to slowly disintegrate, its diameter becoming less and less until its expansion for a given temperature rise is not what the instrument was calibrated for. The remedy, of course, is the use of a new rod of the original diameter and length.

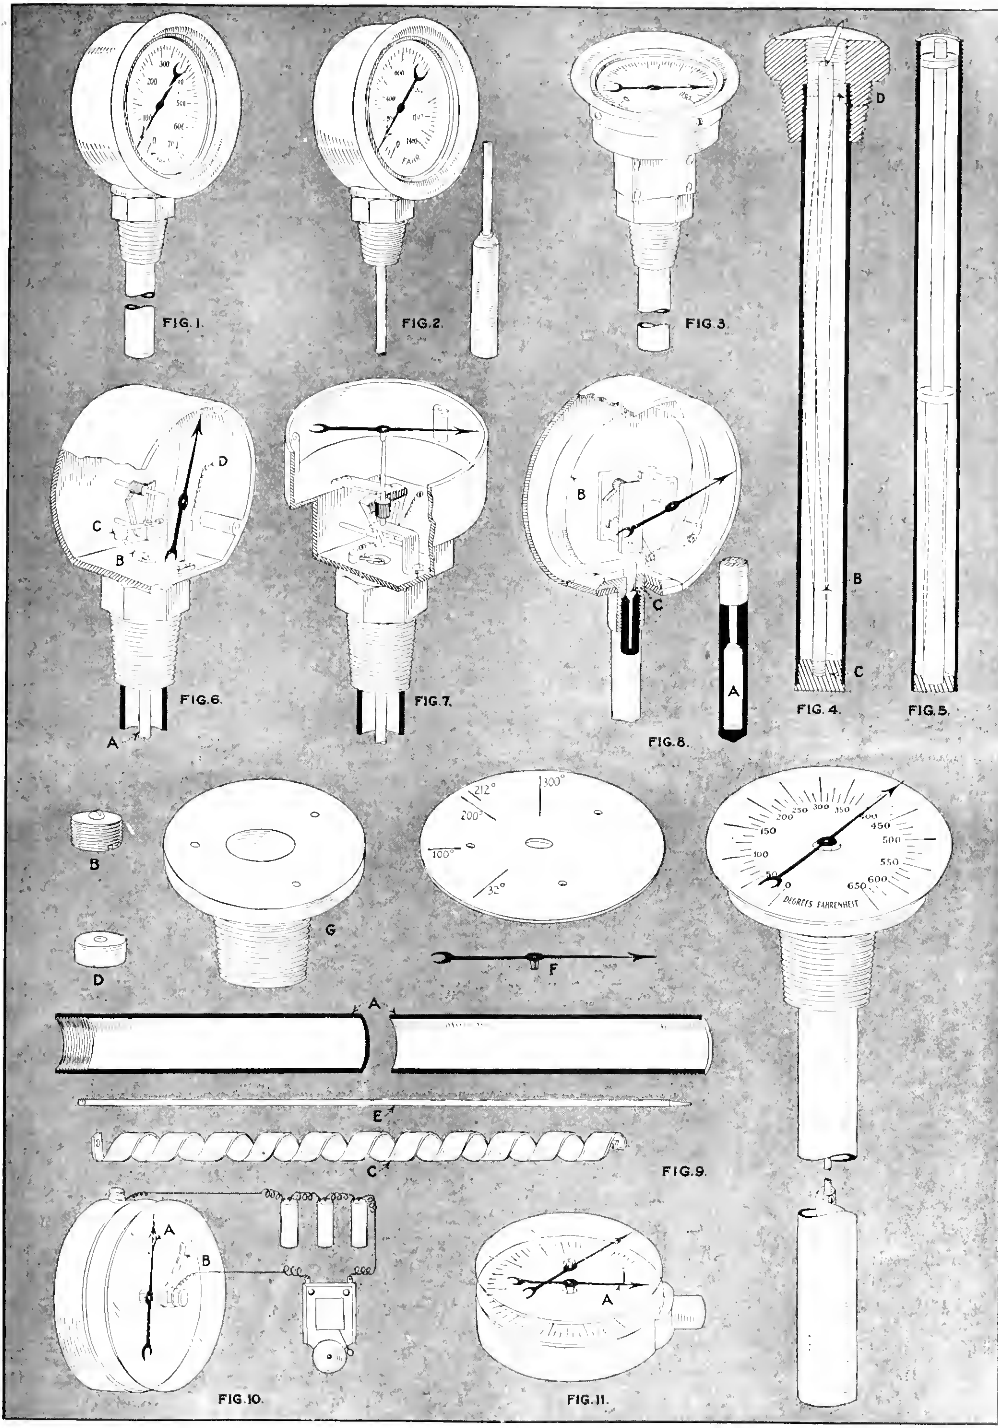
A "Home-Made" Pyrometer

Many plants and shops where a pyrometer is needed only occasionally will find the one described herewith serviceable and accurate. A piece of $\frac{1}{16}$-in. steel pipe *A*, 1 in. diameter and 24 in. long, is threaded inside at one end to receive the plug *B*, and the other end is threaded on the outside to screw into the base of the case. A brass spring strip *C* $\frac{1}{32}$x1¼x30 in. is formed spirally, having ½-in. pitch and ½-in. diameter. This spring will be about 10 in. long. One end is brazed to the plug *B*, and the spring and plug are put into the pipe *A*. The guide-disk *D* is then brazed or soldered to the other end of the pipe. This disk has a $\frac{3}{32}$-in. hole to guide the steel spindle *E*, $\frac{1}{16}$ in. diameter, which should be fastened to the lower end of the spring by a rivet or screw before the spring is put into the pipe. The top end of the spindle should be pointed to permit forcing on a 5-in. hand or pointer *F*. A piece of tin or sheet iron 6 in. diameter is used for the dial. The flange *G* is now screwed into the pipe, the dial fastened, and the pointer laid near-by, ready to be forced on the spindle. The instrument is now ready for calibration.

Pack the stem for its full length in a pail of chopped ice. After about ten minutes force on the pointer, and under and to one side mark 32 deg. F., the freezing point. Next immerse the stem in water kept at 100 deg. F., as indicated by a correct thermometer. When the pointer will move no more make the 100-deg. F. mark on the dial. Next heat the water to 200 deg. and mark the dial. Also, mark it at 212 deg. The stem is next immersed in crude oil heated to 300 deg. F. For the rest of the dial the spaces between 300 and 400, 400 and 500, etc., may be divided off equally up to 650 deg. F., for which range the instrument is well suited.

Pyrometer Alarm

Sometimes it is desired to call the attendant's attention by alarm when a certain temperature has been



INDICATING PYROMETERS AND THEIR MECHANISM. FIG. 9 SHOWS ONE THAT MOST ANY ENGINEER CAN MAKE reached. This may be done by putting on the pointer pin an adjustable piece *A*, Fig. 10, which is held in position by a thumb-nut. A light flat spring is soldered to the pointer and contact poles are fastened to the instrument, as shown. The movable contact piece *B* is set over the desired temperature mark on the dial, and when this is reached the spring on the pointer makes contact, closing the circuit and ringing a bell.

Should it be desired to have the pyrometer indicate the highest point reached after the temperature has fallen, a dummy pointer may be used. This is an ordinary pointer mounted as shown in Fig. 11, and which is free to move so that the indicating pointer may push it around by engaging the projection *A* on the dummy. Usually, the dummy pointer is painted red or white so it can be easily distinguished.

Lining Up Small Turbine Sets

By J. H. Hurley*

The successful operation of any turbo-generator, turbo-pump or turbo-blower set depends so much upon the satisfactory alignment of the complete unit that too much attention cannot be paid to this matter when erecting these machines. The idea that because the unit is on a cast-iron bedplate the latter cannot be sprung is erroneous, as it is easy to twist a bedplate by wedging unevenly or by pulling down holding-down bolts at, say, opposite corners.

Another mistaken idea is that because a machine is fitted with a flexible coupling, alignment between the two ends of the unit is unnecessary. The so-called flexible coupling will take care of a small amount of misalignment and also should eliminate the thrust of one machine being thrown onto the other. In other words, it has the effect of making each end of the machine self-contained, but owing to the high speed at which these machines run it should never be assumed that a flexible coupling will satisfactorily take care of any appreciable misalignment, and the machines should be lined up with a flexible coupling just as accurately as if the coupling were solid.

The rough-and-ready method of lining up with a straight-edge across the two coupling faces, Fig. 1, often

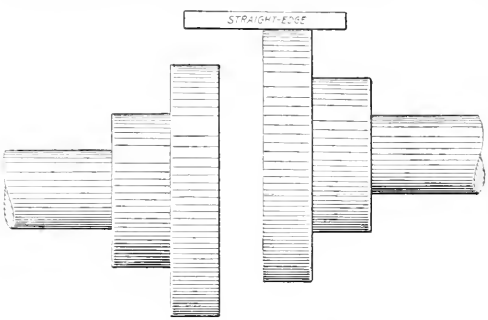


Fig. 1. Lining Up with the Straight-Edge

is satisfactory, but this is only so when the couplings are true in themselves. This condition, however, is often by no means the case and couplings are frequently found to be out of true on their own shaft. To take care of this possibility, therefore, the following method of lining up is suggested, taking into account all the possibilities of untrue couplings in addition to the regular and orthodox method of lining up.

Try out couplings to ascertain if they run true by placing a straight-edge on one half of the coupling, then by the use of a thickness gage, Fig. 2, ascertain the high and low side of one half by rotating one half, then take a mark at 90 deg. from those points and use those

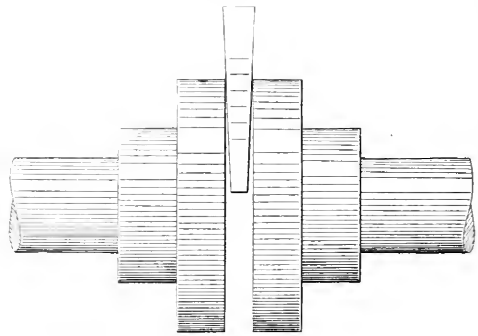

Fig. 2. Application of the Wedge

points exclusively both for horizontal and vertical lines. Then in turn let this half stand still and rotate the opposite half in like manner. Place the straight-edge on both faces at those points until both flanges are flush on the sides, allowing the regular amount on the turbine side, top and bottom, for heat expansion for the generator, boiler-feed pump, circulating pump, blowers or other sets according to their different temperatures when operating.

This same method should be used on the faces of couplings, as it happens sometimes that couplings run out on the faces when they run perfectly true on the sides. In this case a taper wedge may be used to find the high and the low points. Then, when those points are obtained, use such liners as may be required to bring the faces parallel.

It is generally understood that bases are leveled at the works before the sets are bolted down. If this is properly done the sets may be placed for grouting by inserting wedges at all points where it will effect the coupling in the direction required.

Should the set be erected on the job, then follow the usual course by first leveling the base and allowing height enough for substantial grouting, which is usually about ¾ in.; then locate the sets as described.

Always use metal liners or wedges, as wood is apt to shift on account of the dampness of the grouting, with disastrous results. When the grouting is properly set the sets should be checked and the bearings properly

*Mechanical department, the Terry Steam Turbine Co.

washed out before oil is put in. The governor should be worked back and forth to free it and remove rust which may have accumulated while standing.

Many couplings are not drilled to jig and, therefore, the pins will only fit in the holes which are matched. Couplings are generally stamped in a case like this, showing where they should be matched.

When sets are doweled at the works, or if for any reason it is necessary to change liners, the holes should be again reamed when the dowels are taper and should not be driven hard enough to stretch the metal, but tapped slightly until the tapping becomes solid.

All flanges should be brought to the turbine or pump square, and when rigid no soft gasket should be used to draw the sets out of line and shear the dowels.

In lining up generators, place chalk marks at one point on each end of the armature; all aligning should be done from these marks with the use of a wedge or a feeler, as taking several points on the armature would not be correct on account of the high spots in the banding. In all cases make sure that the core of the armature and the core of the polepieces are equally centered with each other so as not to cause a thrust on the turbine bearing. The core of the armature is always longer than the polepieces.

It is hard to decide how far out couplings can be allowed to be and still work satisfactorily, but the writer would say that if they are out more than $^1/_{64}$ in. any way, special care should be exercised in starting the machine, and if it does not run smoothly enough this should be reported, with a special remark about the couplings being out of the true, so that the matter may be taken up with the coupling makers.

The mixture for grouting in a machine should be half pure cement and half sand. After grouting, the machine should be allowed to set for 18 hours. Foundation bolts should be left loose or screwed down by hand until after the concrete is set, when they may be tightened firmly.

In lining up, as previously mentioned, use iron wedges only. They should be placed under the spot where the weight comes and as near the foundation bolts as possible.

Cold-Air Intake Duct for Air Compressors

By R. S. Bayard

SYNOPSIS—Shows by simple explanations and plain calculations how an intake duct drawing air at atmospheric instead of room temperature lowers the average cost of compressed air.

It has often been observed that the output of an air compressor is greater in winter than in summer; that is, it seems that a machine which has had to "hustle" to furnish air in summer, may be able to maintain the required pressure at a reduced speed during the winter. The reason for this is often asked, so an explanation will be of interest.

This difference can be observed only when the compressor takes its air through a duct leading from the outside air, because it is due to the effect of the difference of air temperature between the compressor intake and the place where the air is used or conveyed through.

Imagine a cylinder having a perfectly tight piston held, we will say at midstroke, and the half-cylinder full of air at atmospheric pressure and at a temperature of 60 deg. F. The atmospheric pressure is, with 30-in. barometer, 14.7 lb. per sq.in. With the piston held rigidly and leak-tight, assume that we can heat the cylinder so that the air inside will become 100 deg. F. This will cause the air to expand and try to occupy more space, but if the piston will not move the air cannot expand, so it will increase in pressure. Mathematically, the pressure produced in this way will be

$$14.7 \times \frac{100 + 460}{60 + 460} = 14.7 \times \frac{560}{520} = 15.84 \textit{ lb. per sq.in.}$$

That is, the new pressure, absolute, will be equal to the first pressure, absolute, multiplied by the ratio of the absolute temperatures. (The absolute temperature is found by adding 460 to the Fahrenheit temperature, as done above.)

If, in the cylinder we are considering, the piston is allowed to move as the air expands and if it has no friction, so that the air pressure does not increase, the final volume will be larger than the original volume in the ratio of the absolute temperatures. If the original volume was, say 10 cu.ft., the final volume after the piston has moved due to increase of air temperature will be

$$10 \times \frac{100 + 460}{60 + 460} = 10 \times \frac{560}{520} = 10.77 \textit{ cu.ft.}$$

At the usual room temperatures (about 520 deg. F. absolute) the increase of volume is, roughly, 1 per cent. for every 5-deg. F. increase of temperature.

Let us see how the foregoing applies to a compressor plant. Irrespective of the outside temperature, the air in the shop pipe lines will be nearly at the temperature of the room by the time it reaches the tool. Suppose in winter this temperature averages 68 deg F. and that the air finally reaches the tool at this temperature. If the compressor takes in 1000 cu.ft. of free air (air at atmospheric temperature and pressure) directly from the room, it will also deliver 1000 cu.ft. of free air at the tool, because the final temperature is the same as that at which it entered the compressor.

In summer the same conditions apply as long as the compressor takes its air from the same room in which the compressed air is used; but if the compressor is provided with an intake duct leading from the outside air, the results will be quite different. First, consider the winter condition. Suppose the shop temperature averages 68 deg. F. and the outside air 30 deg. F. If the air is used at 68 deg., its volume will be considerably greater than the volume taken into the compressor from the outside air at 30 deg. If it requires 1000 cu.ft. of free air per minute at shop temperature to run the tools, the compressor will have to take in only

$$1000 \times \frac{30 + 460}{68 + 460} = 1000 + \frac{490}{528} = 929 \textit{ cu.ft.}$$

which is a saving of over 7 per cent. in air capacity, speed and horsepower. In summer, when the outside temperature is practically the same as the temperature indoors, there would be no saving by using the intake duct, except, as is often the case, when the compressor takes its air supply directly from the hot engine room. Thus, it is seen that the compressor would run at a speed about 7 per cent. lower in winter than in summer. The colder the climate, the more pronounced this effect would become.

An actual case where the application of an intake duct to a compressor represented an appreciable saving recently came to the writer's attention. An air compressor furnishing an average of 2500 cu.ft. of free air per minute to a machine shop took its supply from the basement of the engine room, where all the year round the air, heated by a network of steam pipes, averaged 95 deg. F., while the shop averaged 70 deg. F. During the winter months the outside air averaged 32 deg. F., and in summer 70 deg.

Based upon the average consumption of 2500 cu.ft. per min. for 10 hr. a day, the air used amounted to an average of

$$2500 \times 60 \times 10 = 1,500,000 \textit{ cu.ft.}$$

per day at the shop end.

As the compressor-intake temperature averaged 95 deg. F., the compressor was obliged to run fast enough to take in

$$1,500,000 \times \frac{95 + 460}{70 + 460} = 1,500,000 \times \frac{555}{530}$$
$$= 1,570,500 \textit{ cu.ft.}$$

of engine-room air per day.

The cost of compressed air in this plant was found to be 2.8c. per 1000 cu.ft. at the compressor. Thus the cost of furnishing air to the shop was

$$\frac{1,570,500}{1000} \times 0.028 = \$43.97 \textit{ per day}$$

By putting in an intake duct and furnishing air to the compressor at 30 deg. F. in winter, the compressor could have run slower and would have had to take in only

$$1,500,000 \times \frac{30 + 460}{70 + 460} = 1,500,000 \times \frac{490}{530}$$
$$= 1,387,000 \textit{ cu.ft. per day}$$

At a cost of 2.8c. per 1000 cu.ft. at the compressor intake, the average cost of air for the plant during winter would then be

$$\frac{1,387,000}{1000} \times 0.028 = \$38.84 \textit{ per day}$$

During the summer, when the outside and inside temperatures both averaged 70 deg. F., the compressor would take in only the amount used in the shop, or 1,500,000 cu.ft., which at the cost of 2.8c. per 1000 cu.ft. at compressor intake would be

$$\frac{1,500,000}{1000} \times 0.028 = \$42 \textit{ per day}$$

With the intake duct in use we then have a daily cost for air of $38.84 for winter and $42 for summer. The average for the year may then be taken at $40.42 per day, as against $43.96 with the compressor taking air from the engine-room basement.

During a working year of 300 days, the annual cost for air would then compare:

Without intake duct..................	$43.96 × 300 = $13,188
With intake duct.....................	40.42 × 300 = 12,126
Giving a net saving with the duct of............	$1,062

Capitalized at 10 per cent., this would justify installing an intake duct costing $10,620. As this figure approaches more nearly the cost of the compressor than it does the cost of the duct, the conclusion is obvious.

Incidentally, the saving of $1062 per year amounts to more than 8 per cent. of the yearly cost for air. It certainly looks worth while to install an air-intake duct under such conditions.

The Planetary Motion

The planetary motion devised and used by Watt to convert reciprocating into rotary motion is of interest, first because it was brought into use to circumvent a patent previously obtained by Wasborough on the simple crank for the same purpose. The other interesting feature is a condition where two gear wheels of the same diameter engage, but one makes two revolutions for each one revolution of the other. This may be easily tried out, or demonstrated, by using two coins with the edges sharply milled. Hold one of them stationary with the head up, or stick it fast with a little mucilage. Place the other with the head up directly in a vertical line above the head of the first. Now rotate the upper coin to the right around the fixed coin. It will be seen that by the time the former has reached the half revolution or the point directly below the fixed coin it will have turned one complete revolution, standing head up again. Another complete revolution will be accomplished by the time it reaches its original position. It will therefore have made two complete revolutions while engaged with a stationary coin of the same size.

It is obvious then, that if the coin being rotated were held head up all the way around, and the other coin made to rotate as on its center the latter would have to make two complete revolutions by the time the two coins had reached their original relative positions. One revolution is due to the crank motion and the other, to tooth engagement. This is proved by using a traveling gear twice the circumference of the shaft gear, which will produce a 3 to 1 ratio by reason of doubling the larger gear, instead of what might be expected—a 4 to 1.

Examples of the modern application of the planetary gear in the opposite way may be found in some geared chain hoists and also in some automobile transmission gears for slow speed.

Lloyds Safety-Valve Rules require that two safety valves be fitted to each boiler, the combined area of which shall equal at least ½ sq.in. for each square foot of grate area and the accumulation of pressure shall not exceed 10 per cent. of the working pressure. Each valve is to be so made that no extra load can be put on while under steam pressure.

Editorials

Michigan Is in Line

Michigan made a gallant fight for the adoption of the boiler code of the American Society of Mechanical Engineers during the session of the legislature recently closed. A bill (Senate Bill No. 234, File No. 299) provided for the appointment of a board of boiler rules to formulate rules as near in conformity with the A. S. M. E. code as possible. It passed the Senate without a dissenting vote. The bill was then referred to the Committee on State Affairs in the House and two hearings were granted, but those in charge of the bill were unable to secure the reporting of it out of the committee. The belief is general that if this bill had been reported out it would have been enacted into law with little opposition.

It is believed that at the next session of the legislature the A. S. M. E. code will be adopted by the state and a system of license regulations put in force.

It was discovered during the fight for the passage of this bill that opposition on the part of the thresher engine interests and the threshermen's organizations is weakening and coming to a realization that modern boiler practice and means for public safety must prevail and are a good investment.

This is the first time in the history of Michigan that a bill relating to boiler matters or engineers has passed either house of the legislature without a dissenting vote.

Michigan is in line. Let her move up to the window and receive her code.

The National Electrical Safety Code

The two principal sources of hazard to life around a power plant are the boilers and the electrical equipment, particularly where high voltages are employed. Just as safety in the boiler room depends upon the construction of the boilers and their intelligent operation, that in the electrical end of the station depends upon the proper installation of the electrical equipment and the care in handling it. The excellent work of the Boiler Code Committee of the American Society of Mechanical Engineers in preparing its recent boiler code, has been emulated by the Bureau of Standards, which has been at work for nearly two years on an electrical safety code. It is particularly fitting that this work should have been undertaken by this bureau, devoted in its scope to scientific and engineering problems and in a position to approach the subject with an open mind. While the bureau has employed experts especially for this work, it has in no way attempted to force its own opinions on the public, but instead has endeavored to learn the views of various electrical companies and, through conferences and sifting of these views, to arrive at a set of rules which will represent the best practice.

The rules are divided into four parts, the first three dealing respectively with the installation and maintenance of electrical supply stations and equipment, electrical supply and signal lines, and electrical utilization equipment; the fourth covers rules for the operation of electrical equipment as concerns both the employer and the employee. Part 4,* which is printed as a separate bulletin, was first published last August in a tentative form and was widely circulated for comment and criticism. It has now been revised in accordance with a number of suggestions and, in conjunction with Parts 1, 2 and 3, is being circulated for further criticism before final revision.

Lack of space prevents our reprinting the rules, but we would urge those readers who are interested to obtain copies from the Superintendent of Documents at Washington, and send in such suggestions as may seem advisable.

While the Bureau of Standards has no direct power to enforce the observance of such rules, it is believed that most electrical companies and even private plants will find it advantageous to adopt them. Moreover, it will form a set of uniform rules, which public-service commissions or municipalities may find it convenient to enforce.

Taking Charge of a Larger Plant

To "make good" in the new sphere of duty is the honest ambition of every right-minded engineer who is promoted to larger responsibilities. Not always, however, does he find his hopes realized under the changed conditions. Failure to do so may be due to many causes.

Causes beyond the engineer's control cannot be helped. Vicissitudes such as the collapse of a factory business through changed economic conditions, the sale of an industrial plant by the owners to others who prefer to discontinue power production locally because of representation on central-station directorates, or the maladministration of a property through nepotism will discourage any but the trained operator, who knows that in the long run there is sure to be a market for his services. It is more important to consider those factors in service over which the engineer may maintain mastery—those policies which lead to success when properly directed and applied in the new field of usefulness.

On taking over a larger installation the temptation arises to emphasize the weak spots left by one's predecessor and to make a clean sweep of methods which at first appear open to criticism. It is wiser to make haste slowly. The sharpest possible analysis is commendable, but little is lost by taking sufficient time to get one's bearings.

No installation looks the same from within as it does from the outside, and to make a brief inspection of a plant as a possible chief engineer, and then later to go over the installation as its responsible executive are two very different things. No two plants are exactly alike, and even if similar in makeup, will not run in exactly

*See "Power," Dec. 8, 1914.

the same way. The engineer who takes time to learn the personal abilities of his new subordinates and the strong and the weak features of the equipment, individually and collectively, is wise. Let him avoid attempting to reform the whole institution the first week, and by the second or third week he may find it possible to begin to effect some real economies through the coöperation of those under him. While a glaring instance of preventable waste should not be allowed to continue even for a week, it pays to let the old staff discover that the new chief is willing to learn, that he is glad to receive the help of those more familiar than he with the local equipment and load situation, and that he is determined not to act on snap judgment to impress the "boss" with his instant ability to cut costs and make a new record.

An exceptional man may take over a new job of this kind and almost immediately inaugurate an efficiency policy which revolutionizes practice within the station. Such an overturn may be accompanied by a substantial crop of recommendations for discharge, without waiting to find out if the men most familiar with the routine work cannot gradually be brought to work in harmony with the new program. It takes time to find out what those already on the ground can do, and a plant may fail to do its best work for many reasons other than incompetency of the force. It is nearly as important for a new chief engineer promoted from within to introduce his executive ideas moderately. Where a subordinate engineer is not available to promote, the new chief needs insight and tact to get the best from his predecessor's force.

A contented staff has more to do with economical operation than some realize, and whether an engineer takes charge from within or from without, a probationary receptive period is an effectual means of getting acclimated to his new responsibilities.

Recognizing Abnormal Conditions

The ability promptly to detect abnormal conditions in plant operation is most valuable to the engineer. Nothing so clearly denotes the expert as immediate appreciation of the existence and cause of any unusual sound. The same is true with respect to scrutiny of the log sheet and to the study of test data.

While many sources of inefficient operation are soundless, cultivation of a keen sense of hearing is worth much to the engineer. With high-speed machinery, even very slight departures from the normal tend to become magnified. Every plant has in a measure its own sound characteristics, due to the sort of load it carries and to the peculiar combinations and sizes of main and auxiliary units in service. From long experience most engineers will sense abnormalities in sound almost subconsciously, but a new man will need to make a special effort to develop this faculty as quickly as possible. Things happen pretty fast when an unusual condition becomes cumulative, with modern turbine and high-powered auxiliary equipment; the value of machinery under the control of the engineer today runs to figures far in excess of a decade ago; and the ability to see ahead and to catch the drift of sounds which the untrained visitor would never notice is very important.

When examining operating and test records, a similar skill in instantly "spotting" departures from the normal is of great advantage. It takes practice to scan tabular data rapidly without losing their significance. The starting point is to know what to expect in a routine way, and this can be acquired by continued study and observation. Roughly, each plant may be said to have a set of "constants" of its own. That is, the temperature of the feed water will run between such and such limits when every day's record of coal consumption per kilowatt hour keeps down to the average minimum consistent with the local conditions; the variations in steam will follow a well-defined cycle, if this is varied purposely, or will hold close to a predetermined zone above and below a fixed average so long as things go as they should. Seasonal variations will be noted in the temperature of intake and discharge water.

It is the engineer's task to maintain normal conditions of service and instruments help in this work, but perhaps too much reliance is placed on automatic charts at times. The really professional understanding of one's plant is the kind that combines the keen ear and the microscopic eye with a continuous apprehension of a considerable number of physical data which set a standard for every departure from efficient operation. In other words, when the readings of instruments depart from the normal by a certain differential, when test sheets contain figures that jump out of the routine range for a little while, the expert engineer notes them at once and if possible acts promptly and reduces preventable losses.

Intense personal interest in an installation leads to skill in diagnosing the approach of abnormal conditions through knowledge of what seem trifles to the man of mediocre ability or to the layman. The result is a reduced maintenance expenditure and a better record for service continuity, to say nothing of an almost inevitable improvement in operating economy.

The Federal Government inspects the locomotive which draws your train, and no steamer can carry passengers without a certificate from the Federal inspector that its boilers have been inspected and its engineers examined and found safe and competent. The Federal Government also requires the stationary boilers in the District of Columbia to be inspected and requires a competent attendant for them, but only four out of forty state governments are equally solicitous for the safety of their citizens. The people are protected when they travel, because the Federal Government can do it, but not when they stay at home, because the state government will not.

The troubles of the engineer are many and sometimes unique. One of our good friends up along the Hudson River finds so much moisture in the air used for forced draft that in winter ice accumulates on the under side of the grate. Sometimes, especially when the fire is about four hours old, ice so plugs the air spaces in the grate that it becomes necessary to put a steam hose in the ash-pit and melt it so as to pass enough air to keep up the required rate of combustion.

Our contemporary, *The Electrical Review* of London, "cannot approve of all methods adopted by American consuls" in stimulating trade activity with France. Why should they?

Correspondence

Gas Explosions in Boiler Furnaces

In your issue of Apr. 20 I read the interesting communication by L. A. De Blois, concerning a gas explosion in a boiler furnace. The three correspondents appear to be at a loss to explain the formation of an explosive mixture, or, in other words, the entrance of a sufficient amount of air into the formed carbon monoxide under the condition described; that is, with the fire-door closed, the tuyeres blocked by a clinker and the damper wide open. It seems to me that the formation of an explosive mixture under these conditions is a very natural occurrence.

Carbon monoxide is somewhat lighter than air, and on account of the higher temperature in this case it is considerably lighter than the outside air. The open stack with the closed furnace, therefore, represents a vessel having a lighter fluid at the bottom and a heavier one on the top. These two fluids, if not in motion, are in unstable equilibrium, and it is only natural that a slow flow of the lighter gas toward the top on one side of the stack and a corresponding return flow of the heavier air on the other side of the stack would take place. I believe that the sketch will make this clear.

The moment the fireman broke off the clinker and thereby opened the discharge from the fan, rapid combustion was started, with a consequent development of high temperature, probably projecting a flame into the combustible mixture. This started the explosion because the time intervening between the opening of the fire-door and the breaking off of the clinker was not sufficient to remove this explosive mixture from the furnace.

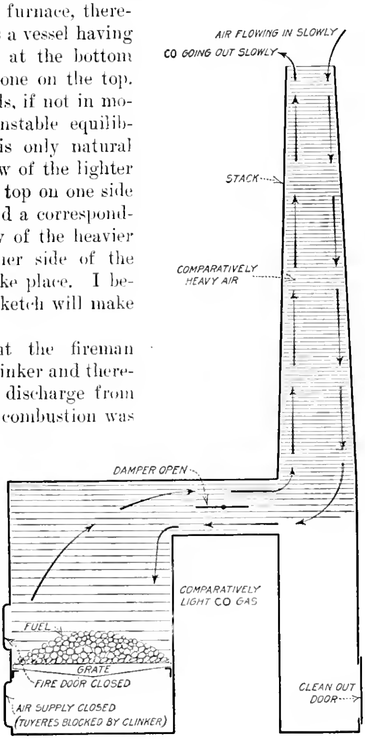

Fig. 1. How Air May Have Entered Furnace and Caused Explosion

It seems to me that a reliable arrangement for preventing this occurrence could be made. If the conditions of the furnace, its operation and the fuel used are such as to permit a constant admission of a small amount of air above the fire, an opening should be provided in the fire-door and it should be made impossible to close this opening. In this case, even if the tuyeres were completely blocked, the constant, if slight, draft would remove any carbon monoxide that might be formed.

If, however, the existing conditions do not permit this sort of an arrangement without destroying the efficient operation of the furnace, a bypass may be provided in the air supply, branching off between the blower and the tuyeres and entering the furnace above the fire. This bypass should have in it an unbalanced damper which is normally closed but which opens when the pressure in the air-supply pipe rises on account of the tuyeres being stopped up. This damper (or virtually, check valve) could easily be provided with an indicator on the outside by which the fireman's attention would be called to the fact that the tuyeres have become clogged (see Fig. 2).

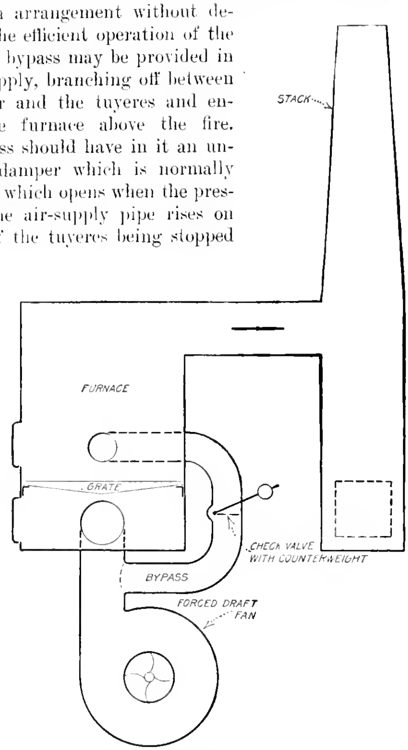

Fig. 2. Bypass around Grate

This analysis is based only on the information which I can gather from the communications as I found them in Power. Should my understanding of the case be incorrect, I would appreciate a word from Mr. De Blois, to clear the situation in my mind.

Robert Cramer.

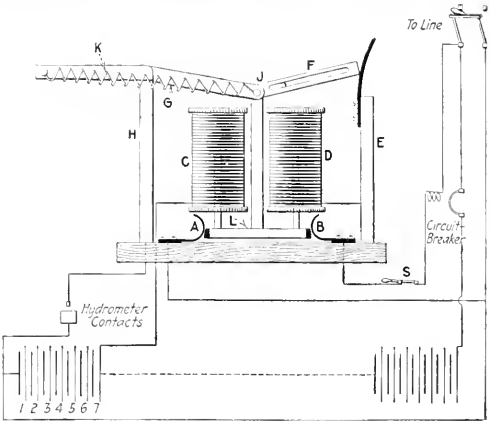
Low-Gravity Cutout for Storage Battery

The battery in question was rated at 50 amp. at an 8-hr. rate and supplied current for lighting and for a few small motors from 6 p.m. until 7 a.m. It had been badly overloaded at times, and despite repeated warnings to various people around the institution, the overloads would recur all too frequently. Finally, it was decided that something more effective than warnings was necessary. After considering various plans, it was decided to install a circuit-breaker which would be tripped when the recording hydrometer dropped to a certain point. This hydrometer was already equipped with a contact on the pen arm, which dipped into an adjustable mercury cup, so that this part of the job was very simple. It was necessary to construct a relay to close the trip coil circuit and install a circuit-breaker. The sketch shows the relay and wiring diagram.



Wiring of Automatic Cutout

When the hydrometer reaches the lowest point desirable, it closes the circuit through solenoids *C* and *D* and part of the battery. It was best that this circuit should be broken as soon as it had accomplished its purpose so as not to further drain the cells. This was provided for as follows:

Current passes from cell No. 7 to coils *C* and *D*, thence to post *E* and the flat spring attached to it, through *F* and *G* and down post *H*, via the hydrometer to cell No. 1. As soon as current flows, *C* and *D* are energized and *L* is lifted and also the rod which is attached to it. This throws the joint *J* upward, and the coiled spring pulls it back, drawing *F* out of contact with *E* and breaking the circuit. Once *L* has been pulled up, it cannot fall, because the spring contacts *A* and *B* are so formed and adjusted as to prevent it. As soon as *L* bridges *A* and *B*, line current flows through the coil of the circuit-breaker and trips that device, thus opening the battery circuit.

If anyone should gain entrance to the engine room and attempt to reset the breaker, the latter would immediately open again, because by the closing of the breaker its trip coil would again be energized. Furthermore, as the relay is under lock and key, no one could reset it except the engineer having the key.

It remains to relate that the principal offender was the first to be caught. When he had carelessly pulled the battery down and the circuit-breaker had opened, he found himself in inky darkness.

William E. Dixon.

Cambridge, Mass.

Crankpin Failure

The photograph, Fig. 1, is of a crankpin that failed recently on one of our 24x36 first-motion hoisting engines. When the pin failed both guides broke, the rear cylinder head was broken out by the piston, and the piston and piston rod were ruined. The engineer shut the throttle the instant the accident happened and threw on the brake, thus stopping the cages where they were and preventing a more serious damage. Fig. 2 gives the dimensions of the pin and shows where the break occurred. This sort of failure is what is called a fracture in detail.

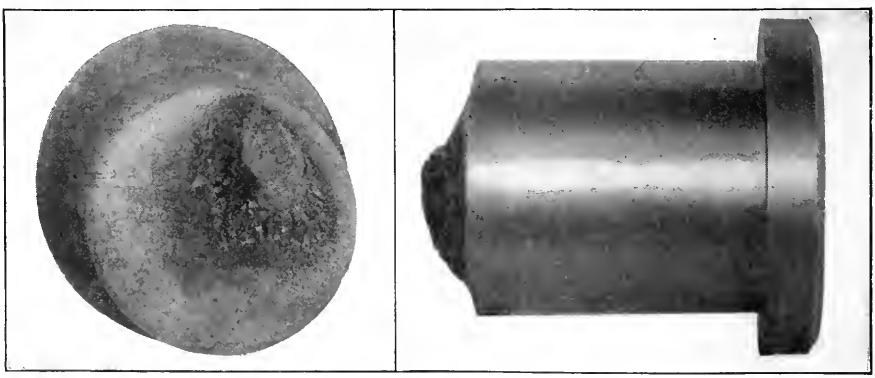


Fig. 1. Two Views of Broken Crankpin

It was not due to any flaw in the material, nor does it seem possible that the pin was too small. The maximum steam pressure carried is 120 lb., and with this pressure on the 24-in. piston the total load on the pin would be less than 55,000 lb. The 4½-in. pin, the cross-sectional area of which is $15\frac{7}{10}$ sq.in., should be large enough to carry the load with a large factor of safety. Of course, if there was any slack rope the starting load would be greatly increased, but the ropes are always kept closely adjusted. No doubt the trouble was due to a fault in the design of the pin. It will be seen that the corners on both sides of the 7/8-in. collar next to the crank disk are perfectly sharp, with no fillets whatever. These were the weak points at which the fracture could start. The 7/8-in. collar mentioned was a part of the crankpin. Probably it would have been better if this had been a

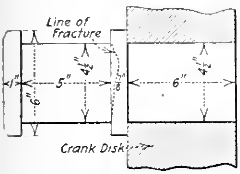

FIG. 2. ORIGINAL DESIGN, FAILED

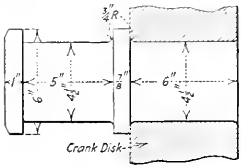

FIG. 3. NEW DESIGN

separate collar shrunk on at the proper place, thereby eliminating the sharp corners. We have three hoists of the same size in service, and considerable trouble has been experienced in the past with crankpin failures. Occasionally, the wrecks have been rather serious. More than once the whole cylinder was wrecked and had to be replaced. Various grades of steel pins have been experimented with, but the results were practically the same. So it was decided to change the design of the pin. Fig. 3 *B* shows the new design adopted. It is thought that the 3/4-in. radius fillets on each side of the collar will stop the trouble. However, these new pins have not been in service long enough to prove anything yet.

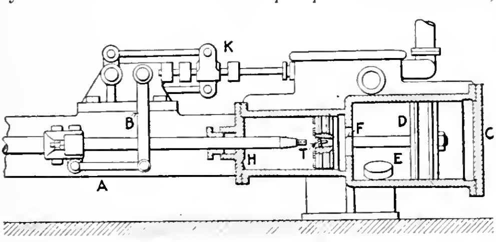
I would like to know whether any of the readers of POWER have had similar experiences, and if so what steps they have taken to remedy the trouble.

F. F. JORGENSEN.

Gillespie, Ill.

Pump Would Not Run

When a duplex tandem compound pump failed to start it was at first thought that the steam valve had shifted, but links *A* were disconnected and the valves operated by lever *B*. One side of the pump made full strokes,



CONDITIONS INSIDE OF PUMP

but the other side moved only a few inches in the center of its travel and struck something solid.

Head *C* and the low-pressure piston *D* were removed, and in the bottom of the cylinder was found the nut from the end of the high-pressure rod, and the large disk *E* which screws in the center of the wall *F* between the two cylinders.

Head *H* was removed and it was found that a follower bolt *T* had dropped out of the high-pressure piston and had worn the cylinder head about half through, at *H*. This bolt was found wedged in the hole in the center of the high-pressure piston, as shown. The bolt *T* was taken out, the high-pressure piston put back on the rod, and the large plug *E* put into its place. The cylinder head *C* was put on, but piston *D* was left out, and by readjusting the spools at *K* the pump ran very satisfactorily until a new piston could be secured.

Lubrication

Your Mar. 23 editorial, subject "Lubrication," suggests a few comments. Modern equipment such as high-pressure compound condensing reciprocating engines, turbines, and Diesel, producer gas, locomobile and uniflow engines, air compressors of several stages, also eight- and twelve-cylinder automobile engines, require the best oil obtainable; any other kind retards smooth operation. Some engineers admit that their engines are better judges of good oil than they are.

The present standard of oil analysis needs revision. Oils varying in chemistry and physical properties materially render selection difficult. Few buyers are able to differentiate between the good and the bad. The Independent Petroleum Marketers' Association, recognizing this deficiency, selected a committee of experts about two years ago to investigate this situation, but so far no report has been made, nor has any new standard been adopted.

Most of the crude oil produced in this country, or about 76 per cent., is of asphaltic base and of low market price. The other 24 per cent. is of paraffin base, ranking very high; in some instances a premium is paid for it. It is the difference between the two that puzzles many engineers. To them the finished oils look alike, whether Eastern or Western products, but when the asphaltic-base oil is used under high-pressure modern conditions, the asphalt condenses at its critical temperature. This deposit may be found in cylinders, packing rings and piston rods, accumulating until sheared off. It causes engines to labor hard, calling for increased oil supply and also finds its way into condensers, reducing their efficiency. Asphalt has no lubricating value and should be abandoned when trouble presents itself.

The paraffin-base oil, mainly from Pennsylvania, has the reputation of being the most reliable oil found anywhere. It is becoming scarcer every year. During 1914 the production in Pennsylvania fell off 963,282 bbl. If the same ratio continues, in about eight years it will cease.

The widely used red engine oil, being of an asphalt base, wears rapidly. It disintegrates after being fed to the bearings a few times and causes abrasion. Next, an imperceptible wear of the metallic rubbing surfaces begins and the oil finally finds its way into the filters, dirty, with its lubricating value reduced until it is gradually worn out. In a short time another barrel must be ordered. Its ultimate cost is high. Buyers may recognize herein why they find it necessary to order oil so frequently. The remedy is to install an outfit which returns the used oil to a filter, and adopt a bright-yellow, good oil (not acid-treated) which may be fed by drops, or in a stream in hot weather. Such an oil wears longer and needs little replenishing and that at longer intervals. Its ultimate cost is low.

Under any given conditions the oil which results in the lowest cost, owing to consumption, cost of coal needed to overcome frictional resistance, and cost of repairs due to metallic wear on metallic journals and brasses, is the best.

A modern high-pressure compound condensing engine requires the best oil obtainable. Such oil cannot be bought at a low price. But it may be the cheapest in the long run. Dependability, long service and ultimate cost are the determining factors. When engines labor and groan and valve and eccentric rods vibrate, or traces of asphalt appear, an immediate change of oil is advisable. Soft spots may appear in cylinders, causing wear, or leaky throttle valves, causing corrosion when the engines are idle. Or the trouble may be due to stale, rancid animal oil used in animal-oil compounds, coming in contact with hot steam and decomposing, forming acids. This causes soft spots, and if not remedied will result seriously. No reputable oil company will use rancid animal oil, or rancid wool fat or De Gras, which may be detected by its odor. Animal oil for compounding should be sweet and fresh and preserved in refrigerators when the temperature is above 50 deg. F.

The writer's method of handling lubrication problems is to diagnose each case by itself. With practiced eye and well-trained ear the remedy is simple. In general, the modern uptodate little-drop method of cylinder lubrication supplied by a mechanical lubricator operated from the valve movement, when accompanied by a good oil, results in perfect lubrication, requiring the smallest consumption, at the lowest ultimate cost.

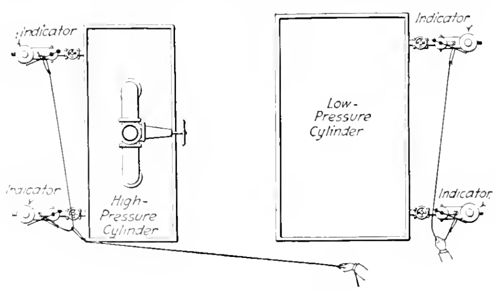
Taking Two or More Diagrams Simultaneously

Taking diagrams simultaneously is essential for the purpose of accurately determining the horsepower developed, and also for valve setting. Sometimes it is neither convenient nor possible to make use of the magnet attach-



OPERATING FOUR INDICATORS

ments in handling two or more indicators. In using magnets dry batteries and wiring connections must be provided. The magnets must be delicately adjusted in order to make the proper pencil mark, and considerable time and trouble are entailed in making such adjustments. In lieu of magnets the following method may be adopted:

At each end of a cord about two feet longer than the distance between the indicator cocks make a loop about six inches in length so that there will be no knots to interfere, pass the loop over the pencil arm, which has been previously provided with an elastic band to hold the pencil off when not indicating. We now have a flexible connection to both indicators, and a pull on the cord will take as many diagrams as desired.

When indicating a cross-compound engine a third cord may be looped about the cord on one cylinder or the latter may be of sufficient length to reach the other cylinder where the operator can control all four indicators simultaneously. I have found this method simple and convenient.

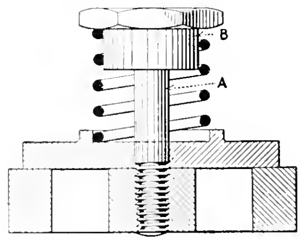
Repairing Pump-Valve Studs

This will help out if your stock has run out and the pump valves have to be repaired before new studs can be obtained. Cut off the old valve stem and use the top part *B* as a nut after it has been drilled and tapped, then



HEAD USED AS A NUT

take a bolt or brass rod and make a stud *A*. This will answer the purpose as well as a new one. The nut may be pinned or riveted on if necessary.

JOHN M. RUPPERT.

Philadelphia, Penn.

Condensation from Waterwheel Casing

Waterwheels expose to the air a large surface which sweats under certain atmospheric conditions. Disposing of this water becomes a troublesome job to the operating engineer.

A channel or flange is usually cast around the periphery of the sub-base and drained to the tailrace. On the 20,000-hp. units in a certain plant several hundred square feet of surface are exposed to the heated air of the power house and the condensation is copious. During the first months much of the operator's time was taken up in disposing of the condensation collecting in the drainage channel, as the operating conditions made it inadvisable to utilize the customary drainage tubes.

The wheel, revolving rapidly in the closed casing, always produces a considerable vacuum at the shaft. This vacuum was utilized through a ⅜-in. pipe tapped into the casing, fitted with a valve, and extended to the drainage channel to remove the water.

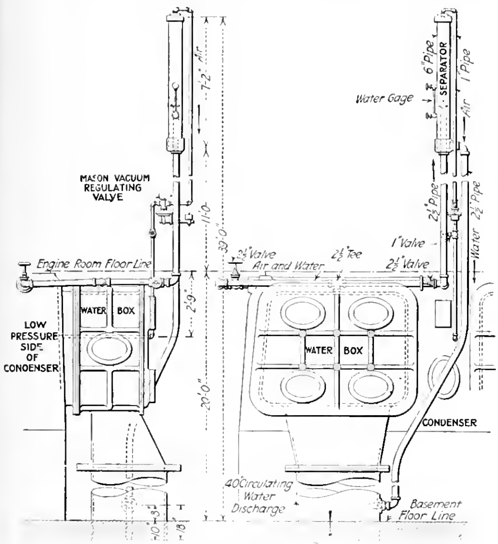
WALTER SWAREN.

Hayward, Cal.

Removing Air from Condensers

At the steam station serving the Twin City Lines we have five Curtis turbines of the vertical type, equipped with Worthington three-pass condensers. A great deal of trouble was caused by the accumulation of air, especially in the water box at the end of the last pass. The top of this box is about twenty-four feet above the level of the water in the river, both the intake and discharge pipes being submerged, making a sealed system.

Various devices were tried to remove the air, among them the plan of tapping the top of the box and connecting to the condenser, the pipe being fitted with a globe valve which was opened and closed by hand. The objection to this scheme was that, if the valve was opened too wide, too much water would be taken over into the



Air Receiver and Pipe Connections to Condenser

condenser. We tried to overcome this by extending the pipe in the form of a loop ∩, the upper part being about forty feet above the river level, but we found that the water would go over in "slugs". We then decided on placing a separator in the uptake side of the loop, and one was made up of 6-in. pipe and fittings approximately the same as shown in the accompanying illustration. Later, we applied the Mason vacuum regulator and have found the 1-in. regulator, with a pipe of the same size, large enough to handle all the air.

"Slugs" of air and water pass up the 2½-in. pipe into the separator through the short piece of pipe shown by dotted lines, the water separates from the air and flows out through the discharge pipe into the circulating discharge. By means of the weights on the lever of the regulator it is possible to obtain any desired vacuum in the separator.

We have found that this device gives excellent satisfaction, and when once adjusted, it needs no further attention on the part of the engineer.

Engineers' Salesmanship

Some time ago there was an editorial in Power on this subject, and it may not be too soon to bring it up again. At that time it was stated that the engineer applying for a position as salesman is handicapped through lack of actual selling experience and because he has no past record of sales ability. The questions now arise: What is sales ability? What qualities must the successful salesman possess?

In order to approach a business man at all it is necessary that one be neat in personal appearance; then, when one gets to his man, one must have a fair command of English and a pleasant disposition to start a conversation and, once the conversation is started, self-confidence in the line and oneself, together with a thorough knowledge of the specialty offered for sale, to maintain the conversation until the goods offered have been shown up at their best. There is such a thing as saying too much in some cases; therefore, tact and a knowledge of human nature are also required.

The qualities mentioned are the principal ones that go into the makeup of a successful salesman. What has the practical engineer to offer his prospective employer in the sales game? The engineer, to be successful in even a fair-sized plant, must have all the qualities mentioned above, with a few more thrown in. He must be tactful, to keep his crew working smoothly; he must be neat about himself and the plant; he must have an agreeable nature, to keep peace with his employer and the tenants in the building; he must have a thorough knowledge, not of one, but of a dozen and one different appliances to keep his plant going; and he must possess facts and figures and know how to present them when he and the central-station man meet on the mat in the manager's office.

The engineer, therefore, can offer the manufacturer of steam specialties the same qualities that the salesman can, plus practical experience, which more than offsets the lack of actual selling experience in the beginning.

The manufacturer should bear in mind a few proved facts. Many a perfectly dependable piece of apparatus has been returned to the makers and condemned because it failed to do what it was sold to do. Why? Because it was installed under conditions where it could not operate efficiently, or otherwise. It was sold by a man who was only a salesman and did not know whether it would operate. A practical engineer would have made no such mistake; he would know from experience that only failure could result.

It is to the interest of the manufacturer, not only that an appliance should operate, but that it should operate at maximum efficiency. Repeat orders are the life of a concern, and a good piece of apparatus will fail unless properly installed.

Last, but not least, while the engineer is not always the buyer he can always be the knocker. An engineer salesman can walk into a plant, and being an ex-engineer, he usually has no trouble making a friend of the average engineer. He sees things about the plant an ordinary salesman would not notice and can probably make suggestions which will lead to a sale. He asks questions the average man would not think of and gets information which the ordinary salesman could not obtain. If there is a complaint about anything he usually gets it first, and thus has the opportunity of correcting the fault before it goes further and causes unpleasant business relations. While going about he can collect trade data at little or no cost; data which usually cost the manufacturer quite a little to secure through other sources.

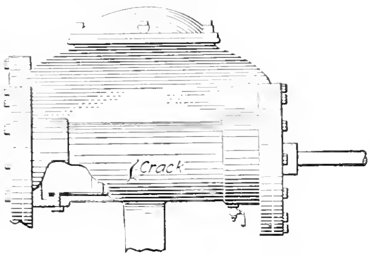
The average buyer of today appears to hail from the corn-cob state; he must be shown, and who is better qualified to show him than the man who can get into a pair of overalls and install and operate his plant? All engineers will not make good salesmen, but in view of what is required of the modern engineer one can safely say that a larger percentage of men who can qualify for salesmanship in the engineering field can be taken from the ranks of the operating man than from any other body of men.

A. H. Pohlman.

Brooklyn, N. Y.

Emergency Pump Repair

In the plant where I am employed a small vacuum pump on the returns from the heating system developed a crack about three inches long in the cast-iron cylinder of the water end. When we overhauled it we found that the crack did not extend through the brass lining and that



Plug Extended into Lining

the water got in between the iron and brass at the drip opening. We screwed a brass plug into the drip opening flush with the bore and smoothed it up nicely. On starting the pump the crack did not leak a bit and had closed up somewhat.

I think the pressure between the lining and the cylinder forced the crack open, as at times it has to work very hard.

Howard H. Whitaker.

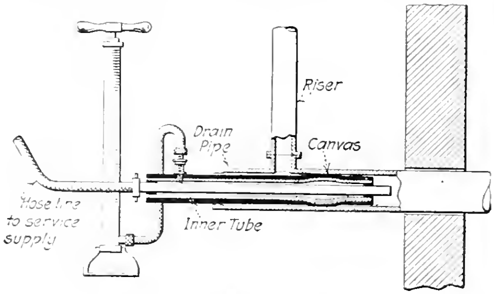
West Somerville, Mass.

A Pneumatic Pipe Stopper

Difficulties are encountered at times in clearing out obstructed drain pipes on account of abrupt turns in the piping, which a steel "snake" or its equivalent is unable to pass around, and it is necessary to use a hose connected to the hydrant pressure to clear the obstruction.

If, however, a plug is removed and a hose connection made, the water, instead of passing through the obstructed piping, will ascend in risers and overflow from the sinks or washbowls above. A case of this kind recently came within the writer's personal experience. The 3-in. drain pipe, with a 2-in. screw plug in the end, passed through a basement wall. About 12 in. from the end of the pipe a 2-in. riser extended to the floor above.

To make a water-tight connection with the drain pipe and prevent backflow in the riser, the device shown was made up in a few minutes from material that happened to be at hand. A 2-ft. piece of a bicycle inner tube, having the valve attached, was cut off and slipped over a $\frac{3}{4}$-in. iron pipe and bound tightly at each end by winding stout cord about it and the pipe. Over this a piece of



Pneumatic Stopper in Use

3-in. cotton hose was placed and bound in like manner. A line of hose was attached to the service supply and connected to the $\frac{3}{4}$-in. pipe, and the end was inserted in the drain pipe as shown and the tube inflated with a foot pump, which produced a water-tight coupling.

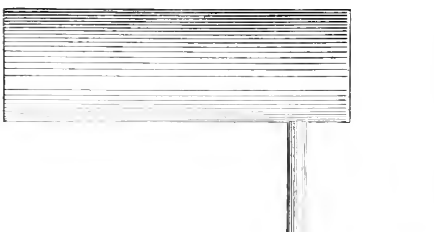
Pittsfield, Mass.

Blowoff Piping

The company for which I am working built a new plant a year ago, and the blowoff piping was something novel to me, although it may not be to all readers of Power.

The engineer who has had to go into a hot combustion chamber and install a new blowoff pipe after an elbow has failed will appreciate this arrangement, as it does away with a threaded elbow. The pipe should be extra heavy



Bent Pipe for Blowoff

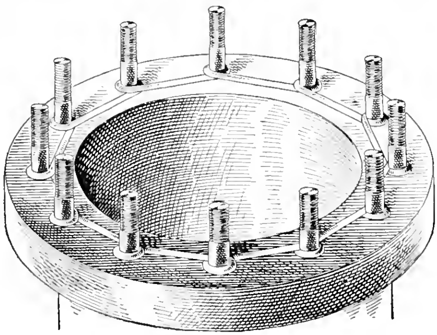
and will be better if made of wrought iron, which is easily bent. This leaves a clear passage for scale and sediment in blowing off the boilers, and if properly protected, I see no reason why it should not last for years; it will certainly reduce the danger from water-hammer and elbow failure. The company furnishing this equipment always uses a bend instead of an elbow, wherever possible.

J. A. Epply.

Thomasville, Ga.

An Emergency Gasket

The writer has used a gasket for a steam main, made as shown in the illustration. Long pieces of lead rope were inserted between the pipe flanges and wound around the bolts. A mixture of red lead and linseed oil was then added, the whole being flattened and spread out by



Lead Rope as a Gasket

the strain on the bolts. This form of gasket may be tightened as required from time to time, taking care that the lead does not spread too much and project into the bore of the pipe.

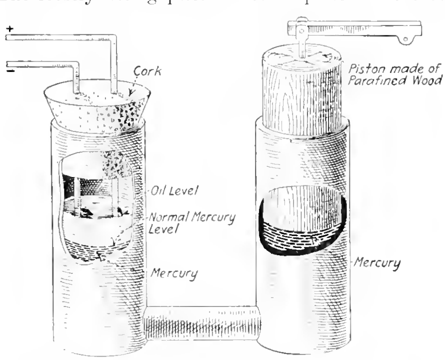
T. W. Reynolds.

New York City.

Signal-Circuit Make-and-Break

Use a U-tube of glass or iron pipe, into which the wires should be fastened by pushing through a cork and varnishing, or, if the tube be of glass, they may be fused in place. The tube should then be filled with mercury to a point slightly below the ends of the wires and enough oil put on it to cover the tips of the wires.

The loosely fitting piston is to be placed in the other



Electric Circuit Completed by Rise of Mercury

side of the tube and so connected to the float or mechanism that is to operate it, that it will be depressed and displace enough mercury to cause the column to rise in the opposite side and close the circuit by submerging the points of the wires. This will be accomplished away from the air and under oil, and may be used with safety around gas or other explosives.

This device does not require attention, as the oil cannot "creep out." It can be made as acid- and fumeproof as the electric conductors themselves, and also "foolproof."

H. King.

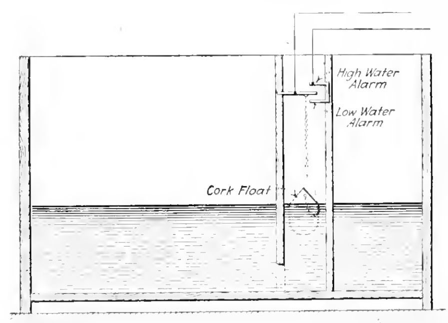
Wilkinsburg, Penn.

Tank Float and Alarm

The illustration shows a high- and low-water alarm for a tank, which we developed after considerable experimenting.

The situation was more difficult than usually met with, on account of the water being supplied to the tank by two pumps discharging at opposite ends of the tank, the agitation causing waves which kept the float and switch in almost constant motion.

A casing open at the bottom was fastened inside of the tank in which the float was placed, and after this the



Float Inside of Casing

surface agitation had little effect. The rising and lowering of this cork float opens and closes the electric circuit which rings the alarm bell in the engine room. The float fits in the casing so as not to turn over, and the light chain allows considerable variation in the water level before the alarm sounds.

Irving Cobb.

Atlantic City, N. J.

A Broom Handle in the Cold-Water Pipe

A water-heating plant gave off various noises and our steam fitter was called to remedy it, and I was invited to go along. The heater was in the basement, and as we entered, the pipes gave off a continual chatter, then got quiet for a time, and then jerked in a way likely to tear the piping out.

At first we thought the steam fitter had got confused in his connections at the top of the tank, but the system had been in successful operation one winter. After finding this connection right we took down the cold-water pipe and found a piece of broom handle inside, which at first was a loose fit in the pipe, and it let the water past for a time, but had filled with sediment, with the results mentioned.

J. N. Woodruff.

W. Liberty, Ohio.

Stand-by Plant Supplying Steam to Central Heating System

The Northwestern Electric Co operates an 18,000 horsepower hydro-electric plant on the White Salmon River. The plant supplies energy to the City of Portland, Ore. A reserve was needed in order to back up the water-power station. The plant installed is described by G. Broili, in the "Journal of Electricity, Power and Gas." It was found that in order to serve the public properly, either a storage battery or a steam plant would have to be installed. The steam plant was finally chosen because of the possibility of installing a central heating system.

Two 3500-kw. turbines were placed in the basement of a large Portland office building. These turbines operate noncondensing and act as voltage regulators on the electric end by varying the field excitation. The turbines can be made to carry enough load to furnish the steam required for the heating system, or the steam can be bypassed through reducing valves, or a combination of both can be used. As the turbines are always connected to the electrical system, they will quickly take up the load should there be any interruption of the service from the water-power plant. No delay can take place, such as often happens on many hydro-electric systems where the steam plant must be brought quickly into operation in emergencies. These turbines are ready to put out their full capacity at all times for an indefinite period, which is not the case with a storage battery.

In ordinary operation one or two turbines are run and all the steam required for the heating system goes through the turbines, carrying a part of the load. An automatic governor developed at the plant keeps the low pressure to within one-half pound of whatever is required. The plant has been operating successfully since starting. The boiler pressure is 185 lb. with 125 deg. superheat. The amount of superheat is greatly reduced in the turbines, but when any steam goes through the reducing valves, there is trouble in the heating main due to the excessive superheat. While a cold spray of water in the heating main beyond the reducing valve will absorb the superheat, experiments are in progress to perfect a system that will be more desirable.

The results obtained show that the central-station service is financially satisfactory, not to mention the item of service which is hard to estimate in money. Steam heat has been furnished for one year to an office building with 152,000 cu.ft. of space, and 1321 sq.ft. of radiation. In a previous year, the fuel cost was $438.40 and the labor cost $520, making a total of $958.40. The steam heat from the central station costs $520 for the year, thus making a saving of $438.40 over the fuel costs in the private plant. Another case is given of a well-built hotel, three years old, with 640,000 cu.ft. of space and 3650 sq.ft. of radiation. The fuel cost during 1913 in the private plant is compared with the net central-station steam cost for 1914 in the following table:

Month	Private Plant (Fuel only)	Cent. Heat. Total
January	$194.60	$145.58
February	174.65	118.58
March	124.75	80.00
April	99.80	67.86
May	99.80	55.10
June	24.95	31.50
July	24.90	40.50
August	49.90	44.01
September	49.90	71.28
October	99.80	99.50
November	123.75	123.53
December	212.54	132.43
	$1179.34	$1009.87

These figures show a fuel saving of $169.47, but in addition to this there was a saving made in labor amounting to about $1200 per year, making a total of about $1370. It will be noted that in the milder months of winter and in summer, central-station service exceeded in cost the amount paid for oil fuel for the private plant. This is explained by the fact that with central-station service better heating is enjoyed at all times and more hot water is used because of its being available, thus giving the hotel tenants a much more satisfactory service in every way.

The pressure in the heating mains is about 5 lb. Two 20-inch lines leave the station, and the sizes are gradually reduced. The lines are tied in with cross-lines wherever possible. Condensation in the mains averages about 0.025 lb. per hr. per sq.ft. of pipe surface and is practically constant regardless of the load or time of the year. Radiation of heat from the underground pipes is reduced to the lowest possible amount by the use of a very efficient insulation made to surround the iron steam pipe. First a layer of asbestos paper is carefully wrapped around the pipe, then an air space of about one inch is provided by centering the pipe within a heavy wooden-stave pipe casing. This casing is lightly banded with steel wire and painted with heavy tar paint. The interior is lined with bright tin to reflect radiated heat from the iron pipe, and between the tin and the wood is a sheet of asbestos to prevent charring of the casing. Expansion and contraction are taken care of by special joints known as variators, placed about every 50 ft. along the street trenches. The right-angled house service connections are taken off at the anchored point where needed.

To Calculate the Horsepower of a Stream of Water

The table gives the horsepower generated by one cubic foot of water per second (7.48 gallons) falling a distance of one foot, which is 0.0965 horsepower, or 72 watts, and is the basis upon which the following table was calculated.

HORSEPOWER GENERATED BY ONE CUBIC FOOT PER SECOND, FALLING DISTANCE 5 TO 200 FT.

Fall or Head in Ft	Hp. of 1 Cu Ft. or 40 In Water	Kilowatts	Fall or Head in Ft.	Hp. of 1 Cu.Ft. or 40 In. Water	Kilowatts
5	0 483	0 360	35	3 380	2 521
6	0 579	0 431	40	3.860	2 876
7	0 676	0 504	45	4 340	3.237
8	0 772	0 575	50	4 820	3 595
9	0 869	0 648	55	5.310	3 961
10	0 965	0 718	60	5.790	4 319
11	1 062	0 792	65	6 270	4 677
12	1 159	0 865	70	6.760	5 042—5 kw.
13	1 255	0 936	75	7 240	5.401
14	1 352	1 008—1 kw.	80	7.720	5 759
15	1 448	1 080	85	8.210	6.124
16	1 545	1 152	90	8.690	6.482
17	1 642	1 225	95	9.170	6 840
18	1 738	1 296	100	9.650	7 198
19	1 835	1 368	125	12 070	9.604—9 kw.
20	1 932	1 441	150	14.48	10.802
25	2 410	1 797	175	16.90	12 607
30	2 890	2 890	200	19 31	14 405

Equivalents from this table may be converted to suit any case by multiplying the horsepower of 1 cu.ft. of water under any head by the head in feet times the number of cubic feet per second of water available.

For determining the flow of a stream, or the amount of water available for power purposes, the water is measured by means of a weir—an instrument quite well-known in all of the irrigating districts. A small weir table is appended.

TABLE FOR WEIR ONE FOOT IN LENGTH

Depth in In. on Crest	Quantity in Cu.Ft per Sec. for Each Ft. in Length	In Miners In.	Depth in In. on Crest	Quantity in Cu.Ft. per Sec. for Each Ft. in Length	In Miners In.
1	0 08	3 2	7	1.50	60
1½	0 15	6	7½	1 66	66
2	0 23	9	8	1.81	72
2½	0 30	12	8½	2.00	80
3	0 40	16	9	2 18	87
3½	0 50	20	9½	2 35	94
4	0 65	26	10	2 55	102
4½	0 77	31	10½	2 75	110
5	0 90	36	11	2 93	117
5½	1 04	42	11½	3 15	126
6	1 18	47	12	3 35	134
6½	1 34	54			

This table was calculated for depths of water from one to twelve inches by one-half inch increments and for a weir width of one foot.

The Cost of Employing Incompetents

At a recent gathering of machine tool builders it was stated that it costs $30 to $35 to engage a workman, test him and discharge him if inefficient. This figure is based on the records of a large manufacturing plant, and it is easy to see how much can be lost per annum if great care is not exercised in selecting the new hands. It is even more necessary to be careful in putting new men on a power-plant staff, since an incompetent man may cause damage running into thousands of dollars in a very short time. The quality of the work done by a mechanic or machine operative can be very quickly gaged, but it is not so easy to estimate the abilities of a shift engineer unless he blunders right at the start. A keen chief will, of course, get to know the caliber of his man before very long, but an emergency may occur, and the mischief may be done before the discovery of incompetence has been made.

Heat Generated in a Circuit represents work done in overcoming the resistance of the circuit.

Ammonia a Heat Vehicle

By Albert Johnson

[The following paper by Albert Johnson, of the Herf & Frerichs Chemical Co., was first read before the American Meat Packers' Association, Chicago, and since then has been read before other like organizations. The explanations and presentation will commend it to those new at operating refrigerating equipment.—Editor.]

HOW AMMONIA CONVEYS HEAT

Let us see how anhydrous ammonia becomes a conveyor of heat. When one pound of anhydrous ammonia has passed through the regulating valve into the low-pressure pipes it remains a liquid until it can grab hold of from 500 to 600 B.t.u. of heat. Then the pound of liquid changes into a pound of gas. But it refuses to change from liquid to gas until that much heat leaves the room and enters the liquid ammonia on the inside of the coils, thereby turning it into gas.

The changing of the liquid into gas is what absorbs the heat. Therefore, it is always necessary to have plenty of liquid ammonia within the low-pressure pipes.

Do not, under any circumstances, allow gas to pass through the regulating valve, for then you only add heat to your rooms instead of subtracting it. Remember, the gas is the loaded vehicle, while the liquid is the unloaded vehicle, being empty. The liquid has plenty of room for heat units, but the gas has little room for heat units, since it is already loaded with them. It cannot carry any more. So it is well to watch and see that only liquid passes the regulating valve into the low-pressure pipes.

This is a more serious question in operation than you may think possible, and the subject is more fully covered in my former paper read before the International Congress of Refrigeration, and entitled "The Value of a Liquid Seal," which can be had upon application, free of charge.

Bear in mind that it requires heat to vaporize ammonia—the more heat, the quicker the evaporation; whereas, the less the heat, the slower the evaporation, which explains why "sharp freezers" are so apt to fill up with liquid in abundance, while the rest of the system may be suffering from the lack of liquid.

After the liquid has been changed into vapor by the heat, it has practically spent its energy as a refrigerant, for the gas has obtained its full load of heat and is ready to carry it away.

USE OF THE REFRIGERATING MACHINE

So far the ammonia, or vehicle, has been "running down hill," requiring no power. At the bottom of the hill is the loading platform where the heat is taken aboard. After this it's an uphill pull, and a good strong horse is required to pull it up to the unloading platform. The horse may be called a "refrigerating machine."

The machine gets behind the heat-laden gases in the frosted low-pressure pipes and pushes them up to the top of the hill to the unloading platform, or ammonia condenser, where the loaded gas is changed back into a liquid. Just at the moment when the gas becomes a liquid it releases or dumps out the heat that it formerly picked up in the rooms, and the water in the condenser then absorbs the released heat units and carries them away.

Thus we see how necessary is the refrigerating machine to push the loaded vehicle, ammonia, along the uphill grade of high pressures direct to the top, or unloading place, at the condenser. But that is all it has to do, for the real work of freezing is performed by the ammonia, not by the machine. The initial as well as the final operation is done by the vehicle called ammonia, which must not be forgotten.

Thus you can readily see how anhydrous ammonia actually becomes a so-called vehicle for removing heat units from insulated rooms and carrying them, with the aid of the refrigerating machine, upstairs or downstairs, around corners and angles to condensers, there to unload its heat. Then it goes back to repeat the operation.

WRONG NAME FOR A VALVE CAUSED TROUBLE

A regulating valve controls the flow of liquid ammonia into the low-pressure pipes. That is all it is there to do. It cannot do any freezing, since only the ammonia does that. I mention this because, way back in the early days of this industry, somebody misnamed that valve—the expansion valve—without thinking of the consequences.

Ever since then many operators got the erroneous idea that this valve actually did the heavy work of freezing, and they would fondle it and handle it, fuss over it and play with it, sometimes resetting it twenty times a day, then listening to hear the gas gurgle or spit through it. The misnaming of this valve has cost the owners of plants hundreds of thousands of dollars in time lost fooling with it and in lack of efficiency caused by relying on this valve during critical moments of climbing temperatures, when the receiver should be watched instead. It is best to call it a regulating valve, to save confusion of ideas, much money and false impressions.

When I speak of heat-laden gases in suction pipes it may surprise you. Try to put your hand on a frost-covered suction line and imagine it contains real heat. It actually does, and lots of it, only it is called latent heat, or insensible heat. A thermometer cannot register it, nor can you feel it by touch. But it is there just the same. Apparently, the pipe is very cold, for it is usually covered with frost, yet the cold gas inside of that pipe will deliver heat enough to warm up enormous quantities of condensing water from 10 deg. to 30 deg. F. per pound.

We learn how the vehicle ammonia is relied upon to take the initiative in the work of removing heat. It is essential to work with not only dry, but pure ammonia. Note the difference between dryness and purity, for volatile hydrocarbons may exist in the liquid itself, which cause abnormally high pressures. Such foul gases refuse to liquefy and they fill up the condensers.

These bad gases must be blown away. Hydro-carbon gases are both colorless and odorless, which makes them hard to find. They are hidden, and like latent heat we know them by the effect they produce when they refuse to liquefy, causing excessive fuel bills or power bills and great ammonia consumption.

It has been estimated that in order to purge 15 lb. of uncondensable or hydrocarbon gas from the system you lose 85 lb. of pure gas, because the two are closely associated or intermingled, so that when the purge valve is opened the good as well as the bad gases are liberated unavoidably together.

GOOD AMMONIA REQUIRES NO PURGING

Good ammonia requires no purging, for good ammonia is free from volatile hydro-carbons. The evaporation test does not disclose the presence of volatile carbon compounds, for they evaporate together with the ammonia. The working test seems to be the most reliable. The test for air in shipping cylinders means little as to quality and has the disadvantage of being deceptive.

Ammonia is like fullers' earth, because both require a working test to prove their effectiveness. In both cases results count more than analysis. A chemical report on fullers' earth is about as valuable as a chemical report on anhydrous ammonia. However, in making an exhaustive examination of ammonia a thorough chemist will demand to see the raw material as well as the finished product. In testing cement, for instance, a thorough chemist will also examine the clinker or raw material as well, in order to obtain data for proper valuation. The clinker may be overburnt or underburnt, and the chemist is right in demanding a sample of the raw material.

The purchase of anhydrous ammonia should be like the hiring of a man. You expect a man to perform some service and keep on doing so. In purchasing ammonia you must expect it to serve you by picking up or absorbing all the heat units possible and unloading them in large quantities day by day, without getting tired or worn out on the slightest occasion. Remember, you do not buy ammonia like other merchandise, to be sold to others from the shelf. Instead of that, you invest your money in an article that must work for you day and night, and produce results in heat-carrying capacity. For, to produce one ton of refrigerating duty the vehicle, ammonia, must fetch and carry away 288,000 B.t.u. of heat from insulated rooms in the shortest time possible, and that is why the question of ammonia as a heat vehicle is so serious as to affect the profits in a refrigerating plant.

New Electric Rate at Ottawa

Electricity for cooking at a price equal to 50c. gas is what Controller Ellis, of the Ottawa Municipal Electric Department, has attained for the city. The present price of gas is $1.25 per thousand cubic feet, less 12 per cent. discount, plus a $2 a year meter rental, or about a net rate of $1.20 per thousand cubic feet.

The annual report of the municipal electric department for 1914 pointed out the reduction in rates since the hydro-electric installation was first made. At that time the rate was 8c. per kw.-hr., less 10 per cent. discount, with no floor-area charge; whereas now the rate is 2c. net per kw.-hr., and 3½c. per 100 sq.ft., less 20 per cent. discount, for floor space, and 1c. net for excess current used other than for lighting.

American Association of Refrigeration

The annual meeting of the American Association of Refrigeration was held in the Hotel Astor, New York City, May 11 and 12. Inasmuch as the association interests itself more in the commercial application of refrigeration than in its technical and engineering side, operating engineers have little to gain from a knowledge of its activities other than to get a broad perspective of the state and advance of the application of refrigeration. To be sure, this is important and it is from this angle that the operating engineer should watch what the association is doing.

The meeting consisted chiefly of three business sessions and a banquet. As President Frank A. Horne, of New York City, was not present at the first session, Past-President Homer McDaniel, of Cleveland, opened the meeting.

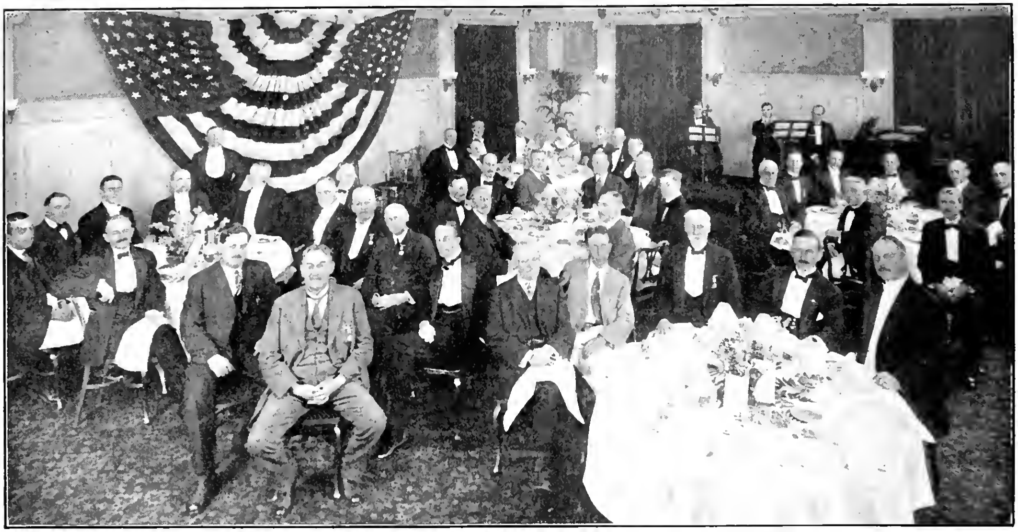
In his address Mr. Horne approved the recommendation of the commission on legislation and administration that the association authorize the engagement of a reporting agency to keep the association in the closest possible touch with proposed legislation—local, state and national—affecting the refrigerating industry. Mr. Horne also recommended the engagement of a paid manager, who, working under the secretary, would devote his whole time to the affairs of the organization. That the president feels the need of more vigorous, extensive and complete committee work was evident from the manner in which he explained the need and value of committee reports.

Dr. H. Dannenbaum, chairman of the committee on trade extensions, in his report stated that the reports of the Department of Commerce show that the value of ice and refrigerating machinery exported from the United States in the fiscal year ending June 30, 1914, was $978,457. Of this, Europe's purchases amounted to $34,883; North America's $271,843; Asia's, $100,010; South America's, $428,266; Oceania's, $138,091; and Africa's, $5364.

The Commission on Legislation and Administration requested Dr. Pennington and Dr. Barnard and Mr. Coe to draft a Federal storage law to be similar to the uniform cold-storage law already drafted.

The banquet, held in the College Room of the Hotel Astor, was enjoyable, and among the speakers were Borough-President Marcus M. Marks; Dr. Mary Pennington, chief of the food research laboratory of the Bureau of Chemistry and chairman of the association's committee on state and national investigations; G. Harold Powell, general manager of the California Fruit Growers' Exchange; and Homer McDaniel, a past-president of the American Warehouseman's Association.

All the officers, with the exception of J. H. Bracken, chairman of the testing committee, were last year's officers reelected: President, Frank A. Horne; vice-president, E. O. McCormick, Thomas Shipley, Homer McDaniel, Col. Jacob Ruppert, Jr., James Craig, Jr., Roderick H. Tait, R. H. Switzler; secretary, J. F. Nickerson; treasurer, John S. Field; chairman of Executive Committee, William J. Rushton; chairman of Advisory Committee, H. W. Bahrenburg; chairman of Committee on Papers and Lectures, Dr. F. W. Frerichs; chairman of Finance Committee, Theo. O. Vilter; chairman of Committee on Trade Extensions, Dr. H. Dannenbaum; chairman of Committee on State and National Investigations, Dr. Mary E. Pennington; chairman of Board of Engineers on Educational Work, Gardner T. Voorhees; chairman of Commission on Gases and Units, Prof. Edward T. Miller; chairman of Commission on Testing Refrigerating Machinery and Insulating Materials, J. H. Bracken; chairman of Commission on Application of Refrigeration to Foods, G. Harold Powell; chairman of Commission on Industrial Refrigeration, Peter Neff; chairman of Commission on Railway and Steamship Refrigeration, Carl Howe; chairman of Commission on Legislation and Administration, E. O. Whitford; chairman of Publication Committee, N. H. Hiller; chairman of Committee on Membership, Bruce Dodson; chairman of Press Committee, E. D. Ansley.



BANQUET OF THE AMERICAN ASSOCIATION OF REFRIGERATION, HOTEL ASTOR

To Calculate Steam Required to Operate Pump

For a direct-acting pump in fair condition, operated at a piston speed of 100 ft. per min., assume an average steam consumption per indicated horsepower-hour of, say 150 lb. dry saturated steam, which is a so-called "water-rate" of 150 ÷ 60 = 2.5 lb. i.hp.-min.; and multiply this water rate by the indicated horsepower of the pump, as shown by the following:

Find the steam required to pump 9000 gal. of water per hour, from a shaft 450 ft. deep, using a simple direct, double-acting pump running at a speed of 100 ft. per min. and discharging through a 3-in. column pipe.

The effective head, in this case, is

$$h_1 = 450 + \left(\frac{9000}{60}\right)^2 \frac{450}{800 \times 3^5} = \text{say } 502 \text{ ft.}$$

The indicated horsepower of this pump will then be

$$H = 0.00034 \times 150 \times 502 = 25.6 \text{ hp.}$$

The weight of steam required to operate this pump, under the assumed conditions, will be

Steam consumption,

$$2.5 \times 25.6 = 64 \text{ lb. per min.}$$

—"Coal Age"

Recent Court Decisions

Digested by A. L. H. STREET

Rights of Water Consumers—A water company which shut off water from a customer's hydraulic elevator on the latter's refusal to pay an excessive bill, is liable for resulting damages sustained by the customer, regardless of whether the error in the bill was innocent or deliberate, according to the decision reached by the Court of Appeals of Kentucky in the late case of Louisville Tobacco Warehouse Co. vs. Louisville Water Co., 172 "Southwestern Reporter," 928. The court, however, upholds the right of a water company to make any reasonable regulations for the conduct of the company's business, including the cutting off of service for nonpayment of just charges which have accrued. But all regulations must apply to all persons similarly situated.

Duty to Install Lightning Arresters—An owner of an electrically propelled passenger elevator is liable for injury resulting to the operator from shock caused by lightning, if the accident be attributable to the owner's failure to install lightning arresters, according to the holding of the Springfield, Mo., Court of Appeals, in the case of Melcher vs. Freehold Investment Co., 174 "Southwestern Reporter," 455. Speaking of the measure of care to avoid injury resulting from use of electricity as power, the court declares that ordinary care requires the exercise of the highest diligence to take precautions against accidents, by installing such safety appliances as are reasonably available. And the decision adds that, since lightning arresters are well-known devices, an owner of an elevator who fails to install one cannot avoid liability for accidents of the kind mentioned by showing that other persons owning similar buildings have not installed them.

Suit for Flowage of State Lands—Suit was brought by the State of Minnesota against the Minnesota & Ontario Power Co., for $200,000 damages claimed to have resulted from flowage of 30,000 acres of state lands along the international border in the maintenance of the company's power dam across the Rainy River. The company, in addition to operating large pulp and paper mills in northern Minnesota, supplies electric light and power to various industries and municipalities. The state threatened another similar suit against the same company on account of prospective flooding of 50,000 more acres of public land near Kettle Falls on the same river, where the company is constructing another power dam. The suit brought, by omitting to claim any right to enjoin operation of the dam, recognizes the validity of the right granted to the company by the United States and Canada to maintain the dam.

Liability for Explosion of Boiler—An employer may be held responsible for injury to an employee, caused by explosion of a defective boiler after the making of repairs thereon, on the theory of negligence in failing to apply the hydrostatic test to the boiler, if that would have disclosed the defect. This is the holding of the Court of Civil Appeals of Texas, lately announced in the case of Ligarde vs. National Railway of Mexico, 172 "Southwestern Reporter" 1140, in which the plaintiff was awarded a verdict for $20,000, which the Court of Civil Appeals declares was not excessive, for injuries sustained by plaintiff in an explosion of a locomotive boiler in repair shops. The following statement of the court, bearing on the duty of inspection, would seem to apply to all classes of steam boilers:

> The engine was old, was in the shop for repairs, and it was the duty of appellant to apply all tests necessary to ascertain how much steam the boiler would sustain. The only perfect test was the hydrostatic, and the jury was warranted in finding that the railroad company was negligent in not applying that test.

Contributory Negligence of Engineer—A stationary engineer, who, being thoroughly familiar with the working conditions of machinery, fails to take proper steps to stop the machinery before placing his hands in a dangerous position, in making repairs, cannot recover against his employer for consequent injury, even though there may have been insufficient light in his place of work. This is the gist of the decision of the Supreme Court of Wisconsin, announced in the case of Hansen vs. Campbell Laundry Co., 151 "Northwestern Reporter," 262. The plaintiff was the engineer in the defendant's plant and found it necessary to tighten some nuts in the mechanism of a pair of automatic underfeed stokers. Instead of shutting off the steam by using one of the three valves, which he knew would absolutely close off the steam, he turned a dial point to zero, and supposing that would stop the machinery, reached his hand into a steel case containing movable mechanism. There was sufficient escape of steam past a regulating valve to cause the machinery to move, and his hand was injured in consequence. He brought suit to recover for his injuries, but the Supreme Court holds that the trial judge properly denied recovery on the ground of contributory negligence. The Supreme Court attributes carelessness to the plaintiff in failing to use the valves, as affording the only safe means of stopping the machinery, and finds that any insufficiency in lighting of the premises did not contribute to the accident by preventing the plaintiff from using the valves, or by ascertaining whether the dial point was at zero.

PERSONALS

C. E. Lesher, associate geologist of the land-classification board of the United States Geological Survey, has taken charge of the work of compiling the statistics of coal production published in the annual volume "Mineral Resources." This work has heretofore been directly under Edward W. Parker, whose resignation from the Geological Survey is effective July 1.

ENGINEERING AFFAIRS

A. O. S. E. Convention—The American Order of Steam Engineers will hold its twenty-ninth annual convention at Atlantic City, N. J., during the week commencing June 21. The local convention committee, assisted by the officers of the American Supplymen's Association, are hard at work completing the final arrangements. The Continental Hotel on Tennessee Avenue has been selected as the headquarters, and the elaborate mechanical exhibit will be located at the Morris Guards Hall, on New York Avenue.

A. S. M. E. Spring Meeting—The spring meeting of the American Society of Mechanical Engineers is to be held at Buffalo, N. Y., June 22 to 25. The society has met at Niagara Falls before, but this will be the first time at Buffalo. David Bell is chairman of the local committee of arrangements; James W. Gibney, vice-chairman; C. A. Booth, secretary, and C. H. Bierbaum, treasurer. The Engineering Society of Buffalo is to join with the local A. S. M. E. members and engineers generally in acting as hosts. The headquarters will be at the Hotel Statler, where all sessions will be held except the first one, which will be at Niagara Falls in the large auditorium of the Shredded Wheat Biscuit Co. The papers to be presented include "Laps and Lapping," by W. A. Knight and A. A. Case; "Model Experiments and the Forms of Empirical Equations," by E. Buckingham; "Rational Design and Analysis of Heat Transfer Apparatus," by E. E. Wilson; "Influence of Disk Friction on Turbine-Pump Design," by F. zur Nedden; "A Study of an Axle Shaft for a Motor Truck," by John Younger; "Corrugated Furnaces for Vertical Fire-Tube Boilers," by F. W. Dean; "The Effect of Relative Humidity on an Oak-Tanned Leather Belt," by William W. Bird and Francis W. Roys; "The Relation between Production and Costs," by H. L. Gantt; "Design of Rectangular Concrete Beams," by Howard Harding; "Some Mechanical Features of the Hydration of Portland Cement and the Making of Concrete as Revealed by Microscopic Study," by Nathan C. Johnson; and "Surface Condensers," by Carl F. Braun.

Chicago A. S. M. E. Discusses the Electric Locomotive—Friday evening, May 14, was the last meeting of the season for the Chicago Section of the American Society of Mechanical Engineers. As usual, the meeting was an informal dinner session in the Red Room of the Hotel La Salle. At a preliminary business meeting the following officers were selected for the following year: H. M. Montgomery, chairman; Joseph Harrington, vice-chairman; Robert E. Thayer, secretary; other members of the committee, Charles E. Wilson and H. T. Bentley. The subject for the evening was the "Electric Locomotive." It was a timely topic for Chicago and a goodly number of the engineers took advantage of the opportunity to learn what has been done and what is being done in this field. A. F. Batchelder, chief engineer of the locomotive department, and A. H. Armstrong, assistant engineer of the railway and traction department, both of the General Electric Co., gave talks of exceptional interest on the subject. The former confined himself to the design and by means of numerous lantern slides traced the development from the first locomotive installed by the Baltimore & Ohio R.R. Co. in 1895 to the recent combination passenger and freight locomotives for the mountain divisions of the Chicago, Milwaukee & St. Paul Ry. The designs of truck, control arrangement, type of motor and other interesting features were illustrated in the numerous slides presented. Mr. Armstrong centered his talk on where the locomotive is used, the excuse for its existence and a comparison with the steam locomotive. He dwelt particularly on the Butte, Anaconda & Pacific 2400-volt direct-current locomotives, those of the New York Central and the immense machines recently built for the Chicago, Milwaukee & St. Paul Ry. Data on tractive effort, weight on drivers, efficiencies and limitations were given, and upon request were followed by an interesting summary on the development of current collectors. Both talks were highly appreciated by the audience, and no doubt valuable information was absorbed, which may help in the solution of one of Chicago's knotty problems—the electrification of its steam railways.

The National Association of Manufacturers will hold its 20th annual convention at the Waldorf-Astoria Hotel, New York City, May 25 and 26. Among those scheduled to address the convention are ex-President Taft, whose subject will be the "Clayton Act and Other Things;" Senator Warren G. Harding, of Ohio; Dr. Eugene L. Fisk, M. W. Alexander and Arthur D. Little. James A. Emery will outline the work of the newly created Federal Trade Commission. Walter Drew, of the National Erectors' Association, will discuss the work of the Federal Commission on Industrial Relations. Committees will report on fire and accident prevention, union label, immigration, uniform state laws, trademarks and copyrights, and industrial betterment. Incidental to the convention will be a unique exhibition devoted to various phases of industrial education with students actually at work in various lines of industries. In this will be included exhibits from New York City; Newark, N. J.; Fitchburg, Mass.; New Haven, Conn.; Altoona, Penn.; Detroit, Mich., and other places where well-known trade schools are established.

BOOKS RECEIVED

VALVES AND VALVE GEARS. Volume I. By F. D. Furman. John Wiley & Sons, Inc., New York. Cloth; 253 pages, 6x9¼ in.; 300 illustrations. Price, $2.50.

POWER HEATING AND VENTILATION. Part III. By Charles L. Hubbard. McGraw-Hill Book Co., New York. Cloth; 408 pages, 6x9¼ in.; 220 illustrations; tables. Price $3.

THE "PRACTICAL ENGINEER" POCKETBOOK AND DIARY FOR 1915. Distributed by the Magnolia Metal Co., New York. Cloth; 632 pages; 3½x5 in.; numerous illustrations and tables.

TRADE CATALOGS

Kerr Turbine Co., Wellsville, N. Y.—Bulletin No. 52. Economy turbo-pumps. Illustrated, 24 pp., 6x9 in.

Cresson-Morris Co., Philadelphia, Penn. Form No. 1001. Barometric condensers. Illustrated, 28 pp., 9x12 in.

The Richardson-Phenix Co., Milwaukee, Wis. Bulletin No. 40, Phenix oil and graphite cylinder lubricator. Illustrated, 4 pp., 8½x11 in.

The Draper Mfg. Co., Port Huron, Mich. Catalog No. 7. Valve facing tools, ball check valves, brass, iron and steel balls, pneumatic flue welders, pneumatic tube welders, etc. Illustrated, 40 pp., 6x9 in.

BUSINESS ITEMS

Negotiations were recently closed for the sale of the Cleveland Clutch Co. to the Reliance Gauge & Column Co., 5902-5912 Carnegie Ave., Cleveland, Ohio.

The contract for furnishing material under circular No. 891 for complete pumping plant for Dry Dock No. 1, Balboa Terminals, Balboa, C. Z., was awarded by the Panama Commission to Henry R. Worthington, 115 Broadway, New York.

August Mietz, 128 Mott St., New York, has recently secured orders for Mietz & Weiss oil engines from the Grinden Art Metal Co., of Brooklyn, N. Y. (2); the Town of Schleswig, Iowa (2); I. H. Pitts & Son, Waverly Hall, Ga.; Marcus Mason & Co., South Framingham, Mass.; George Buckley, Menlo, Iowa; U. S. Government, for lightships Nos. 101 and 102 (two 200-hp. direct reversible marine-type oil engines and four 50-hp. oil-engine air-compressor outfits).

NEW EQUIPMENT

ATLANTIC COAST STATES

The Cambridge Electric Light Co., Cambridge, Mass., has made application to the Board of Gas and Electric Light Commissioners for authority to issue $100,000 in additional capital stock, a part of which will be used for making additions to the system. W. E. Holmes, Newton, is Treas. and Gen. Mgr.

The Hudson Ice Co, 136 Oakland St., Jersey City, N. J., is preparing to build a 100-ton ice plant at Central and Jefferson Ave., Jersey City. S. H. McKnight is Pres.

It is reported that the Council has engaged W. S. Temple, Philadelphia, Penn., to prepare plans for the construction of a municipal electric-lighting system for Millville, N. J.

It is reported that the Town Council of Patton, Penn., is considering the establishment of a municipal electric-light plant. Service is now furnished by the Penn Central Light & Power Co., Altoona.

SOUTHERN STATES

It is reported that the Planters Oil Mill & Gin Co., Kosciusko, Miss., is in the market for additional power equipment and boilers.

The City of Oberlin, La., has appointed a special committee to engage an engineer to prepare plans for the construction of a municipal electric-light plant. W. D. Stockwell, Mayor, is Chn. of the Com.

CENTRAL STATES

The municipal electric-light plant at Ashley, Ind., was destroyed by fire recently at a loss of $4000. George W. Caryl is Mgr.

At a recent election in Chalmers, Ind., the citizens voted in favor of installing an electric-lighting system. It is reported that the plant will be constructed by a stock company, and will eventually be purchased by the town. T. C. Smith, Chalmers, is Engr.

The City Council, Lanark, Ill., is considering the establishment of a municipal electric-light plant.

It is reported that the Board of Public Works, Oshkosh, Wis., has been instructed to advertise for bids for a dynamo and connections for an independent lighting system for the new high school in Oshkosh.

WEST OF THE MISSISSIPPI

It is reported that the Iowa River Light & Power Co., Eldora, Iowa, contemplates spending about $50,000 for improvements to its system. A new power station will be built, and the output of the steam plant increased. J. C. Lundy is Mgr. and Cont. Agt.

The city of Shellsburg, Iowa is considering the question of establishing a municipal electric-lighting system. The estimated cost is $10,000. It is reported that the Cass Interurban Co. has also made an offer to build a transmission line from Urbana to furnish electrical service to Shellsburg.

The town of Marietta, Minn. is considering the question of establishing a municipal electric-lighting system.

The citizens of Kirwin, Kan., have voted in favor of a bond issue of $12,000 to be used for the installation of a municipal electric-light plant.

The town of Corder, Mo. has appropriated $6000 for the purpose of buying light and power equipment.

The city of Poplar Bluff, Mo., has voted $75,000 in bonds for the purpose of establishing a municipal electric-light plant. Contracts for the installation of the plant have been awarded.

L. B. Myers, El Reno, Okla., and associates, will establish, according to press reports, an electric-light and power plant and ice factory at North Pleasanton, Tex. The estimated cost is $40,000.

It is reported that the city of Seguin, Tex., will make improvements and extensions to the municipal light and power plant to include the construction of a new building and penstocks, the installation of a 187-kw., three-phase, 60-cycle, 2300-volt, waterwheel type generator, exciter and switchboards, two 150-hp. vertical waterwheels and transmission machinery. Owen A. Gofford is Mgr., Cont. Agt. and Supt. of the plant.

It is reported that Morris Sass, Ardmore, Okla., is in the market for power equipment, including a gasoline engine.

It is reported that the City Council of Reno, Nev., is considering a bond issue of $750,000 to be used for the construction of a municipal electric-light plant and water-works system. J. R. Parry is City Clk.

Bids will be received until May 28 by R. W. Davis, Mayor, Harrisburg, Ore., for one 35-hp. motor of 900 to 1300 r.p.m., one 25-hp. motor, 900 to 1200 r.p.m., and one 5-hp. motor of about 1500 r.p.m.

The City Trustees of Escondido, Calif., have decided to call a special election to vote on the question of a bond issue to be used for purchasing the property of the Escondido Utilities Co.

CANADA

It is reported that the city of Sherbrooke, Que., will purchase electric meters, controllers, etc., to the amount of about $27,000. W. E. C. Gatien is City Clk. No bids will be asked.

The Canadian Niagara Power Co., Niagara Falls, Ont., contemplates making extensive improvements in its plant. Philip P. Barton, Niagara Falls, is Gen. Mgr.

The City Council of Kelowna, B. C., is considering the establishment of a municipal electric-light plant, estimated to cost $120,000. It is reported that a bylaw will shortly be submitted to the rate-payers.

Vol. 41 — NEW YORK, JUNE 1, 1915 — No. 22

The Salesmen's Reply

BY WILLIAM A. DUNKLEY

An answer to "The Troubles of the Manager," in the March 30 issue.

We get our hot times here on Earth, then climb the "golden stair."

THE MANAGER'S a grouchy cuss, although he has it soft
And lounges in an easy chair and wears out good broadcloth
He has his car, he has his golf; these joys cannot allay
The grouch that grips his vitals when we boys come his way.
Outside his door an office boy confronts us with a frown
And says, "Come back some other time, the 'Old Man's out of town'
And if at last we pass the door and beard him in his lair,
He acts as though "Old Nick" himself would be more welcome there.

He sits and smokes our good cheroots (We buy them three for five),
And he is game to buy our goods in case he can survive.
We show him how to save his dough and how to spend it too.
He may have tried some other line, but ours is "something new."
We're agents of prosperity and keep him up to date,
And any plant without our goods would meet a sorry fate.

But when he gets to Satan's realm, he'll find no salesmen there.

Some time ago we met a chap who ran a power plant,
And every day he'd tear his hair, and cuss, and rave, and rant.
Directors had him going right, the dividends were slim,
And costs were soaring out of sight; looked like "good night" for him.
His durned old plant was out of date, and leaks were everywhere,
And here a groan and there a knock, were crying for repair.
He wasn't wise to boiler scale, much less to CO_2
And half his good bituminous was wasting up the flue.

We talked to him until our throats were parched as desert sand;
But "soda water" fixed us up (guess you will understand).
And finally, he was convinced and purchased half our line;
And now, that same old power plant is running something fine.

We are the manager's best friends, we help him to progress,
And steer him up the narrow path to honor and success.
And when at last he shuffles off, beyond the milky way.
We have a line of golden harps to make his future gay.
And if instead, he goes below in spite his good intent,
We'll lag him well with fireproof paint, asbestos and cement.
But when he gets to Satan's realm, he'll find no salesmen there;
We get our hot times here on Earth, then climb the "golden stair."

Power Plant of the Hughes Electric Co.

By C. P. Larsen

SYNOPSIS—This power plant supplies electrical energy for motor and lighting service and for operating the pumping plant. Exhaust steam is used for district steam heating. Lignite containing 6590 B.t.u. per lb. is used as a fuel. Burning 42 lb. of coal per square foot of grate area. 3 lb. of water is evaporated per square foot of boiler heating surface.

The power house of the Hughes Electric Co. supplies the town of Bismarck, N. D., with light, heat and power and also pumps the water for the Bismarck Water Supply Co. The boiler room, Fig. 1, contains four water-tube boilers, each rated at 306 hp., having 3060 sq.ft. of heating surface, and two return-tubular boilers, each rated at 150 hp. The boilers are hand-fired, as no stokers are known for burning lignite that will give as good results as are obtained with hand firing. Each furnace of the large boilers is equipped with 48 sq.ft. of grate surface, or one to each 63.75 sq.ft. of heating surface. The grates used are of the flat sawdust type, perforated with half-inch holes, which give about 20 per cent. air space. This does not conform with modern practice for burning low-grade fuel, as with an increased grate surface a boiler can be forced to a greater extent, but it is a question if the combustion will be so complete with a lignite fuel that is low in carbon and contains so much volatile matter that must be taken care of to obtain efficiency. With this ratio of grate to heating surface, 3 lb. of water is evaporated per square foot of heating surface and 42 lb. of coal is burned per square foot of grate surface.

Fig. 1. Boiler Room of the Hughes Electric Co.'s Power Plant

Lignite burns much like dead wood or brown paper, with a natural slow draft, and it can burn like a blacksmith's fire and give off very little heat. It will slack and turn into dust, and when fired under a boiler in this condition the design of grate is of importance, as with a 40 per cent. air space there is little chance for the fuel to rest while it burns, for it is in continual motion, rolling around and mixing with ashes, which results in a flameless fire. If the air pressure under the grates is increased, holes will be blown in the fuel bed through which air will pass freely and cool the furnace.

It is necessary to level off the bed of fire or fill the holes with a fresh supply of coal, but if the fire is in bad shape there is no remedy, and the only thing to do is to pull it and start a new one. With less air space the fuel has a chance to rest on the bridges between the holes and each hole will form a little burning jet, as a higher air pressure can be maintained under the grate. The greater the velocity of the air through the holes, the greater the increase in the temperature; about 1900 deg. is obtained and a flue-gas temperature of about 450 deg. F., with an average of 12 per cent. CO_2.

There is a peculiarity in burning lignite coal as it can be easily wasted owing to the amount of air required for combustion. The long flame, with its low temperature, carries the unignited gases through the boilers and up the smoke-stack and produces a deceiving temperature of flue gases. It is possible to burn 60 lb. of coal per square foot of grate surface and evaporate but 3 lb. of water per square foot of heating surface and have a flue-gas temperature of but 350 deg. F. Then again, it is possible to change the air supply, break the coal to suitable sizes, burn 35 lb. of coal per square foot of grate surface, evaporate the same amount of water per square foot of heating surface and have a flue-gas temperature of 450 deg. F., a decrease in fuel consumption of 41 per cent.

An average evaporation of 4.5 lb. for a month's run is obtained in many tests, and during short tests as high as 4.85 lb. of water per pound of coal has been evaporated; the temperature of the feed water being 190 deg. F., steam pressure 140 lb. and the coal containing 6590 B.t.u. This is equal to an evaporation of 8.8 lb. of water from and at 212 deg. F. per pound of combustible and shows an efficiency of about 77 per cent. These results are obtained by using forced draft with a slow velocity, so that the heat in passing through the boiler is absorbed by the water. It is not advisable to force a boiler above its normal rating. It is easy to force the fires and send a flame out at the top of a 50-ft. stack, but at the same time the boiler is not generating steam in proportion to the fuel burnt.

It is not an easy matter to lay down a general rule for burning lignite. The coal burned at this plant is a low-grade fuel containing about 6500 B.t.u., between 35 and 40 per cent. moisture and from 5 to 10 per cent. ash. It is not suitable for long shipments or storage in warm weather, as it slacks, or pulverizes, like burnt lime when it loses its moisture.

It is delivered to the power house in railway cars and unloaded into a bucket conveyor about 150 ft. long, extending 60 ft. outside of the building alongside the railroad track. Two cars can be unloaded at the same time. In the overhead run the conveyor is provided with chutes for each boiler. Its capacity is 25 tons per hour and it is driven by a 10-hp. motor. The cars on the side track are moved by a car puller driven by a 5-hp. motor.

The cost of handling the coal from the cars into the boiler room is 9c. per ton. The plant is 25 miles from the mine and the coal, which runs in size from 6-in and down to dust, costs $1.75 per ton delivered at the plant. Once in a while a car of slack is received, at $1.15 per ton, which helps to bring the average price of the fuel down.

The boiler room is 60x80 ft. and 30 ft. high. There are three steam-driven boiler-feed pumps, two vacuum pumps, one air compressor, one boiler-washing pump and one open feed-water heater. The last is merely a tank, and as the condensation from the heating system has at times a temperature of 165 deg. F., it is found to be more economical to turn the exhaust from the vacuum and boiler-feed pump into the heating system when live steam is required. Otherwise, it heats the feed water up to about 200 deg. F.

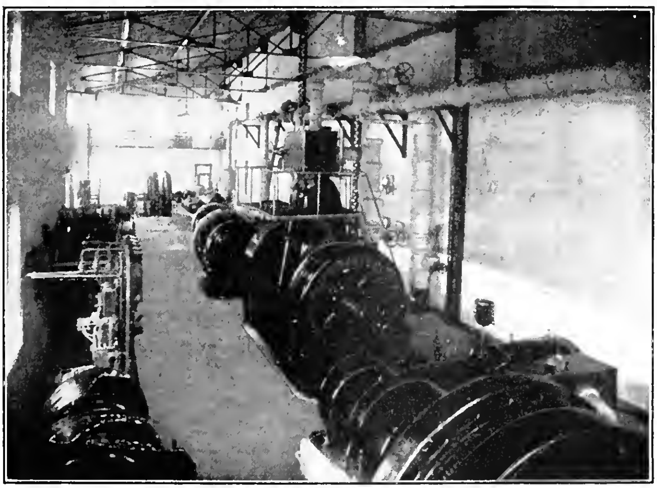

Fig. 2. General View of the Engine Room

A 30-in. fan for forced draft is driven by a 15-hp. motor. The air for this fan is taken from above the boilers and as it passes through the combustion chamber to the ashpit, it is warmed to some extent. The main boiler-feed pump has an 8-in. suction pipe and a 6-in. discharge, with 2.5-in. feed line to each boiler. The regulating valves are conveniently located; the steam pipe from the boilers to the 12-in. header is 6-in., equipped with automatic stop valves. All pipes, fittings and valves are extra heavy.

The engine room, Fig. 2, is 30x115 ft. and 25 ft. high; it is neatly finished, and contains only the generating units, exciter and switchboard. It has a terrazza floor with marble borders, and the side walls are wainscoted 5 ft. high with white enamel brick; the engine beds above the floor line are painted silver gray; across one end of the room is a balcony, where the chief engineer has his desk. A winding iron stairway leads to this balcony.

The engine room contains five units. The smallest is a 12x12-in. engine running 270 r.p.m., with a steam consumption of 28 lb. per i.hp.-hr., and is directly connected to a 75-kw., 230-volt, direct-current generator. Unit No. 2 is a 16x16-in. engine running 270 r.p.m., with a steam consumption of 28 lb. per i.hp.-hr., and is directly connected to a 100-kw., 230-volt, direct-current generator. Unit No. 3 is a 20x18-in. vertical engine running 200 r.p.m., with a steam consumption of 35 lb. per i.hp.-hr. and is directly connected to a 200-kw., alternating-current, 60-cycle, 2300-volt generator. Unit No. 4 is a 11¼&25x18-in. cross-compound engine running 200 r.p.m., and uses 22 lb. of steam per i.hp.-hr.; it is directly connected to a 250-kw., 60-cycle, 2300-volt alternating-current generator. This unit has its exciter on the main shaft. Unit No. 5, Fig. 3, recently installed, is a 23x30-in. engine running at 150 r.p.m., and uses 23 lb. of steam per i.hp.-hr.; it is directly connected to a 500-kw., 60-cycle, 2300-volt, alternating-current generator. This generator is excited by a 35-kw., 125-volt, direct-current generator driven by a 50-hp. induction motor. Switches are arranged so that either unit can be excited from the 35-kw. exciter. A motor-driven exciter is used for No. 3 unit, as the company furnishes either direct or alternating current to its customers. There is also a 100-kw. motor-generator set, and as this is usually generating direct current the power factor in the alternators is increased by having this synchronous motor in the circuit. The switchboard has fourteen marble panels and is equipped with voltage regulator for the alternating-current circuit, circuit-breakers, switches for the generators and transmission lines, voltmeters, ammeters and wattmeters, and synchronizing indicator. In the engine room is a 30-kw. constant-current transformer for city arc lights.

The plant has equipment sufficient to supply an ordinary city of 20,000 inhabitants with electricity. Bismarck has a population of 7000 and about thirteen years ago the company started an electric plant with a 50-kw. unit. The rapid growth of the city, however, has constantly made demand for more units. The rate charged for cooking service is 3.5c. per kw.-hr., for lighting service it is 10c. to 12.5c., and for power service the rate is according to the amount used, from 1.5c. up.

The company is operating the city pumping station located on the banks of the Missouri River. The water flows by gravity into a receiving well 12 ft. in diameter. From there the water is pumped to three reservoirs on a hill 200 ft. above the river. Each reservoir holds about one million gallons. A 13x16-in. triple-plunger pump, belt-driven by a 100-hp. induction motor was recently installed. The speed of the motor is 150 r.p.m. with a 26-in. diameter pulley; it is belted to a countershaft with a 70-in. diameter pulley, 22-in. face. A 20-in. double-ply leather belt is used, and the crankshaft is speeded down to 34 r.p.m. by cut gears. The plungers have a displacement of 935 gal. per min. and the water pumped is 926.5 gal. per min. This allows 8.5 gal. for slippage, or 0.9 per cent.; 46 kw. are recorded by the wattmeter at this load, and as the theoretical kilowatt consumption for lifting 926.5 gal. to an elevation of 200 ft. is 34.8, this gives a 6-in. connection to the feed-water heater, and a 12-in. main to the heating system. The condensation is returned to the heater by vacuum pumps. Central heating has proved so satisfactory that the demand for steam has increased more rapidly than the electrical output, and to such an extent that in cold weather about 60 per cent. of the total steam generated in the boilers passes through a reducing valve to the heating system. The rate for steam is 40c. per 1000 lb. All customers are charged on a meter basis.

Condensation from the mains and branches is trapped off where the pipe enters the customer's building. These bleeders trap off about 20 per cent. of the steam output from the boiler. In the 16-in. header is a 16-in. oil and steam separator, from which the condensation trapped off amounts to 12 per cent. The condensation from the

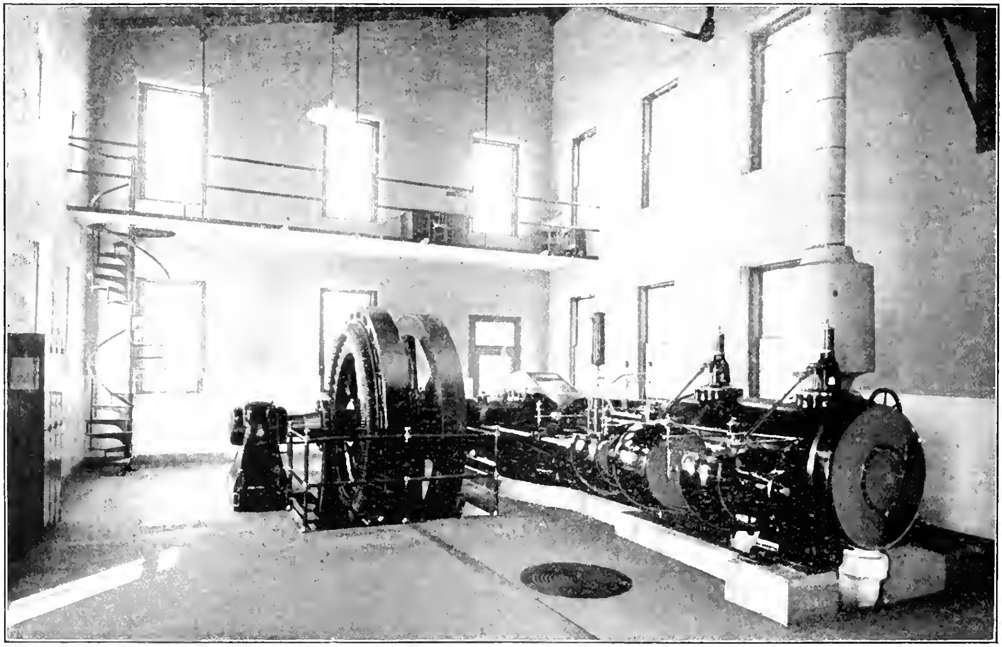

Fig. 3. The Latest Engine Installed Driving a 500-Kw. Alternating Generator

a combined efficiency of 75.7 per cent. for the motor and pump.

There is pumped 1208 gal. per kw.-hr. to an elevation of 200 ft., 13 ft. of this being suction lift. As the Nos. 4 and 5 units give the best steam efficiency, these are operated the most. With either, 8 lb. of lignite coal is burned per kilowatt generated and put into circuit; this includes steam for operating the boiler-feed pump and the vacuum pump for the heating system; also current for operating the forced-draft system, for the motor and for the station lighting. In summing up the combined efficiency of these units and the pump, it shows that one pound of this low-grade lignite coal is elevating 151 gal., or 1258 lb., of water 200 ft.

A central heating system is also operated. The exhaust pipes from the engines are connected to a 16-in. exhaust header, which has a 12-in. outlet to the atmosphere, high-pressure pipe line and receiver, steam separators and exhaust from the boiler-feed pumps, enters the open feed-water heater and amounts to about 4 per cent. The total of those items amounts to 36 per cent. of steam generated but not passing through meters. Those losses are not constant, as the percentage lost is less in cold weather with a greater steam consumption, though owing to these condensations the company receives only 27c. per 1000 lb. of steam generated; still, the output of steam for the month of December, 1914, made a favorable showing, as 9,844,000 lb. was recorded by the meters in the heating system and 3,444,400 lb. of coal was burnt during the month, at a cost of $2686.32, or $1.56 per ton. As during the winter months there are many sunshiny days with a comfortable temperature, considerable exhaust steam escapes to atmosphere during peak loads. This is a natural loss and cannot be controlled.

PRINCIPAL EQUIPMENT OF THE HUGHES ELECTRIC COMPANY'S POWER PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
4	Boilers	Franklin water-tube	306-hp.	Steam generators	Hand-fired, steam pressure, 140 lb.	Franklin Boiler Works Co.
2	Boilers	Return-tubular	150-hp.	Steam generators	Hand-fired, steam pressure, 130 lb.	Western Supply Co.
1	Blower	Sturtevant	30-in.	Forced draft	Motor-driven	B. F. Sturtevant Co.
1	Motor	Direct-current	15-hp.	Driving blower		General Electric Co.
1	Coal conveyor	Bucket	25 tons per hour.	Car and elevt coal.	Motor-driven	Link-Belt Co.
1	Motor	Direct-current	9-hp. inclosed	Driving coal conveyor	Intermittent	General Electric Co.
1	Pump	Outside-packed	14x9x16-in.	Boiler feed	140 lb. steam	Union Steam Pump Co.
1	Pump	Duplex	8x6x12-in.	Boiler feed	140 lb. steam	Dean Bros. Steam Pump Works
1	Pump	Duplex	7x5x10-in.	Boiler feed	140 lb. steam	Dean Bros. Steam Pump Works
1	Pump	Duplex	5x3½x8-in.	Boiler washing	140 lb. steam, as wanted	Geo. F. Blake Manufacturing Co.
2	Pumps	Duplex	7x9x10-in.	Returns from heating system	Winter months	Dean Bros. Steam Pump Works
1	Air compressor	Locomotive type	9x9x10-in.	Cleaning generators	Steam-driven	Westinghouse Air Brake Co.
1	Car mover	Geared down to drum	Two loaded cars.	Moving coal cars	Motor-driven	Link-Belt Co.
1	Motor	Direct-current	5-hp. inclosed	Driving car mover	230 volts	General Electric Co.
1	Engine	Simple horizontal	12x12-in., 125-hp.	Generator drive	140 lb. steam, 270 r.p.m.	American Engine & Electric Co.
1	Generator	Direct-current	75-kw.	Light and power	270 r.p.m., 230 volts	General Electric Co.
1	Engine	Simple horizontal	16x16-in., 160 hp.	Generator drive	140 lb. steam, 270 r.p.m.	American Engine & Electric Co.
1	Generator	Direct-current	100-kw.	Light and power	230 volts, 270 r.p.m.	General Electric Co.
1	Engine	Simple vertical	20x18-in., 300 hp.	Generator drive	140 lb. steam, 200 r.p.m.	Bates Machine Co.
1	Generator	Alternating-current	200-kw.	Light and power	60-cycle engine drive, 200 r.p.m., 3 phase, 60-cycle	General Electric Co.
1	Engine	Cross-compound, horizontal	14¼&25x18-in., 300 hp.	Generator drive	140 lb. steam, 200 r.p.m.	Buckeye Engine Co.
1	Generator	Alternating-current	250-kw.	Light and power	Three-phase, 60 cycle, 200 r.p.m.	General Electric Co.
1	Engine	Simple Lentz	23x30-in., 750-hp.	Generator drive	140 lb. steam, 150 r.p.m.	Erie City Iron Works
1	Generator	Alternating-current	500-kw	Light and power	Three-phase, 60-cycle, 2300 volts, 150 r.p.m.	General Electric Co.
1	Motor generator	Alternating- and direct-current	100-kw.	Light and power	Three-phase, 60-cycle, 2300 volts, 150 r.p.m.	General Electric Co.
1	Exciter	Motor-driven	35-kw., 125 v.	Exciting generator	Reversible	General Electric Co.
1	Motor	Induction	50-hp.	Exciter drive	Motor driven	General Electric Co.
1	Exciter	Motor-driven	11-kw., 125 v.	Exciting generator	60-cycle, 1200 r.p.m.	General Electric Co.
1	Motor	Induction	20-hp.	Exciter drive	Motor-driven	General Electric Co.
1	Exciter	On engine shaft	80-amp., 125 v.	Exciting generator	60-cycle, 900 r.p.m.	General Electric Co.
1	Transformer	Constant-current	30-kw., 2200 v.	Arc lights	Engine-driven	General Electric Co.

During the heating season there is no consideration given to an economical cutoff in the engine cylinder, as with a 50 per cent. cutoff the terminal pressure is about 60 lb., and as this volume passes into the heating system it gives a momentarily increased velocity 300 times a minute, which is noticeable all through the system, and for this reason good service has been given with as low as 2.5 lb. pressure at the power house.

Simplex condensation meters are used in the system, and steam traps are the standard traps in use where advisable.

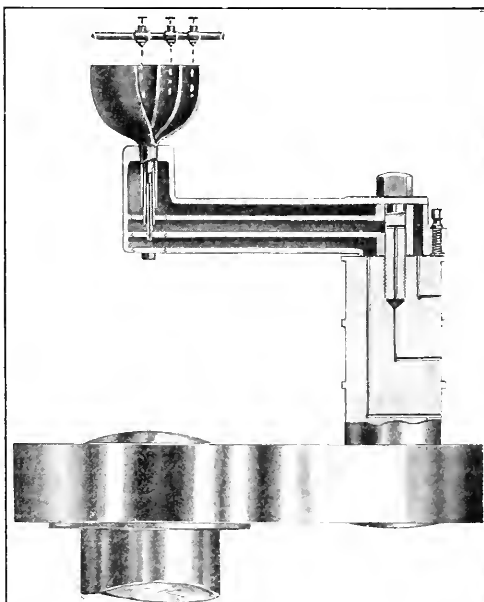
The output of electricity for the month of December, 1914, was 175,495 kw. Of this 25,000 was sent through a 6600-volt transmission line to a railroad shop five miles from the power house. This leaves 150,495 kw. for Bismarck with its 7000 inhabitants, or over 20 kw. for each person per month.

Central Oiler for Vertical Crankpin

Maintaining an adequate supply of oil on vertical crankpins has never been an easy problem, and when the pin carries two or perhaps three bearings, as in the case of angle-compound-centrifugal pumping units, the difficulties are increased.

As an easy solution to this problem Wm. W. Nugent & Co., of Chicago, are offering the central crankpin oiler shown in the accompanying illustration. It consists of a horizontal oiler arm and a funnel to receive the supply of oil. One end of the arm is secured to the crankpin by a bolt, and the receiving end is centered over the vertical shaft. It is evident that while the funnel revolves with the crankpin there is no lateral movement, so that the funnel will remain under the oil feed shown just above. Depending on the number of bearings on the crankpin, the central arm has one, two or three compartments fed through an equal number of concentric funnels.

In the illustration shown the pin has three bearings for the three connecting-rods of a triple-expansion engine. As a consequence there are three compartments in the arm and three funnels, one feeding to each compartment and each compartment feeding a bearing through oil holes



NUGENT OILER FOR A VERTICAL CRANKPIN

bored in the crankpin. By means of the open feeds above the funnels the supply of oil to each bearing can be regulated to suit requirements while the unit is in operation.

Feeding through the Blowoff Pipe—About the only excuse for feeding a boiler through the blowoff is that it helps keep the pipe clear. A circulating pipe connected outside of the setting will do as well and allow the boiler to be fed in a safe manner through an internal feed pipe.

Interior Wiring for Lighting and Power Service--V

By A. L. Cook

SYNOPSIS—Power panel-boards; the two-wire direct-current system, and single-phase, two-phase and three-phase systems for power. Full directions for calculating circuits are given, together with illustrative examples. The series concluded.

The choice as to the use of conduit or open wiring for power circuits in factories can be based upon the same considerations as were discussed in connection with the calculations of lighting circuits. If open wiring is to be used, it should be confined to the feeders, which can be located on the ceiling of the room, where they are not exposed to damage; and the branch circuits, which must run in more exposed places, should be placed in conduit. If a combination system of this kind is employed, a suitable bushing such as a condulet should be used at each end of the conduit, since an ordinary iron conduit bushing will not be approved by the inspector. This also applies to the end of the conduit at the motor and at the switchboard. The wire used is the same as for lighting service and is installed under the same rules.

Usually, the branch circuits for a group of motors can best be supplied from a common point at which a panel-board is located. Each branch circuit on the panel-board should be supplied with a knife switch and fuses. Sometimes a switch and fuses in the main busbars of the panel are also provided, but this is not necessary unless other subfeeders are supplied from the panel. Spare circuits should always be provided in every panel-board, the size and number depending upon the probable additions to the motor equipment.

For an installation of any size, one or more switchboard panels must be provided either at the service point or the power station. These panels should contain a circuit-breaker for each feeder and may or may not have a knife switch, depending upon the type of circuit-breaker used. If the board is under expert supervision, as in a power plant, fuses for each feeder may be omitted. The "Code" does not allow a fuse larger than 600 amp. for 250 volts or less, and 400 amp. for 550 volts; so circuits of larger capacity must be protected by circuit-breakers alone. For direct-current service, the carbon-break type of circuit-breaker with overload trip is satisfactory for most uses. For alternating-current service the carbon-breaker type is satisfactory for 110 or 220 volts, but for higher voltages an oil circuit-breaker is much better. For these high voltages it is difficult to get sufficient spacing on the switchboard between adjacent circuits to make the use of carbon circuit-breakers safe. The cost of the oil type is greater, but the resulting saving in the size of switchboard and the more satisfactory operation make its use desirable.

For power feeders it is always best to provide circuit-breakers of some kind rather than to use fuses only, because the fluctuations in load would result in great expense for replacing blown fuses if they were depended upon to open the circuit in all cases of overload. The first cost of the switchboard is, of course, greater, but the saving in replacing fuses and the ability to restore the service more promptly after an overload fully justifies the use of circuit-breakers, particularly in industrial establishments. They can often be used to advantage in protecting individual motors, and of course they must be used for loads exceeding the rating of the largest fuses. According to the "Code," if circuit-breakers are used for smaller loads, fuses must also be used unless the circuit-breakers are under expert supervision, as in a power house.

Two-Wire System

The method of laying out a two-wire system for power is similar to that for lighting. The usual arrangement would be similar to that shown in Figs. 8 and 9 (page 668, May 18, 1915), each panel-board supplying a number of motors. Usually, the two-wire system is employed for direct-current supply, the single-phase system, which also uses two wires, being suitable only for small motors. In the following, therefore, only the direct-current two-wire system will be considered. A two-wire supply for motors may be obtained from a three-wire system by connecting across the outside wires of the system. Sometimes the motors are run from the same feeders that supply the lights on a three-wire system, but this is not desirable because of the voltage fluctuations and greater liability of interruption; and it is therefore best to run separate power and lighting feeders from the supply point.

In locating the panel-boards and switchboards, the same considerations apply as for lighting service, already discussed. The size of wires for the individual motors may be obtained from Table 11 (page 703, May 25, 1915). This table does not take into account voltage drop, which should be calculated by means of the wiring chart, assuming full-load current on the motor. If the drop exceeds about 1.75 per cent. the size of wire should be increased. When the size of wire has been checked in this manner, the fuses for the branch circuit should be chosen, using Table 7 (page 642, May 11, 1915), and fusing to the full capacity of the wire, unless this fuse is the only protection for the motor, in which case 25 or 30 per cent. overload should be allowed.

The total connected load on each panel-board may be obtained by adding together the full current of all the motors on that panel, with a proper allowance for spare circuits. This result is then multiplied by the load factor, an estimate of which must be made carefully; in the absence of definite information 0.75 would be a fair figure to use. After the load has been calculated, the size of the feeder may be determined by reference to Table 7. The voltage drop with the given load should then be determined, and if it exceeds about 3.25 per cent., the size of wire should be increased. If the feeder supplies several panel-boards, or if the motors are connected to various points on the feeder, the drop should be calculated for each section separately and these values added to obtain the total drop. The size of fuses or the setting of the circuit-breakers on the feeders should be such as to allow the full current capacity of the wires in accordance with the values given in Table 7, irrespective of the actual loads on the feeders.

Three-Phase System

The three-phase system for power supply would employ three wires with equal voltages between them. The four-wire, three-phase system would not be used for motors, the neutral wire being used only when lighting is to be supplied. Ordinarily, three-phase motors requiring three leads would be used, although small single-phase motors might be run from a three-phase system by connecting them across one of the phases. The general arrangement of the branch circuits and feeders would be similar to that for direct-current. Because of the higher voltages which may be used, however, the branches may be made longer and the number of panel-boards thereby decreased.

The sizes of the branch circuits for individual motors are given in Table 12 (page 703, May 25, 1915), which applies to squirrel-cage motors. If motors of the wound-rotor type are employed, the wire should be made large enough to carry at least 1.5 times full-load current, using column A or B of Table 7 (page 612, May 11, 1915), to determine the size. In this case the starting current would be only slightly greater than the full-load running current, consequently fuses selected to protect the branch circuits would also protect the motor, so that the so-called "running fuses" used for squirrel-cage motors could be omitted. All three of the wires should be of the same size, as the currents are equal in all of them.

Table 12 takes no account of the drop in voltage on the wires, therefore this should be checked. If a drop of 1.75 per cent. is allowed between terminals of the motor, as previously specified, a drop of 0.58 of this value, or 1 per cent., can be allowed in each wire. After figuring the direct-current drop for one wire, calculate the alternating-current drop by the method previously described. Take, for example, a 50-hp., 440-volt, 60-cycle, three-phase motor. From Table 12 it will be found that the size of wire should be at least No. 0. The full-load current is 61 amp. If the length of the branch were 100 ft., the direct-current drop would be 1.24 volts for two wires, or 0.62 volt for one wire. Assuming that the wiring is in conduit, it will be found from Table 14 (page 705, May 25, 1915) that the ratio of reactance to resistance is 0.38. With a power factor of 0.85 (see Table 15) the drop factor is 1.07; hence, the alternating-current drop per wire would be $1.07 \times 0.62 = 0.66$ volt, and the total drop, $1.73 \times 0.66 = 1.14$ volts. This is only $\frac{1.14}{440} = 0.002$, or 0.2 per cent., which is much below the maximum of 1.75 per cent. allowed for the branch drop. In this case, therefore, the size of wire is taken as No. 0 because it is the smallest wire which will carry the current safely. If it had been found that the drop was greater than 1.75 per cent., the wire size would be increased as required.

In determining the total load on a panel-board, it is necessary to estimate the maximum load which would have to be supplied at any particular time. As previously explained, this would generally be less than the sum of the full-load currents of all the motors supplied from the panel. With squirrel-cage induction motors care should be taken that the wire is large enough to carry the starting current of the largest motor together with the normal running current of the others. For example, suppose a panel-board supplies the following motors:

One 15 -hp., 220-volt	38.6 amp. full load
One 5 -hp., 220-volt	13.4 amp. full load
One 7.5-hp., 220-volt	19.6 amp. full load
One 10 -hp., 220-volt	26.6 amp. full load
Total	98.2 amp. full load

Suppose that, from a knowledge of the operating conditions, the load factor can be taken at 0.75; the maximum current would then be $0.75 \times 98.2 = 73.6$ amp. There is also a 20-hp. motor supplied by this panel-board, which, when starting, takes 158 amp. The total is the combination of the running current of the several motors and starting current of the 20-hp. motor. The running currents are, however, at a power factor of 0.80 and the starting current at a power factor of about 0.50, hence, they cannot be added together directly; in fact, the total current is less than the sum of these two currents. To add these currents, we have to divide each into a "reactive" part and a "resistance" part by multiplying by the proper factor. The values of these factors for the usual power factors are as follows:

TABLE 16—REACTIVE AND RESISTANCE FACTORS

Power Factor	Reactive Factor	Resistance Factor
1.00	0	1.00
0.95	0.31	0.95
0.90	0.44	0.90
0.85	0.53	0.85
0.80	0.60	0.80
0.75	0.66	0.75
0.70	0.71	0.70
0.65	0.76	0.65
0.60	0.80	0.60
0.55	0.84	0.55
0.50	0.87	0.50
0.45	0.89	0.45
0.40	0.92	0.40

Applying these factors to the example,

Resistance Factor	Reactive Factor
$73.6 \times 0.80 = 59$	$73.6 \times 0.60 = 44.2$
$158 \times 0.50 = 79$	$158 \times 0.87 = 137.5$
138	181.7

The total current is $\sqrt{(138)^2 + (181.7)^2} = 228.2$ amp.

From Table 7 it will be seen that a No. 00 wire would probably be sufficient. If the two currents were added in the usual way the result would be 231.6 amp., which in this case would approximate closely the total current. The nearer alike the power factors of the two currents, the less need there is for employing the exact method given above.

The arrangement of feeders and subfeeders supplying the panel-boards may be laid out in the manner already described. Usually, there will be two or three panel-boards supplied from one feeder, but the number will depend upon the size of the motors and their location. It is desirable to keep the number of feeders a minimum, and on the other hand, it is not wise to use excessively large feeders, because of the great voltage drop. In general, the use of a feeder larger than 300,000 circ. mils is not justified when alternating current is used. The drop on the feeder should be calculated in a manner similar to that employed for the branch circuits, as has already been explained. The current to be used should be the maximum-load current, which is calculated by multiplying the sum of the full-load currents of all the motors (including an allowance for the spare circuits on the panel-board) by the proper load factor. When a motor is starting there will be a larger voltage drop, but this occurs only for a brief period and can generally be neglected if there are a number of motors on the feeder. When squirrel-cage induction motors are starting the current is large and the power-factor is about 0.50. There would therefore be momentarily a very large drop if the motor starting is large as compared with the other motors. An approximate value of this drop can be determined by neglecting the drop due to the motors running, and calculating the drop for the motor starting alone. The actual drop would then be somewhat greater than this owing to the current taken by the motors running, but would be less than the sum of these two drops. The reason for this is that we have a different power-factor for the running motors and the motor starting, and therefore, the total drop is less than the sum of the two drops.

Two-Phase System

Either the four-wire or the three-wire, two-phase system may be used. If the four-wire system is used, the two windings of the motor are connected across the two phases of the supply; with the three-wire arrangement, the windings of the motor are connected between the outside wires and the common wire. Care must be taken that neither of the windings is connected across the outside wires, as this would subject the winding to an excessive voltage. If the motors are provided with three terminals, the common terminal must always be connected to the common wire. If the direction of rotation is to be changed, this should be done by reversing the connections to the outside lines, keeping the common lead connected to the common wire of the system. If a motor having four terminals is to be connected to a three-wire, two-phase system, the two windings of the motor must be identified, by testing if necessary, and then one terminal of each winding must be connected to the common wire. The three-wire, two-phase system is commonly used, because of the saving in the cost of the circuits. The relative values of voltage and current in the various leads of the two-phase systems have already been explained in connection with the calculations of lighting circuits, and the length and general arrangement of the branch circuits are governed by the same general rules as were given for the other systems.

In Table 13 is given the full-load current and the minimum wire size for two-phase, four-phase, squirrel-cage induction motors, the current given being the value for each of the four wires; the size of wire also refers to each of the four wires. If a three-wire, two-phase system is used the currents in the outside wires and the sizes of these wires are as given in the table, while the current in the common wire is 1.42 times that given and hence the size of this common wire must be increased proportionately. For example, assume a 50-hp., 220-volt, two-phase motor, with a four-wire system; the size of each of the four wires would be No. 0000 and the full-load current 105 amp. With a three-wire, two-phase system the two outside wires would be No. 0000 and each would also carry a current of 105 amp. at full load. When starting, the current in the outside wires is 2.9 × 105 = 305 amp., which requires a No. 0000 wire, as given in the table. The starting current in the common wire, however, is 305 × 1.42 = 434 amp., and from Table 7, a 400,000-circ.mil wire will be found necessary.

If the wound-rotor type of motor is used, the wire should be sufficient to carry at least 50 per cent. overload continuously. Hence, in the case of this 50-hp. motor the current would be 1.50 × 105 = 158 amp. If four rubber-covered wires are used they should each be No. 000, and if three wires are used the outside wires should be No. 000. The maximum current in the common wire would be 158 × 1.42 = 224 amp., which would require a No. 0000 wire. In the case of squirrel-cage motors running fuses are required; that for the common lead having a capacity about 1.42 times that for the outside leads.

In the foregoing no account has been taken of the voltage drop, the size of wire given in Table 13 being the minimum size that should be used. It frequently happens that the voltage drop for the branches is small for either three-phase or two-phase systems because of the high voltages used. In any case, however, where there is a possibility of the drop being excessive, calculations of this should be made. In a four-wire system, since the two phases are independent, calculate the circuit as if it were a two-wire, single-phase system, and calculations need be made only for one phase. The drop on one phase can first be calculated by means of the direct-current chart and then the proper correction made for alternating-current by means of Tables 14 and 15. The allowable percentage drop in the branch circuits is about 1.75 per cent. for each phase. For example, take the 50-hp. squirrel-cage motor already mentioned. Assume a frequency of 60 cycles, a power factor of 0.85 and a length of branch circuit of 200 ft. Assuming a four-wire system, the smallest-sized wire which can be used is No. 0000 and the full-load current is 105 amp. Hence, the direct-current drop on one phase would be 2.1 volts. If the wires are in conduit the ratio, from Table 14, is 0.76 and the drop factor is given in Table 15 as 1.27. Therefore, the alternating-current drop is 1.27 × 2.1 = 2.67 volts. This is 2.67 ÷ 220 = 1.2 per cent., and the size of wire is satisfactory.

If a three-wire system were used, the drop would be calculated as follows: The current in each outside wire would be the same as before, namely, 105 amp. Hence, the drop in each of the outside wires would be 1.05 volts, from the direct-current chart. With alternating current, the drop in each outside wire would be one-half that previously found, or 1.34 volts. Since the curreuts in both outside wires are the same, the current in the common wire is 1.42 × 105 = 149 amp. under full-load conditions. It has already been found that the minimum size of this wire is 400,000 circ.mils, and the direct-current drop for this wire, with 149 amp. flowing, is given by the chart as 0.8 volt. For alternating current, the ratio in Table 14 is 1.49 and the drop factor 1.67 from Table 15. Hence, the drop on this wire is 1.67 × 0.8 = 1.34 volts. The total drop on one phase is $\sqrt{1.34^2 + 1.34^2} = 1.9$ volts or 0.9 per cent., which shows the sizes chosen to be correct.

In finding the total load on the panel-board the methods described under the three-phase system should be employed, using the proper load factor and allowing for the starting-current. The drop in the wires may be calculated by the rules given for the branches, since in all cases the loads are balanced. The same rules regarding the combination of currents at different power factors apply.

Increasing Boiler Capacity

By Joseph Harrington

SYNOPSIS—Stirling boiler furnace equipped with Roney stoker remodeled so that the capacity of the boiler was increased from 130 to 309 per cent. of rating. Attention to the dampers increased the draft over the fire. An extension of the furnace arches and the stopping of needless poking of the fire obviated dense smoke.

Having had occasion recently to overhaul a plant for the combined purpose of increasing capacity and decreasing smoke, the results obtained may be of interest to Power readers. The plant in question consists on its steam-generating side of 500-hp. Stirling boilers equipped with Roney stokers having 105 sq.ft. of grate surface. Two 175-ft. stacks serve the two lines of boilers through straight breechings of ample proportions.

This plant had not only been making objectionable smoke, but it was not possible to get from it much more than the boiler rating. Preliminary tests under the former operating conditions gave but 650 hp., or 130 per cent. of rating. These unsatisfactory results were partly the fault of the initial design and partly the result of defective stoker conditions and operation.

As in the majority of smoke problems, this one was founded on the insufficiency of the draft. When the furnace draft was brought up to the point corresponding to normal conditions, combustion was noticeably affected. The actual increase was about 50 per cent., or from 0.33

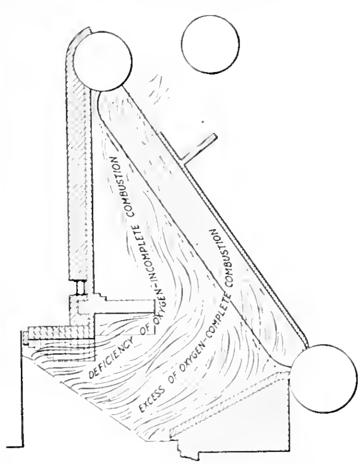


Fig. 1. Diagrammatic Analysis of Original Conditions

to 0.48 in., which under these conditions meant a radical difference in the furnace efficiency.

A part of the draft loss was due to a large damper in the main breeching near the stack. This was originally intended to be operated by a damper regulator, but had fallen into disuse and, although left wide open, was responsible for considerable interference with the gas flow. Its removal was a benefit, and owing to the slight friction loss in the breeching the stack draft was approximated at the boiler dampers. Dampering is usually overdone or underdone, and its influence for good or evil is still but little recognized. With the writer the conviction is gaining that a main breeching damper

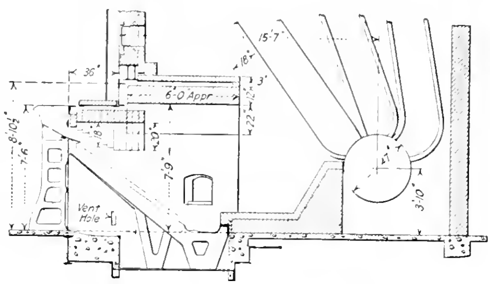

Fig. 2. The Remodeled Furnace

should be used only in certain special cases which must be selected with discretion.

Another heavy loss was chargeable to dampers, only this time it was the individual boiler dampers. Like the majority, these dampers did not close tight enough to exclude air leakage through the cold boilers. This was heavy, and the resultant volume of gases and infiltrated air was so great as to overload the stack. Temperatures were affected and the friction loss increased so that nothing like normal draft intensities were reached until this infiltration was stopped. Some day the idea of having airtight boiler dampers will be seriously proposed and find many advocates.

Sufficient draft in the furnace having been acquired, it was necessary to see that the furnace itself was able to take care of the increased volume of gases evolved at the higher capacities. An analysis of the furnace conditions is shown in Fig. 1. The cause of the smoke is apparent at a glance. Much of the volatile matter was slipping around the end of the short arch, across the chamber above, to the upper end of the first bank of tubes. The heavy excess of air at the lower end of the fire was filling the flame spaces of the front bank and holding away the hot gases that might otherwise have come into contact with the tubes. At the upper end of the furnace, temperatures were so far down that further combustion was impossible. The rest of the story was readable at the top of the stack.

Just as the cause became apparent, the remedy was obvious. In Fig. 2 is shown the furnace designed for this case. Extended comment is unnecessary. A more liberal supply of air was provided under the Roney arch and the proper fuel-bed thickness for different ratings was determined.

An important item was the handling of the stoker. The men seemed to think that the more they poked the better they did. This was all changed and the stoker allowed to do the work. Intelligent and effective coöperation on the part of the chief engineer resulted in the development of skilled firing, with less distress to the men and far better results from the stoker. It became apparent immediately that the stoker would do the work if left alone, and today it is the practice to poke only when there is special reason for it. Poking is done locally and as little as may be required to trim the fires in that particular spot.

Capacities up to 213 per cent. of rating were obtained for eight-hour periods, with an average increase in efficiency of 8 per cent. The highest hour showed 1545 hp., or 309 per cent. of rating. This was done without any injury to the stoker or furnace and without objectionable smoke. Furnace temperatures naturally were high, owing to the high rate of combustion and the reduction in excess air. On the high rating test an average of 13.17 per cent. CO_2 was obtained at the end of the flame and 11.96 per cent. at the damper. Moreover, practically all of the combustion took place in the *furnace*, which besides producing a high temperature was favorable to the absorption of the heat, the completely burned gases sweeping over the entire heating surface. The damper draft was 1.28 in. and the furnace draft 0.578 in.

While reference was just made to the highest capacity test of the series, the average was well above double rating. To give a better idea of the principal results, a table containing some of the averages is appended.

SUMMARY OF PRINCIPAL RESULTS

Test No.	Uptake Draft, In. of Water	Fur. Draft, In. of Water	Flue Temp., Deg F	Coal per Sq Ft. of Grate	Capacity, Hp.	Evap. F. and A as Fired, Lb.	Per Cent. Excess Air	Fur. and Grate Eff.	Combined Efficiency

Preventing Corrosion From Electrolytic Action

To prevent the electrolytic corrosion of boilers and similar vessels, the Cumberland Engineering Co., of London, Eng., has developed a rather interesting apparatus. Essentially, it consists of anodes that are insulated, that is, connected to the boiler shell by an insulated bolt, and that form the positive side of the circuit, while the shell itself is connected to the negative side, making it the cathode. The aim is to pass low-tension current, which may be regulated by resistances fixed on a switchboard or similar place. The current is supplied at from 6 to 10 volts, and an ammeter mounted on the board enables the operator to tell how much current he is sending through.

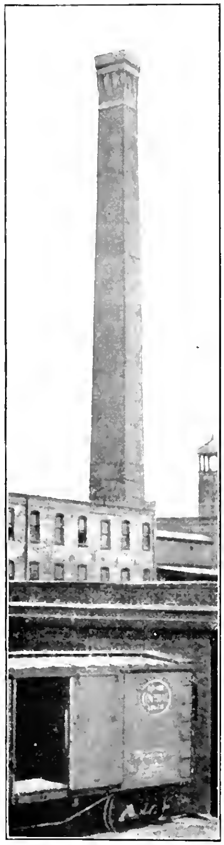
The elements of the water contained in the vessel are electrically charged when the current is on, and at the anodes there assemble the anions. When this occurs a film of hydrogen is said to form over the immersed portion of the vessel, thus protecting the latter; the oxygen, acid and other corrosive agents being attracted to the iron anodes, which become reduced just as zinc slabs do and must be renewed.

The claim is made that hydrogen, in being liberated from the surface of the metal in bubble form, tends to take from the surface any scale or other matter that may be clinging to it. This claim, then, presupposes that water must get under the scale, for the hydrogen bubbles must have their source in the water and not in the metal.

The development of this elaboration on the zinc-plate method of combating corrosion will be watched with interest.

A Brick Chimney Which Floats

In 1884 the Schlichter Jute Cordage Co., of Frankford Junction, Penn., started to put up a 200-ft. brick chimney, when it was found that the ground upon which the chimney was to stand overlay a quicksand into which a 3/8-in. iron rod would settle, if released, beyond hope of recovery. Mr. Herman Dock, to whom the design and construction of the chimney had been intrusted, simply cast a block of cement 30 ft. square and 5 ft. in thickness in an excavation, where it was desired that the chimney should stand, and built the chimney upon this floating block without any piling or other support. The chimney is square, as shown in the accompanying photograph, 13 ft. at the base and 11 ft. 6 in. at the top, and is composed of solid masonry without any core, the internal dimensions being 6 ft. at the bottom, and, contrary to the usual practice, 6 in. greater at the top. Its height is about 200 ft. and its total weight something like 1000 tons. It sways freely in the wind, and its movement may be felt by putting the hand between it and the engine-room wall, but it has suffered no permanent departure from the vertical. Four hundred barrels of Portland cement were used in casting the floating base; 1200 hp. of boilers are attached.



THE FLOATING CHIMNEY

Steam Consumption in Pumping—The common type of direct-acting pump, so much employed in mining, is well known to be wasteful in respect to the consumption of steam. This is owing to the necessity of using steam at full pressure throughout the entire length of stroke. Only a comparatively few pumps are designed to use steam expansively and these are not adapted to the commonly high lifts in mining. Steam consumption, in pumping, ranges from 10 or 15 lb. per i.hp. per hr., in triplex, flywheel pumps when run condensing, to an average of 150 lb. per i.hp. per hr. in direct-acting pumps. The consumption of steam, in pumps of the latter type, varies from 100 to 200 lb. per hp. per hr., depending on the speed of the pump and its condition. In this class of pumps, the consumption of steam is less as the speed is increased.—"Coal Age."

Some Notes on Elevator Pumps

By Thomas J. Rogers

The pump or pumps used in connection with a hydraulic elevator system should be of sufficient capacity to deliver the maximum quantity of water required promptly on demand. There are times during the day when the elevator system is heavily and quickly loaded and the water required is considerably more than the average quantity per minute pumped during the rest of the day. A pump large enough to care for these rush periods at a slow speed would, of course, be uneconomical during light-load periods. A common practice is to have a relay pump which may be run together with the main pump when the quantity of water required exceeds the capacity of one unit.

The crank and flywheel pumping engine for large elevator installations is superior in steam economy to other types, but is not available in small units, because it cannot be stopped and started automatically; and if kept running constantly it will pump through a bypass part of the time and much of the possible economy will be lost.

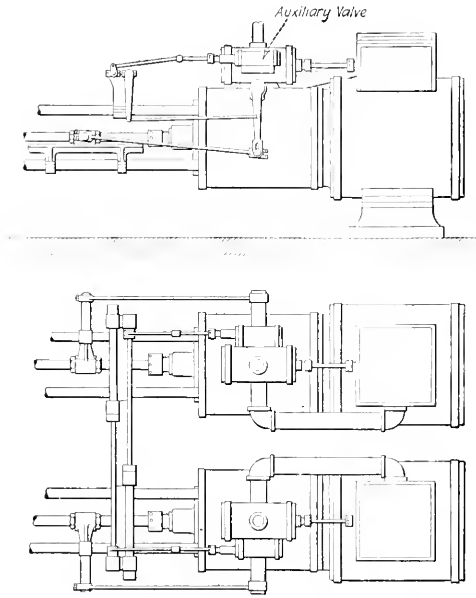
The writer has obtained good results with a compound separable duplex pump, in which either side may be operated independently of the other or both run together in duplex. This machine can be operated intermittently according to the demands of the service, and it is under governor control; it can be stopped when the proper pressure has been established and there is no demand for water, and started quickly when a slight drop in pressure occurs in the tanks due to the operation of the cars. When running duplex each of the two steam ends has control of the closure of its own steam valves, and the opening of them is controlled by the opposite engine.

The stroke is long and constant and the valve area large, though each valve is of small diameter. This type of pump closely approaches the economy of the crank and flywheel pumping engine, requires less attention, and the cost of operation and repairs is so much less than for the crank and flywheel type that, considering first cost, cost of foundations and installations, it is quite as economical an installation. It has the further advantage that it can be run either duplex or simple, one side only being operated during the periods of minimum demand, such as for night service, Sundays and holidays. This feature is particularly convenient when it is necessary to examine the piston packing, valves, etc., or when making examination or repairs to the steam end, as one side may be operated while such work is being done to the other side. This, of course, is impossible with the ordinary duplex pump or the crank and flywheel engine.

The maximum economy of any steam engine is obtained only when it is running at its full normal speed. In the case of a duplex or a crank and flywheel pump operating during the periods of minimum demand, the engine is necessarily run much below this speed; but in the case of the separable duplex type described, one side is shut down and the other operated at its full normal speed, meeting only the decreased demand.

On the steam end the method of connecting up is simple. It is well to use one valve in the main steam line and one in each of the branches, the exhausts being brought out and connected together in the most convenient manner to suit the situation. The side elevation shows the auxiliary steam chest and the control valve fitted to the side of the main steam chest, and by means of which the proper "timing" or duplex action of the two pumps is secured by movement of the piston in this auxiliary chest through the duplex levers and rods shown. Working duplex, this machine operates positively and is a true duplex, but not subject to short-stroking. Throwing the pump in or out of duplex is the work of but a minute, requiring only the pushing in of the handles of the control valve on the auxiliary chest on both sides to throw the pump into duplex running, or throwing them out of duplex by merely pulling these handles out.

When the pump is running as a duplex machine and it is desired to shut down one side, both handles are pulled out, leaving the pumps running for the minute as two separate units, then by shutting the valves on one side



Elevation and Plan of Elevator Pump

that pump is cut out, while the other side continues to operate as a single-cylinder, double-acting pump.

The water end should be fitted with two valves next to the cylinders which should connect to the main pump discharge through a tee. In case of running one side and opening the other cylinder for repairs, renewal of valves, etc., the closing of the valve next to the cylinder out of commission would isolate that one on the discharge side. The suction may have two separate lines at the pump.

In fitting an elevator pump, no matter what type, it is well to put relief valves on the water cylinders so that if by any chance the pump should be started with the stop valve in the main discharge line closed, excessive pressure will not be created in the pump cylinders. In such cases the relief valves usually discharge into the surge or the suction tanks.

Pumps used for delivering water up to about 250 lb. pressure into a closed tank, as on hydraulic-elevator systems under air pressure, are usually controlled by a pump pressure regulator. Where the pressure carried is above 250 lb. and up to an exceedingly high pressure an accumulator is used to govern the speed of the pumps.

Owing to the nature of the service being intermittent, the water on the suction side should flow to the pump by gravity with a head of from four to five feet over the under side of the discharge valves.

A necessary fitting to the water end of a hydraulic elevator pump is a suction air chamber. While the machine is in operation the water is rushing into the pump with considerable force, and should the regulator act and the machine stop at the end of its stroke, the water will continue to rush in with force enough to raise the suction valves from their seats and allow them to fall back with a loud pound. The pump air chamber prevents this.

The discharge air chamber should be kept at least three-quarters filled with air under pressure, and by application of a gage-glass its contents can be seen at a glance. A good method of recharging the discharge air chamber with air, should it become filled with water, is to run a line from the top of the air chamber to an air compressor with a check valve in the line close to the air chamber. If an air compressor is not available the best way is to attach an aërating valve in the suction line between the suction valve and the pump, and by running with this valve open to the atmosphere and the suction valve closed or partly closed, the machine will draw in air and force it into the discharge air chamber.

Motors to Put Engines Out of Business

By Bill B. Banger

SYNOPSIS—The alarming prospect revealed by the clipping (and it is an actual one that is reproduced) from the Eureka ——————. What it really shows is central-station enterprise.

While I was loafin' around my engin' room th' other day a feller blew in and started to look over th' shebang. He seemed mighty interested in th' generators, peeked into 'em here and there until I began to fear it would be necessary to send for an ambulance or an undertaker.

"Mr. Banger," said he after a spell, and I pretty nigh lost my equilibrium, seein' it's so long since I was called anythin' but Bill, except by th' firemen, who call me most anythin'. "Mr. Banger," says he, "this electricity stuff is all to th' futurity; you and I may not live to see any particular progress along electrical endeavors, but it will come, it's sure to come!"

I hadn't given th' feller much attention more'n to see he didn't get electricuted or fall into th' flywheel or some such minor accident, but his remarks made me hesitate in th' even tenor of my ways and squint at him over th' top of my glasses, which I have to wear on special occasions. A man with such broad perception of th' general trend of things, especially along electrical lines, was worth lookin' at a second time, by heck. Somehow or other, I had got th' idea that some considerable progress had been made in th' electrical generation and transmission of power and was somewhat surprised to hear that it wasn't likely that th' stranger and myself wasn't liable to live to see any material progress in electrical matters, leastwise not of a startling nature. Seein' I didn't have anythin' to say, I kept my mouth shut for once and waited for the next spasm.

"You'll be surprised, Mr. Banger," said he, "to see how electrical matters are progressin' in our town of Eureka. Of course, we don't come up to New York, but when you compare th' difference in size we are a close second, and lots of people are beginnin' to tumble to th' fact that we are on th' map. Of course, our trolley service ain't as big as what you have in this here city, but we get there just th' same.

"And our great white way is some class, I can tell you. One big electric light in front of th' grocery store and two in front of th' movin' picture sho', all on th' main street. Some town, I tell you."

Before I had a chance to say anything he started off again until I thought he was wound up for good. "I'll tell you, electricity is goin' to work havoc with th' steam and gas engin's and I can prove it." Whereupon he pulled out a newspaper clippin' and handed it to me to read. Here is what it said: [A reproduction of the clipping is shown herewith.—Editor.]

WILL USE ELECTRIC POWER.

Two Large Eureka Institutions Will Use New Power.

Electricity is rapidly replacing steam and gasoline engines as a means of power. The Eureka Roller Mills has placed an order with the Eureka Light and Power Company for a 20 horse power motor. This large motor will soon be here and will be given a thorough tryout by the milling company. As soon as the motor has proven to the satisfaction of the manager that it will do the work expected of it, the engine now used will be discarded.

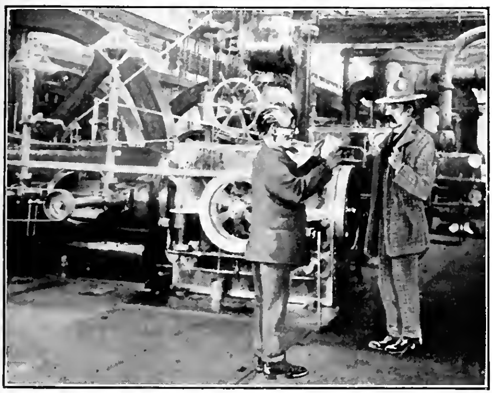
The Home Steam Laundry will install five electric motors. These are now here and will be connected up in a few days. This order consists of five motors—two 5-horse, two 2-horse and one on-half horse. These five motors will do the work now done by a steam engine and are supposed to be much more economical. The steam engine, however, will be retained in order to furnish steam and hot water for laundry purposes.

Well, I swan! When I finished readin' that clippin' I felt like putty nigh goin' over in a heap on th' engin' room floor. Just to think of a large 20-hp. motor bein' given a tryout to see if it would act satisfactorily! If th' motor does come up to th' scratch—and I calculate that there might be some doubts about it, seein' it's such a monster—I suppose th' large 20-hp. steam engin' what has been runnin' th' mill will have to go.

My visitor said there wasn't any more progressive parties in th' town than th' mill and th' laundry people, but I wondered how th' laundry people figures th' thing out that th' 15½ hp. in motors was goin' to be a gain, when they were goin' to keep th' old boiler—no it's th' engine—to furnish steam and hot water for laundry purposes.

It looks to me as if th' roller mill and laundry people wern't th' only ones that had their eyes peeled. It seems somewhat like as if the central-station evil, as it's sometimes called, was abroad in th' midst of Eureka and that th' business solicitor was a feller what was on to his job.

When I finished readin' th' clippin' Mr. Man was standin' with his thumbs in th' armholes of his vest, and



I SWAN! WHEN I FINISHED READIN' THAT CLIPPIN' I PRETTY NIGH FELL INTO A HEAP ON TH' ENGIN'-ROOM FLOOR

was teterin' back and forth on his toes and heels like a circus performer, and lookin' prouder nor a pussy cat with a litter of little toms.

"Some units," says he, "and it all goes to show that our people are awake to th' savin' what can be had by usin' electricity."

"That's as may be," says I. "Of course, I don't know how old that 20-hp. engin' is or how much steam it chews up per horsepower developed, which might be from 17 or 18 up to 60 or 70 lb. per horsepower, it all depends on th' engin' and th' engineer what has been nursin' th' thing.

"If th' engineer at th' mill is goin' to be kicked out in th' cold and th' steam plant shut down, and if th' charge for electrical energy is low enough and if th' steam engin' was a steam eater, why there is a chance—mind, I say a chance—that th' mill people will come out at th' big end of th' horn. If th' engin' is a good one and th' engineer knows his business, and if th' cost of juice ain't right, then I would advise them mill fellers to keep cool and not be in a hurry to threw th' engin' and boiler out onto th' scrap heap. They might be glad to start 'em up again when th' contract with th' electric company runs out," says I.

Th' stranger kinder looked stalled awhile and said he didn't think any mistake had been made and that even if it did cost more to run th' mill by motor than by steam, it didn't matter much, but showed that they were progressive anyhow. "Don't you know that th' introduction of all new innovations is prone to result in financial losses, more or less?" says he.

"Well," says I, "there is somethin' in what you say and so we'll let th' mill proposition drop and take a whack at th' wash factory. Accordin' to th' clippin' th' boiler—no th' engin' but we'll assume it's th' boiler—is to be hung onto and kept in th' business. It will take just as many men to run that boiler for keepin' up steam and heatin' water as it did to run th' boiler and th' 15½-hp. engin'. Th' only difference in th' operatin' cost will be in th' savin' of fuel that was necessary to burn to keep th' engine' goin', and a few quarts of engin' oil once in a while. Now, accordin' to all precedents, it's goin' to cost more to run them motors than it would to buy coal to run th' engin', unless a mighty low rate for juice has been made. I would give th' wash fellers th' same advice what I handed out about th' mill. It won't be a mite foolish for 'em to keep th' engin' right to home, for there have been lots of cases where engin's have been started up again after havin' been put on th' shelf while th' company was learnin' wisdom by experience and handin' out dollars to th' central-station fellers."

When th' feller was gettin' ready to get out, I gently put my hand on his shoulder and told him that what looks big in one place was less than commonplace in another, especially in electrical matters, and that although th' two enterprises in Eureka had put in a total of 35½ hp. in motors and while it might be a big thing in that town, it was not a criterion that all steam and gasoline engins were goin' to be put out of business all over th' country. A 20-hp. motor may be some stunt in Eureka, but it would hardly be able to shift th' brushes on th' 3750-kw. shunt-wound, direct-current generator that was built about a year ago.

"Down in th' so called sleepin' city of Philadelphia," says I, "they have a 35,000-kw. turbin' generator and out in Chicago they have a small 25,000-kw. unit. Out on th' Mississippi River there is a plant that will, when it's finished, generate about 300,000 hp., and 150,000 hp. is now in, and out on th' Pacific coast they have an electric transmission line 400 miles long, and one line out that way carries 150,000 volts every day, by heck.

"Just let me give you a little tip," says I. "Electricity may be for futurity, as you said, but it's a mighty big proposition now, and unless both of us turn up our toes pretty dinged soon we are goin' to see some more big stunts pulled off. They won't cause much stir, because things move so fast these days that it takes somethin' more than an ordinary earthquake to make us take notice—we take it as a matter of course and don't give a ding.

"When th' next feller in Eureka puts in a 25- to 30-hp. motor you won't pay much attention to it, for you'll be gettin' used to progress and take it as a thing to be expected. On th' other hand don't be surprised if th' mill and laundry fellers go back to th' steam engin' just as soon as they get th' chance. Goin'? Well, so long."

Most Economical Vacuum for Turbines

By Winslow H. Herschel

SYNOPSIS—Discusses the conditions which influence the degree of vacuum which it is best to carry on a turbine.

It is unfortunate that the word "economy" is used for steam consumption, as a low water rate does not necessarily mean economy at the coal pile. That depends upon the gain in power as compared with the increased cost of obtaining higher pressures, superheat or vacuum. The whole question of cost of power is complicated and depends to such an extent upon local conditions that it is impossible to find any general formula for obtaining power at the lowest cost. Without considering variations in pressure and superheat, factors which mainly depend

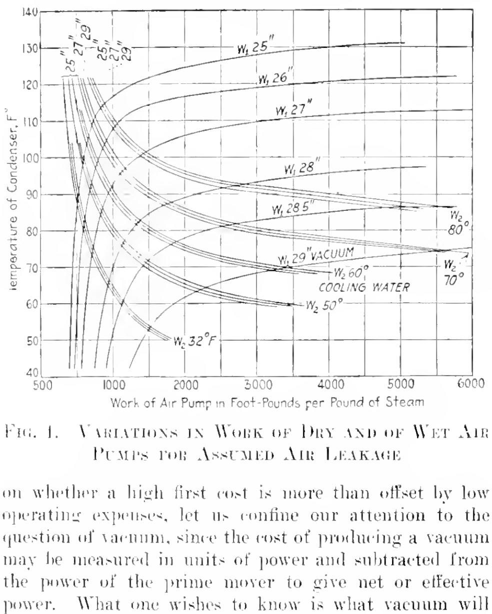


Fig. 1. Variations in Work of Dry and of Wet Air Pumps for Assumed Air Leakage

on whether a high first cost is more than offset by low operating expenses, let us confine our attention to the question of vacuum, since the cost of producing a vacuum may be measured in units of power and subtracted from the power of the prime mover to give net or effective power. What one wishes to know is what vacuum will give the maximum effective power.

In steam engines, as is well known, the large size of cylinders required and the great amount of cylinder condensation prevent high vacuums from being truly economical or from giving a very low water rate, so that a vacuum of about 26 in. is as high as it is advisable to go. With steam turbines, on the other hand, it is possible to have the steam at exhaust nearly at the point of saturation, so that the question of condensation is of minor importance, and it is feasible, at least in large-sized turbines, to design the blading to take care of the highest vacuum which an air pump can produce. The most economical vacuum is therefore not determined by the same considerations as in the case of steam engines.

To simplify the matter it will be assumed that the cooling water is delivered to the condenser by gravity, and neglecting the cost of the cooling water and the higher cost of an installation capable of producing a higher vacuum, we shall consider merely the power required to produce the vacuum by pumping the cooling water, condensed steam and air from the condenser out against the atmospheric pressure. This problem has been investigated by Stodola ("Die Dampfturbinen," Fourth Edition, p. 518) where he has assumed that the ratio of cooling water to condensed steam is equal to 50. It is obvious, however, that this is only an average or special case, since the higher the temperature of the cooling water, the greater will be the amount of it required to produce a given vacuum. In fact, the temperature of the cooling water available is often the deciding factor as to whether a steam turbine or some other form of prime mover shall be adopted, and frequently leads, in warm climates, to the substitution of the Diesel engine.

The presence of air in the condenser is mainly due to leakage through the stuffing-boxes. According to tests of George A. Orrok ("Journal A. S. M. E.," 1912, p. 1625), while the volume of air in city water at 52 deg. F. was over 4 per cent., this had been reduced to less than 1 per cent. in the feed water with a temperature of 187 deg. F. He found that with turbines of from 5000 to 20,000 kw. capacity, the amount of air discharged by the dry-air pump, at atmospheric pressure and temperature, varied from 1 cu.ft. per min., with the units in the best condition, to 15 or 20, when ordinary leakage was present, or to 30 to 50 when the units were in bad condition. These figures are checked by Stodola's statement that we may ordinarily expect the air to amount to 1.5 to 2.5 cu.ft. per min. for each 1000 kw. capacity.

Thomas C. M'Bride (Power, July 14, 1908, p. 74) points out that manufacturers of condensing apparatus for steam engines usually allowed for handling from 4 to 6 volumes of air per 10,000 volumes of exhaust steam, and gives results of tests in which the amount of air varied from 18 to 74 volumes. These figures are based on a 26-in. vacuum and a hotwell temperature of 110 deg. F. He also states that the amount of air to be handled should be as definitely specified as the amount of steam, or else the air-pump manufacturers should not be held responsible for the vacuum obtained.

In a more recent article, Prof. C. L. W. Trinks (*Proceedings* of the Engineers' Society of Western Pennsylvania, June, 1914, p. 497) gives the weight of air normally expected by builders of air pumps as 0.25 to 0.50 per cent. of the weight of steam. This would indicate a growing recognition of the large amount of air usually present in a condenser and its marked effect in reducing the vacuum which would otherwise be obtained.

In the calculations three different amounts of air leakage have been assumed—0.31, 0.62 and 0.93 per cent. of the weight of steam. These amounts correspond respectively, to about 20, 40 and 60 volumes of air per 10,000 volumes of exhaust steam, when reduced to M'Bride's basis of comparison, or to approximately 15, 30 and 45 cu.ft. per min. for every 1000 kw. capacity.

Comparing our assumed values with those of the authorities quoted, we may say that the smallest amount of air could be obtained with stuffing-boxes in the best condition, the second amount under ordinary conditions, while the third value might be reached and exceeded with the stuffing-boxes in poor condition.

The work done by the air pump is found as follows: If p is the pressure in the condenser in pounds per square foot and p_s the steam pressure as given in the steam tables for the temperature of the condenser, then the pressure of the air in the condenser is the difference between these two pressures. Therefore, the weight per cubic foot of the air is $D = \frac{p - p_s}{RT}$, where T is the absolute temperature (that is, 459.6 plus the temperature in degrees F.) of the condenser, and R is the air constant 53.34. Let D be the weight per cubic foot of steam at temperature T. Then, if we have C pounds of air with each pound of steam condensed, the weight of mixture to be pumped for each pound of steam is $C\left(1 + \frac{D_1}{D}\right)$. The theoretical work to compress this weight of mixture, that is, the work required with an ideal air-pump efficiency of 100 per cent., will be

$$W_1 = C\left(1 + \frac{D_1}{D}\right)\frac{k}{k-1}RT\left[\left(\frac{p_b}{p}\right)^{\frac{k-1}{k}} - 1\right]$$

where p_b is the barometric pressure and k is the exponent for the adiabatic compression of the mixture of steam and air which may be taken equal to 1.41. To get the total work of the air pump, $W_1 + W_2$, we must add to W_1 the work required to pump out the cooling water, which is

$$\frac{m\,(p_b - p)}{D_2} = W_2$$

where D_2 is the weight per cubic foot of the water and m is the weight of cooling water per pound of steam condensed. The value of m may be found from the equation

$$m = \frac{H - t_1}{t_1 - t_2}$$

where H is the total heat of the steam, t_2 is the temperature of the cooling water, and t_1 is the temperature of the condenser. The heat H is determined by the vacuum, t_2 may be estimated approximately for any given locality, and t_1 remains to be determined so that the sum of W_1 and W_2 shall be as small as possible. It may make the matter clearer if we imagine two separate pumps—the dry-air pump which does the work of compression, W_1, and the wet-air pump which does the work of pumping, W_2. Then it is evident that with a given temperature of cooling water and a certain amount of air leakage, the vacuum may be increased to the desired amount by increasing the work of either of the two pumps; that is, the vacuum may be improved by decreasing the temperature of the condenser by the use of more cooling water, or by decreasing the pressure by speeding up the dry-air pump. For a given vacuum, W_1 will increase with a rise in the temperature of the condenser, while W_2 will decrease, and at a certain condenser temperature, depending on the vacuum and on the temperature of the cooling water, $W_1 + W_2$ will be a minimum.

In Fig. 1 are shown variations in W_1 and W_2 for an assumed air leakage of 0.62 per cent. of the weight of steam. As W_1 is proportional to the leakage of air, it is easily found for any other amount. Since W_2 varies with the temperature of the cooling water (though W_1 does not), different sets of curves are shown for temperatures of 32, 50, 60, 70 and 80 deg. F., each set consisting of three curves for vacuums of 25, 27 and 29 in. By means of this diagram we have obtained by trial the condenser temperatures which would make the total

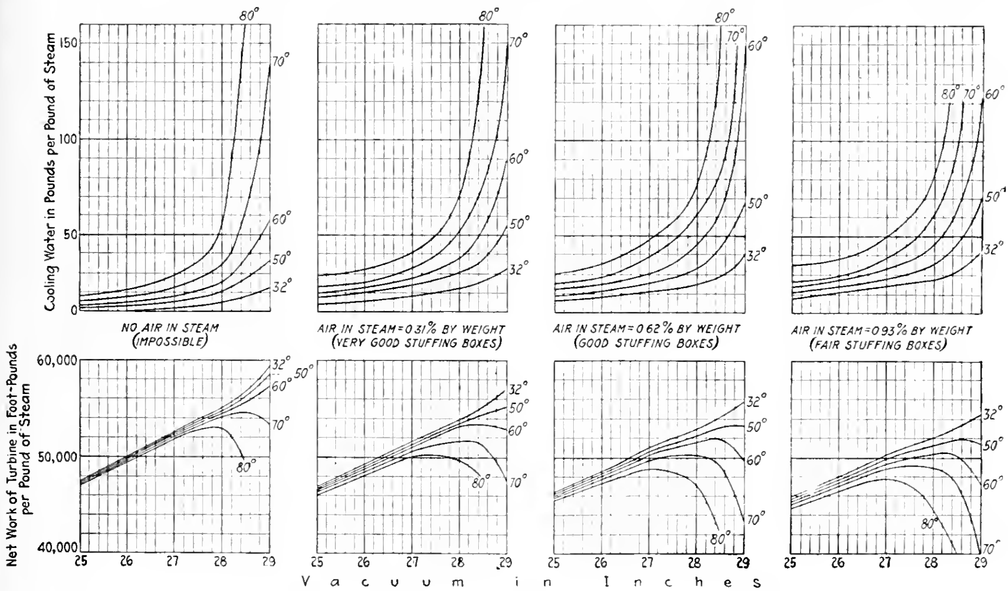

FIG. 2. GRAPHICAL PRESENTATION OF DATA CONTAINED IN TABLES

air-pump work a minimum under various conditions. The results are shown in Table I. With the temperature of condenser known, we are in position to find values of m which are also given in Table I and shown in Fig. 2.

In London *Engineering* of Jan. 9, 1914, p. 38, is given a diagram "due to J. M. Newton," showing values of m for various vacuums and initial temperatures of cooling water. The effect of varying amounts of air leakage is, however, not shown as in Fig. 2 herewith. In most cases m would be easier to measure than the average temperature of the mixture in the condenser and could be used as an indication of whether the dry- and wet-air pumps were each doing its proper share of the work.

To find the vacuum which will make the net work a minimum, we must assume the water rate of the turbine and the efficiency of the air pump. By net work is meant the work developed per pound of steam by the turbine, minus the air-pump work per pound of steam needed to produce the vacuum. We have assumed the turbine to be acting under 150 lb. gage pressure, dry steam, without superheat, and have taken air-pump efficiencies of 50, 65 and 80 per cent. Stodola assumed for the air pump an efficiency of 50 per cent. and took for the turbine an admission pressure of 142 lb. with an initial temperature of 572 deg. F., or 218 deg. superheat. Using, as he did, an indicated efficiency of 65 per cent. and a mechanical efficiency of 90, this would be equivalent to assuming that the water rate varied with the vacuum, as shown in Table II, which also gives the water rates herewith employed.

TABLE II

Vacuum in Inches	Water Rate Used by Stodola, Lb. per B.hp. per Hour	Value in Ft.-Lb. of 1 Lb. of Steam	Water Rate Used in Fig. 2, Lb. per B.hp. per Hour	Value in Ft.-Lb. of 1 Lb. of Steam
25	14.0	63,300	18.5	47,900
26	13.5	65,600	17.6	50,300
27	12.8	69,100	16.7	53,200
28	12.1	73,100	15.9	55,700
28.5	11.5	77,100	15.4	57,600
29	11.0	80,500	14.7	60,300

The writer has assumed that the turbine was designed for a vacuum of 27 in. and that, consequently, the efficiency decreases slightly from the maximum of 50.0 per cent. when the vacuum is either higher or lower than the normal. The efficiencies are somewhat lower than the constant value of 58.5 per cent. taken by Stodola and apply more especially to small-sized turbines, while his value would be more suitable for the larger sizes.

Stodola assumed various rates of air leakage up to about 150 cu.ft. per min. for a 1000-kw. turbine, and found that with his assumed efficiency the most economical vacuum was always over 29 inches, increasing with a decrease in the amount of air in the condenser. He used a temperature of cooling water of 50 deg. F. and a value of $m = 50$. Table III shows the results obtained with m having a variable value as in Table I. Where the most economical vacuum is different for two different efficiencies of the air pump, both vacuums are

Note—Where the most economical vacuum is different for two different efficiencies of the air pump, both vacuums are given, the values of the net work, which are not maximum, being inclosed in parentheses.

included in the table, the values of the net work, which are not maximum, being inclosed in parentheses. The same results are shown graphically in Fig. 2 for air-pump efficiency of 65 per cent. For each of the four amounts of air leakage, from zero to 0.93 per cent., there are five curves for the five different temperatures of cooling water assumed. It will be seen that the most economical vacuum is by no means always as high as 29 in.

In the last column of Table III is given the net work of a turbine, assuming the same efficiency for the air pump and the turbine as taken by Stodola, but taking values of m from Table I. A comparison of columns 4 and 7, Table III, shows that a higher turbine efficiency makes but little difference in the most advantageous vacuum, so long as the efficiency of the air pump is the same. In no case, however, would the most advantageous vacuum, for given conditions, be as high as here calculated, because no account has been taken of the cost of bringing cooling water to the condenser, which increases with m and hence with the vacuum.

⁂

Before Applying a Hydrostatic Test to any boiler, gage lines should be located and gages fixed in order to detect any tendency to bulge or become distorted when under pressure and show whether the parts return to their original contour or not. Otherwise, the test will be of little valne or may even do serions damage, leading to failure later. Such tests should be made by skilled and experienced men, never by thoughtless amateurs.

JUST FOR FUN

A Painstaking Job, but in the Wrong Place

A green man taking down some circuits cut the wires and instead of carefully separating the ends on the live side he spliced the two lines together, then soldered and taped the joint. That evening when it was time to turn the current on that line, things were lively for a while. —*Harry D. Everett, Washington, D. C.*

What Is Electricity?

I'm going to slip you one by Ike Hedges. He says: "In the fall of 1913 I dropped off at Bologna, Italy, on my way from Venice to Florence. Consulting my Baedeker, I learned that the famous thing about Bologna was its ancient university, and that three great men in the electrical world had at one time attended this famous institution of learning—Galvani, Volta and Marconi. The conclusion, therefore, is inevitable, that whatever electricity may be, its basic principal is sausage." (Well, it might be "wurst.")—*Terrell Croft*, St. Louis, Mo.

A Lively Time

The second item in the "Just for Fun" column, Mar. 9 issue, reminded me of a similar incident.

The electrical system was being changed from a two- to a three-wire system, and a temporary wooden switchboard was being built above and to one side of the one in use. The carpenter above was nobly trying to balance a long piece of "two by four" that was slowly but surely getting away from him. He yelled for help. His helper below, a large steel square in his hand, realized the need of quick action. He looked around for a place to lay the square, and one of the main switches happened to be the place. The action was quick. No one was seriously hurt, though there was a most confusing mixup of men, fire, noise and the "two by four." The helper, who had vanished as though swallowed by the earth, "showed up" four days later.—*C. H. Dalrymple, New York.*

"A Pound's a Pound the World Around"

I read your "Just for Fun" column with considerable pleasure and was particularly interested in an article in the Feb. 23 issue, page 261, in which the member of the school board made such wise remarks about the flow of steam. It reminded me of a somewhat similar experience while superintendent of a municipal plant in a mining town in Illinois. After a new boiler had been completely installed the Village Board came down to the plant to see it put under pressure. Among the various suggestions for raising the necessary hydrostatic pressure, one was to fill it full, close all valves and build a light fire so that the expansion of the water would give the desired pressure. The idea was all right, only I explained to them that the safety valve was set for only 150 lb. and would blow at that pressure, and would have to have a gag on for the test and that I could pump up the pressure in a much less time. One of the members, the owner and operator of a steam-operated brick yard, said that it ought not to lift at 150 lb. water pressure as 150 lb. steam pressure was equal to 250 lb. water pressure and the valve was set for steam pressure.—*W. P. Martin, Connelton, Ind.*

First Uniflow Plant on Pacific Coast

SYNOPSIS—The requirements demanded generating sets capable of providing elevator and lighting service without flickering lights and also to take care of a large roof sign which is thrown on and off every thirty seconds. The engines and boilers are in a common room; there is no dust, as fuel oil is burned in the boiler furnaces. The uniflow engines on test with less than 150 lb. steam pressure showed an average steam consumption from one-fourth to full load of less than 20 lb. per indicated horsepower-hour.

The power-plant equipment of the New Hotel Rosslyn, Los Angeles, Calif., presents the solution of an engineering problem which will be of interest to engineers. This hotel is 12 stories in height, with basement and sub-basement, and contains, with an annex, 850 rooms. There are four passenger and three service elevators, of the high-speed traction type. It was required to provide generating capacity that would take care of the elevators and lighting load from the same circuit without causing the lights to flicker. Clusters of tungsten lamps against light-colored ceilings and walls were to be used, which would have a tendency to magnify the least flickering of the lights.

In addition to the fluctuating elevator load, provision also had to be made to take care of a large roof sign which was to be thrown entirely off and on at intervals of 30 sec. Besides being able to cope successfully with the fluctuating nature of the load, the plant had to be an economical one, because electricity in Los Angeles is sold on a sliding scale, making it possible for large users to purchase it at a rate of approximately $0.0135 per kw.-hr.

The building was originally laid out with the intention of purchasing current, and therefore the space that could be allotted to the power plant was very small. This difficulty was largely overcome by the fact that oil-burning boilers were installed. The space between the nearest engine and the boilers would hardly permit the slicing of fires if coal were used for fuel.

E. L. Ellingwood, consulting engineer, of Los Angeles, was employed by the architects, Messrs. Parkinson & Bergstrom, to make the plans for the power plant and heating system.

Three "Universal Unaflow" engines were selected, two being of 200-kw. capacity at 200 r.p.m., and the third of 100-kw. capacity at 225 r.p.m. (Fig. 1). Direct-current three-wire generators were selected. The boiler plant consists of three 196-hp. water-tube boilers (Fig. 2), equipped for the burning of fuel-oil. The steam pressure is 150 lb. at the boilers. Saturated steam is employed. The engines on a test at somewhat lower steam pressure than 150 lb. showed an average steam consumption from one-fourth to full load of less than 20 lb. per i.hp.-hr. The plant is a good investment for the owners of the hotel, as the total cost of operation, including interest, depreciation and a charge of $0.50 per sq.ft. per year for floor space, is $0.0116 per kw.-hr.

The total connected load is about 760 kw., of which 260 kw. is motor load; and although this is of a decidedly fluctuating nature, owing to the traction elevators and the intermittent electric sign, no flickering of the lights in any part of the building can be noticed.

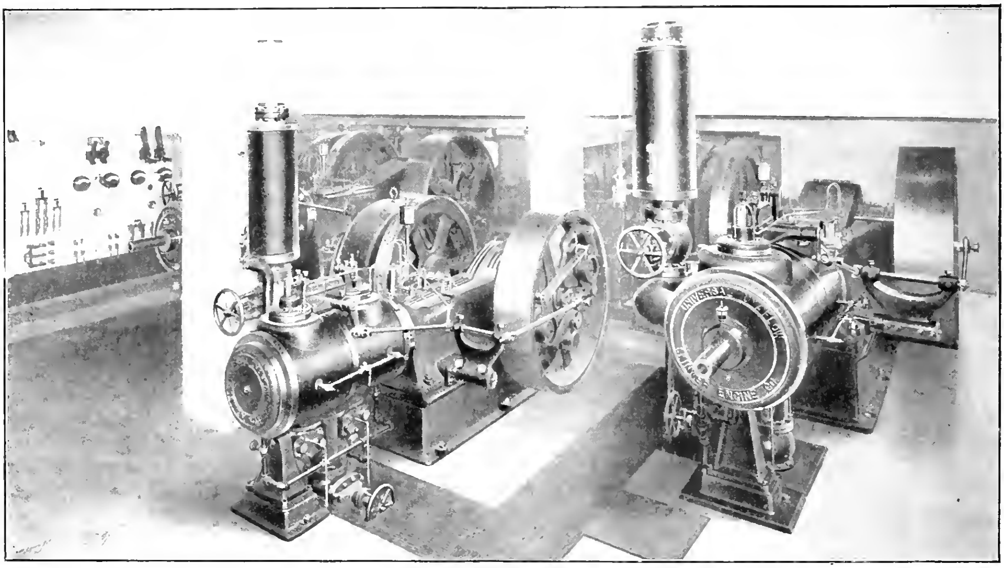

Fig. 1. One 100-Kw. and Two 200-Kw. "Universal Unaflow" Engines Directly Connected to Direct-Current Generators

The engines and boilers will attract the attention of Eastern engineers, owing to the fact that they are placed in one room, which is finished in white. This arrangement is possible and practicable on account of burning fuel-oil under the boilers. The engine and boiler room is well lighted by 200-watt tungsten lamps suspended close to the ceiling. Fig. 3 is a view of the switchboard, which is also shown in part in Figs. 1 and 2.

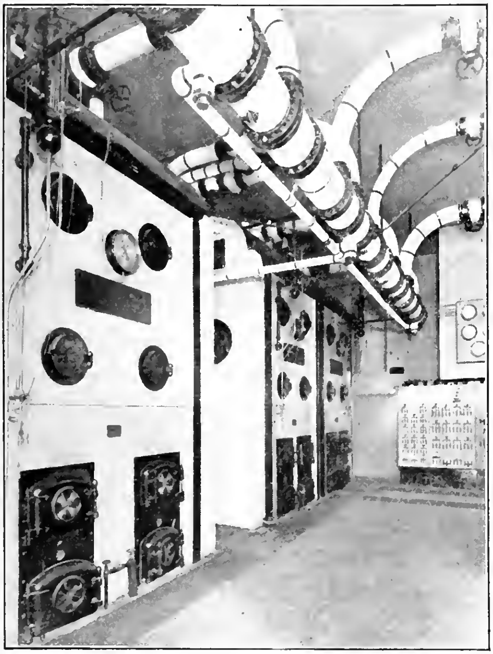

Fig. 2. Three 196-Hp. Water-Tube Boilers; Fuel Oil Is Used in the Furnaces

In addition to the power plant, there is a refrigerating system calculated to provide circulating water in every room at a temperature of 37 deg. F., the test conditions being rigid, as only 8 oz. of water was allowed to be drawn from the faucets in order to arrive at the test temperature of the water. The refrigerating equipment

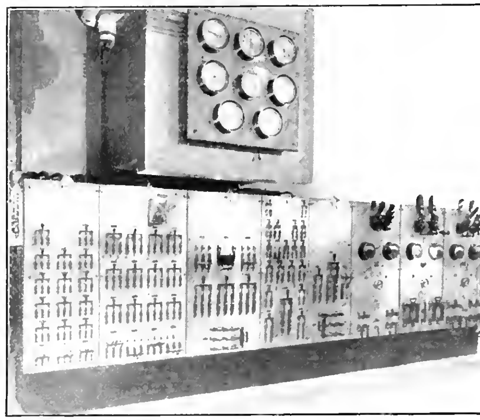

Fig. 3. Switchboard for Generator and Circuit Control

consists of one 18-ton horizontal ammonia compressor, direct-driven by a Corliss engine at 66 r.p.m. The plant manufactures 1200 lb. of ice every 24 hours, and furnishes refrigeration for all cold boxes in the storage department of the hotel, the bar, the cigar and flower shops.

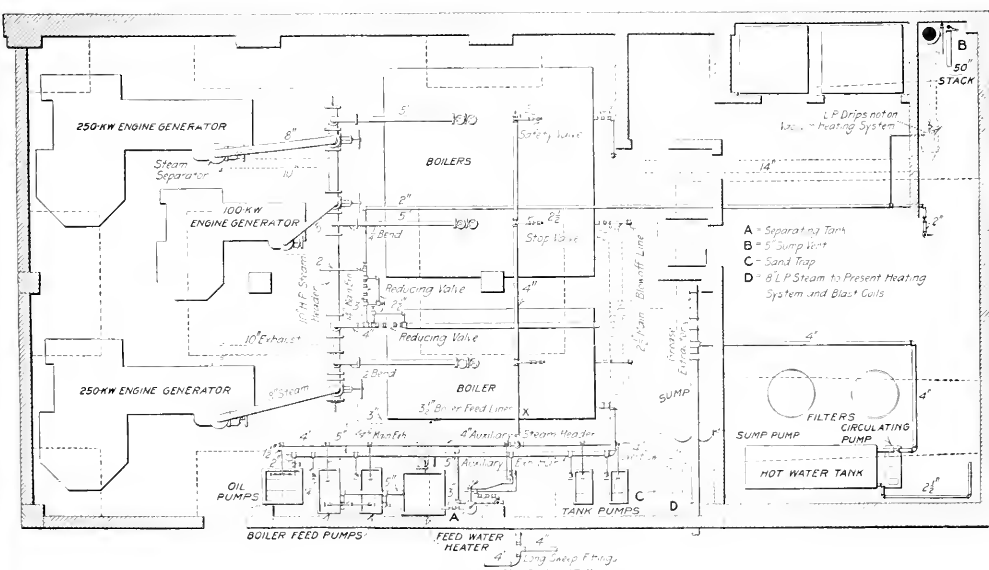

Fig. 4. Plan of Engine and Boiler Room

PRINCIPAL EQUIPMENT OF THE HOTEL ROSSLYN, LOS ANGELES

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
2	Engines	Universal Unaflow	200-kw	Main units	200 r.p.m., 150 lb. steam, saturated	Skinner Engine Co.
1	Engine	Universal Unaflow	100-kw.	Main unit	225 r.p.m., 150 lb. steam, saturated	Skinner Engine Co.
2	Generators	Direct-current	200-kw.	Main units	200 r.p.m., three-wire system	Crocker-Wheeler Co.
1	Generator	Direct-current	100-kw.	Main unit	225 r.p.m., three-wire system	Crocker-Wheeler Co.
3	Boilers	Water-tube	196-hp.	Steam generators.	150 lb. steam, saturated	Badenhausen Boiler Co.
1	Compressor	Ammonia	18-ton.	Refrigeration system	Engine driven, 66 r.p.m., 1200 lb. ice per 24 hr.	Vulcan Iron Works.
1	Engine	Corliss		Driving ammonia compressor	150 lb. steam, 66 r.p.m.	Murray Iron Works
1	Pump	Tank		Water to storage tank		Henry R. Worthington
2	Heaters	Tank		Hot water for house	Thermostatically controlled	Frank L. Patterson
	Dunham heating system for the building, using exhaust steam.					C. A. Dunham Co.
	Ventilating system, exhaust fans.					B. F. Sturtevant Co.

Water for lavatory, laundry and kitchen purposes is heated in a battery of two combination tank heaters thermostatically controlled, the water being circulated throughout the building by centrifugal pumps. The water-supply for the building is from roof storage tanks of 34,000 gal. capacity, automatically filled by a steam-driven tank pump located in the sub-basement.

Steam heat for the building is by means of a system using exhaust steam exclusively.

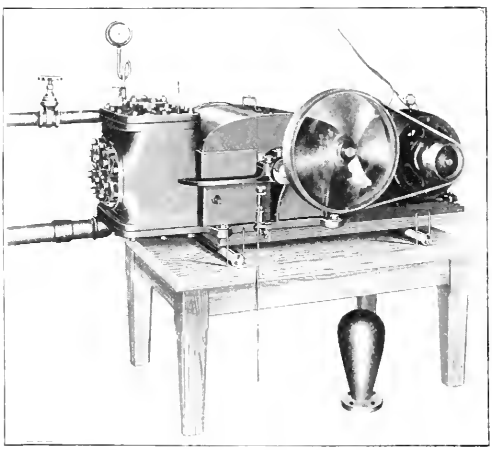
The ventilation in the service department, lobby and dining room and the exhaust ventilation from all the toilets, lavatory and bath systems is provided by fans.

The water for refrigerator, laundry and boiler-room use is treated by the lime and soda process, as Los Angeles city water runs from 22 to 26 deg. German hardness.

The compact nature of this plant, as shown by the plan, Fig. 4, was necessary on account of the limited floor space turned over to the engineer for the installation of the equipment.

Luitwieler Double-Acting Triplex Pump

At the factory of the Luitwieler Pumping Engine Co., Rochester, N. Y., may be seen a double-acting triplex pump operating at speeds from 100 to 300 r.p.m. The



PUMP RUNNING WHILE RESTING ON ROLLS

illustration shows the pump operating upon a pair of polished steel rollers 2 in. diameter, the rollers resting on the top of a table. There is no air chamber on the pump and the gage needle stands still, showing that the water pressure is constant. To show that no vibration exists, a wire nail 5 in. long stands motionless upon the top of the pump; on either side of the rollers other nails of the same size stand on end touching them. If there was any movement of the rollers the nails would topple over, but the pump operates at these high speeds day after day with the same nails standing immovable.

The Luitwieler pump was described on page 53 of the July 8, 1913, issue. All the driving mechanism is inclosed in a bath of oil and needs practically no attention.

Dimensions, Weights and Costs of Steam Turbines*

By A. A. POTTER† AND S. L. SIMMERING‡

Tables 1 and 2 were compiled from data supplied by manufacturers and should prove of value in connection with preliminary estimates. The dimensions, weights and cost data are for condensing units and include the turbines and alternating-current generators.

The values in Table 2 were plotted and the following equations were deduced, giving the cost in dollars (C) of the turbine and generator, in terms of the capacity in kilowatts.

$$\text{Impulse types } C = 5040 + 9.2 \text{ kw. (Dollars)}$$

$$\text{Reaction types } C = 7400 + 8.26 \text{ kw. (Dollars)}$$

Duty of a Pump—There are different definitions for what is termed the "duty of a pump," each giving a different estimate of value. The duty is sometimes defined as the weight (lb.) of water raised through a vertical height of 1 ft. for each 100 lb. of coal burned; or, more simply, the theoretical work (ft.-lb.) performed per hundredweight of coal burned under the boiler. It is observed that this definition is faulty, because it combines furnace and boiler efficiencies with that of the pump itself, besides estimating only the theoretical work performed, thus eliminating friction, which is often a most important factor. The true definition of duty in pumping is the actual work performed in a given time (ft.-lb.), per million B.t.u. delivered to the pump in the same time. Or, less frequently, the duty is estimated in foot-pounds of work performed per thousand pounds of dry saturated steam consumed.—"Coal Age."

Editorials

Accepting the Inevitable

Always present in every community are the "kill-joys," who see nothing but ruin ahead if this or that is done. Yet somehow, we always have lived through the administrations that were prophesied to bring the country to disaster and, strangely enough, we are getting better all the time. It seems as though progress has a certain momentum that will carry it on in spite of all obstacles, including the well-meaning people who cannot anticipate success except by time-worn methods.

In this connection a recent utterance of George Otis Smith, director of the United States Geological Survey, in an address at the University of Illinois, is to the point:

The trouble with so many of the business men of the day, and especially with those who come to Washington to oppose new legislation, is their nearsightedness. They cannot see country-wide public opinion and do not appreciate the obvious fact that the financial centers are not also the centers of national thought. The result of this, as I expressed it in conversation last winter with a New York gentleman who was largely interested in water-power development, is that the business interests oppose something at one Congress which two years later they would accept; but the next Congress is already considering a more advanced legislative proposition. We are all more or less progressive, I told him, but the opposition has been just one lap behind.

The bright light of publicity is coming to shine more and more upon the inner workings of all private business which has anything of the public-service character. Only about three years ago, at a conference on water-power policy, I heard the representative of the banking houses interested in the hydro-electric business tell the Secretary of the Interior, with considerable warmth of spirit, that one thing the men who make possible the development of our country by their contribution of capital would not stand for was any legal requirement of inspection of their accounts by the Government. A corporation has its rights, they contended, just the same as a private man in business. Last year in the same room, when the utilization of a large power site owned by the Government was being discussed, I heard those asking for the permit dismiss the question of Federal inspection of their books with the remark, "That need not be discussed, our books will of course be always open to any authorized representative of the Government." The ultimatums pronounced by the ambassadors from Wall Street, State Street and West Adams Street are short-lived in the present atmosphere of popular interest in these business questions.

To go back to our first thought that progress is going to "get there" "nevertheless and notwithstanding," the situation is much like that of a trolley car or automobile trying to cross a busy street. People and traffic will continue to hold up the car by passing in front of it like so many obstructionists until the Law, personified in the traffic "cop," gives the car the sign to come ahead. Then the pedestrians have to look out for themselves and let the car pass. The car loses a little time, and so do the people, but eventually all get on and no harm is done. So it will be with the questions that Congress or State Legislatures are called upon to decide. Ultimately, they will be settled the right way, and the sooner opposition is withdrawn the sooner conditions will adjust themselves to everyone's satisfaction. Right is the good of the majority, and private interests mindful only of their profit will do well to accept the inevitable without expensive delay. It is futile to hinder progress.

Principles versus Details

To most engineers the study of principles is less interesting than apparatus embodying them—details of valves, piping, generators, etc., grip the attention far more readily than what look to be theoretical abstractions. This is only natural, for most people think in concrete terms; the specific appeals to the intellect of the great majority more than does the general; and iron and steel, water and coal, copper wire and insulation, belong so positively to the realm of things seen and handled that many minds never get much beyond these visual conceptions.

Mastery of details is essential to engineering success, but advancement to professional standing calls for recognition of principles. We hear too much about the "man behind the throttle," as though mere manipulation were the index of the engineer's ability. Striking phrases like these are useful in their place, but are largely figures of speech, and their symbolism should not be taken too literally. Without brains to guide the hand on the throttle, to appreciate what goes on on each side of the valve disk, and to anticipate in imagination the results of various steps in plant operation, we should have short shrift from the business world. Power to think in terms of principles—to theorize—is the means to rise out of mediocrity into distinction. Acquiring it means drudgery and plenty of it, but it also means advancement on a solid foundation, with a broad comprehension of the significance of details which mere cleverness in mastering the latter can never supply.

Appreciation of the laws of steam, hydraulics and electricity, knowledge of the strength of materials and comprehension of the chemical and physical principles bearing upon combustion of fuel, the production of steam or producer gas, a broad grasp of the elements of lubrication and of the essentials of heat phenomena, will serve the engineer well in time of need. It goes without saying that to understand the *why* of his work as well as the *how*, these important matters cannot be neglected. Even after a man has gone through a rigorous course in mechanical engineering and spent several years in practice within the plant, it will pay him to occasionally review the fundamentals of his profession. Defects in early training can thus be remedied, and most of us have weak spots in our technical armor.

In these days of distributed information, with interesting bulletins and catalogs coming from all quarters of the land at the price of a postal card, it is easy to form the habit of following *applications* of principles to the exclusion of studying fundamentals themselves. It is amazing how helpful it is to review the elements of steam engineering, for example. Much of the matter can be gone through rapidly, but such a review strengthens the grasp of the reader on the great essentials of his occupation and thereby better fits him to grapple with fresh problems in his own field. Judgment in the application of these principles is developed as the seasoned operating man refreshes his mind again and again with the foundations of his profession; the true significance of detailed practice becomes more apparent, and the ambitious worker thus prepares himself for greater responsibilities and more accurate decisions.

For Industrial Betterment

General industrial activity makes for our prosperity as a nation. If the shops and mills are inactive, this depression affects all seriously, including the operating engineer, whose function it is to keep the power wheels in motion.

As the time approaches for the convening of the two largest organizations of operating engineers in America, it is to be hoped that, with their avowed objects for general good and their tremendous possibilities for advancement in knowledge and prosperity, they will give some heed to the upset and unrest of business conditions and find means to coöperate with the commercial interests in seeking a remedy.

While the war has had its influence, helping some business although hurting most, it would not account for so much idleness when the crops are big and their prices high, when our financial condition is strong, and when labor and capital were never so willing to coöperate. Conservatism, or in other words, lack of confidence seems to be the trouble. It is a time when the cautious are very slow about taking even the slightest risks.

One contributing cause of this uncertainty and fear is that honest business interests are in doubt as to just what they can do lawfully in the face of so much new and untried legislation. They do not know how to conduct their affairs in accordance with laws that are apparently interpreted one way today and another tomorrow, consequently, some have ceased to do business; their plants are closed and their employees idle. A wild "tooting on the horn of plenty" is merely noise, not a remedy, nor is the "popular" legislation of those politicians who are actuated by narrow and sordid self-interest. Our industrial prosperity furnishes the sinews of our citizenship, and our membership in the engineering organizations gives us ample authority to work in every legitimate way for those interests. No one influence has been so powerful as that of the engineers in placing wise boiler laws on the statute books, in safeguarding lives and property against criminal operation of power plants, and in framing the license laws governing our fellows. Is it not time, then, that we voice our protest against unwise legislation, investigation and control wherever and whenever it affects us? Our Government is a government of the people; we have a part in it. It is sovereign in its power to so adjust and fix conditions that we, the people, may enjoy the honest activity in our vocations, which is our right.

We need a much wider publicity for each proposed legislative measure, whether it affects our field directly or only indirectly. Therefore, we believe that every organization whose purpose it is to uplift and promote the interests of its members should have timely knowledge of proposed laws, and when affected by them should have the chance to express its approval or disapproval.

Cutting "Lumber" out of Reports

Ability to write a clear-cut, straightforward report unencumbered with superfluous material is worth cultivating. Many an operating engineer would dread the task of preparing a report, for instance, on the desirability of replacing a vertical cross-compound engine with a turbine. Usually, it is not so much the engineering problem as the literary end of the work that looks burdensome. Sound figuring is demanded first of all, but if the correct conclusion is reached there should be little further anxiety.

The form of report desired will depend on the employer, but most busy men want a terse, clear statement of conclusions, to which they can turn at once. While it is proper to include it, the reasoning upon which the recommendation is based is secondary. It is very easy to encumber a report with useless description and discussion. Such matter has appropriately been called "lumber" by an engineer experienced in scanning written matter, and good judgment in eliminating it is profitable.

In the case mentioned, a well-considered report might follow a statement of the problem in hand, with the conclusion that it will pay to make the change and that the annual saving would be about a certain sum. The rest of the report may then be an appendix in support of the contention.

The argumentative part of the report might include a statement of the capacity and service of the equipment to be displaced and the present operating costs and fixed charges, taking care to mention all assumed factors, like the percentage of interest, insurance and depreciation allowed. Test data on which existing cost figures are based may be summarized, and the limitations of the equipment in point of space, in meeting a growing load, etc., discussed. Then should follow an estimate of the cost of substituting a unit of increased capacity, with the fixed charges and estimated operating cost, with the statement of authority for steam consumptions assumed, guarantees offered, etc., and a final tabulation of yearly cost of a stated service, with a checking of the total against the present total if desired, or a comparison of unit expenses at the busbar. Modifications in auxiliary plant should also be covered in their proper places.

In presenting such information literary style will largely take care of itself if the report is logical and intelligible at all points. If it lacks clearness, if it cannot be checked by another competent engineer without consulting the writer, if it includes long and rambling accounts of possible equipment combinations without predicting definite results, and if it fails to concentrate similar information effectively, the force of the engineer's recommendations may be greatly weakened.

It is the technical judgment of the engineer that the employer values, and the selections of factors, the arithmetical processes and methods adopted concern him less. To an extent, the less language a report contains, the more helpful it will be to the employer's decision.

In January, 1909, a half dozen years ago, President Roosevelt wrote:

> The people of the country are threatened by a monopoly far more powerful, because in far closer touch with their domestic and industrial life, than anything known in our experience. A single generation will see the exhaustion of our natural resources of oil and gas and such a rise in the price of coal as will make the price of electrically transmitted water power a controlling factor in transportation, in manufacturing and in household lighting and heating.

And it still threatens; witness the defeat by its proponents of administrative water-power legislation in the late Congress.

Correspondence

Theoretical Efficiency of Heat Engines

The article by Mr. Heck in the issue of Apr. 20, concerning "Theoretical Efficiency of Heat Engines," contains a reference to an earlier statement by myself in POWER of June 9, 1914. In general, the detailed analysis of the problem by Mr. Heck is entitled to unqualified approval, were it not for the risk that some of the inferences might contaminate the future bibliography on the efficiency of heat engines because of an incomplete quotation of my remarks. The omission of the closing sentence of the paragraph to which reference is made is herewith supplied: "This (53.3%) cannot be approached on account of practical limitations." This would seem to be sufficient reassurance that I am not disposed to attach any value to the perfect gas formula as an indication of the attainable performance of heat engines.

In stating the "perfect gas" formula as a limit, I am not only safe, but also following the practice of authorities in thermodynamics sufficiently to remove the second law, for which the formula is simply an algebraic expression, from the realm of discussion. There may be other and lower limits for particular operations, but they do not serve as a means of disproving the validity of the Carnot cycle as one of limiting high efficiency. Nor do they establish "ideal steam cycles," as there are alternatives to the Rankine cycle which surpass it in efficiency.

There is a process, as indicated by Boulvin in 1897 and reproduced in the translation by Bryan Donkin of "The Entropy Diagram and Its Applications," which produces a working cycle for any fluid, including steam, attended

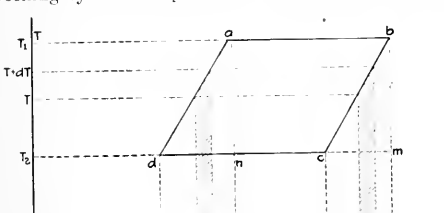

FIG. 1

by a higher efficiency than that of the Rankine cycle. In fact, carried to the limit it would have the same efficiency as the Carnot cycle, theoretically. In order to avoid a further misinterpretation I will now insist that this cycle, like that of the Carnot, cannot be completely realized on account of practical limitations. Nevertheless, an incomplete process can be devised and has actually been applied with noticeable improvements over the Rankine cycle.

Referring to the entropy diagram Fig. 1 (Fig. 7, Boulvin-Donkin) as reproduced without reference to a scale, *ab* and *cd* are isothermal lines, *bc* is an arbitrary path of the working fluid, *ad* reproduces and is exactly parallel to *bc*. The heat converted into work is proportional to the area *abcd*, or its equivalent as a rectangle *abmn*. The heat rejected in the cycle consists of two parts represented by the areas *cdd'c'* and *bcc'b'*. The latter is exactly equal to the heat required to carry out the process *da*. If, in the course of rejection of heat along *bc* and the drop of temperature from $T + dT$ to T a means is provided for storage of this heat and the maintenance of such tem-

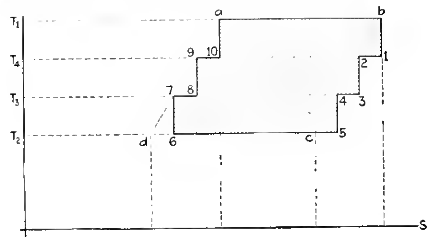

FIG. 2

peratures, it may with adequate equipment be applied to the heating of the fluid at a certain part of the path *da* without the intervention of a source of heat. The heat stored is represented by *bcc'b'* and is returned to the fluid as the area *d'daa'*. The efficiency of the cycle is the ratio

$$E = \frac{abcd}{d'dabcc'} \quad \frac{abmn}{a'abb'}$$

Since an infinite number of heat reservoirs cannot be applied, the theoretical limits of the cycle cannot be realized. But a modified adaptation of a limited number of regenerators or heat reservoirs, each operating in a particular temperature range, can be applied, with the result that the limit of thermal efficiency may be considerably higher than that of the simple Rankine cycle. The latter is not, therefore, an "ideal steam cycle."

Referring to Fig. 2 (Fig. 8, Boulvin-Donkin); replace the continuous line *bc* by the broken line *b 1 2 3 4 5 c* and the line *da* by a similar broken line *d 6 7 8 9 10 a* and we have a cycle having the same efficiency as the Carnot and which may be designated as a system for "regenerative" feed heating. The essential features of this cycle consist of abstraction of heat from the steam during its transit through a multiple-expansion engine and a successive higher heating of the feed water in a number of closed heaters, transferring their heat at different temperatures between T_1 and T_2. For example, the heat absorbed during the operation *1 2 4 3* and between the temperatures T_3 and T_4 is transferred to the feed water after it has been heated to the temperature T_3 and through the part *7 8 9 10* of the cycle. A perfect storage and restorage of heat in this manner is impossible, but a move in that direction, with highly gratifying results thermodynamically, has been made in the case of the multiple-expansion pumping engine for the Wildwood station of the City of Pittsburgh and devised by B. V. Nordberg.

A simple addition of but two elements of this regenerative feed-heating process is capable of such improvement of the Rankine cycle and of the illustrative example proposed by Mr. Heck that his figure of 0.335 for thermodynamic efficiency is too low and is not therefore an "ideal steam cycle." Moreover, the limitation of saturated-steam temperatures to 380 deg. F. is one which engineers need not hesitate to transgress, as pressures of 700 lb. per sq.in. and more on certain types of small boilers have been applied without calamity. The rapid improvements in the construction of steam turbines reveal that their designers are possessed of sufficient courage to venture on even to the utilization of a modified regenerative feed heating to further improve the cycle of operations, when, if ever, we may hope for a near approach to the realization of an efficiency indicated by the "perfect gas formula."

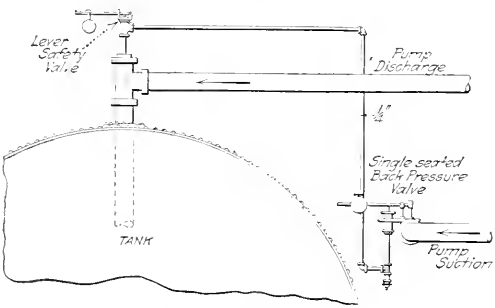
South Chicago, Ill.

Pump Regulator

The owner of a greenhouse wished to install a gas-engine-driven pump for watering. To provide for future demands for more water, and to avoid excessive pressure if the demand should decrease while the pump was being operated, it was necessary to provide for controlling the flow by means of the variation in pressure.

An ordinary single-seated back-pressure valve with outside dashpot was purchased and remodeled, the dashpot being placed on the opposite side so that pressure under the piston tended to close the valve. A common lever safety valve was connected to the discharge pipe near the tank, with its discharge leading through a 1/4-in. pipe to the bottom of the dashpot. A drip-cock was placed in this line for relieving the pressure, but it was not necessary.



Piping of Regulator

In operation, when the pressure exceeds that for which the safety valve is set, the valve opens and admits water under pressure to the dashpot. This raises the lever and weight and closes the valve. The pump then runs idle until the pressure in the tank falls and the safety valve closes. The slight leak around the stem of the safety valve relieves the pressure and the suction valve opens, due to the weight.

The pipe leading to the safety valve is extended nearly to the bottom of the tank to avoid loss of air, which would leak much faster than water if the seat of the valve should become worn.

To prevent the pump from becoming air-bound when running idle, it was necessary to drill and tap the water passages at the ends of the cylinder and connect check valves. The discharge from these was run through a globe valve to the hopper of the engine, and the overflow led to the sewer. This gives the engine cooling water in sufficient quantities when the pump is working, and the water in the hopper is sufficient for cooling when the pump is running idle.

The device will operate to open or close the suction with a variation of 5 to 6 lb.

A. H. Bullard.

Syracuse, N. Y.

Preventing Water Hammer in Blowoff Pipes

Regarding the suggestion of a safety valve on the blowoff line by Mr. Fenwick in the issue of May 11, page 650, and the editor's comment that the boiler might be drained of water should the safety valve on the boiler become sluggish, there is little likelihood of the valve opening at all after it has been in use a short time. Such has been my personal experience with safety valves on hot-water outlets, unless moved off their seat every day.

A safety valve will work on cold water, air and steam, but if hot water containing even a small quantity of lime or other scale-forming material is allowed to pass through it, the valve will become so attached to the seat that it may require a sharp blow to loosen it after the spring is removed. The surest way of preventing water hammer is to use two valves—one a slow-operating screw stem and the other a quick-operating one if desired—and always open the quick-acting and close the slow-acting valve first.

Stopping Leak in Heater Tube

By exploring with a lighted candle over the tops of the tubes in a vertical-tube heater under slight pressure, it was found that one was leaking. The candle would be instantly extinguished when held over the leaking tube, but not when held over the others. By sliding a wad of waste into the tube on a wire it was determined that the leak was about half-way down. The heater could not be spared long enough to put in a new tube. The question was how to stop the leak. To plug the tube in the usual way the heater would have to be taken down to get at both ends.

The first attempt consisted in driving into the tube each side of the leak a wood plug long enough to reach the heater heads at both ends. This did little good.

Next, a quantity of Smooth-On cement was put on top of the plug below the leak, another plug driven in, with its top above the leak, more Smooth-On cement added, with still another plug on top extending to the upper head. Had sufficient time been allowed for the cement to harden, this plan would probably have been successful, but the tube got to leaking again after a time.

The trouble was finally stopped as follows: A plug long enough to reach to the bottom head of the heater was driven below the leak and a quantity of molten babbitt was poured in and tamped tight with an iron bar. Then another plug long enough to reach from the babbitt already in to a point above the leak was driven in, and more babbitt was poured and tamped. A plug reaching to the top head was then put in, and the leak was effectually stopped.

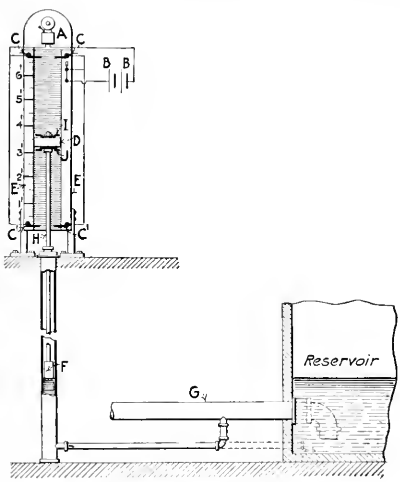
Reservoir Indicating Gage

Originally, the only way of telling the amount of water in our 17,500-gal. reservoir was by going out and looking down into it. In summer it was not so bad, but when the thermometer registered 40 deg. below zero it was different.

I constructed a gage to indicate the water level, which works to perfection. On a 1x6-in. board, the length of which corresponded to the depth of the reservoir, I fastened two pieces of 2-in. maple flooring *E* with their grooves facing each other. A block *D*, to slide freely in the grooves, is fastened to a light rod *H*, and on the end of this rod is a float *F*. A 3-in. pipe is used for the float to work in, and this extends down to the level of the bottom of the reservoir. A ½-in. pipe connects the 3-in. pipe to the suction pipe *G* (or to the bottom of the reservoir itself) and maintains the same water level in the 3-in. pipe as that in the reservoir. To the block *D* are fastened springs *I* and *J*, and to the top and bottom of the board



Indicator and Alarm

are fastened contacts *C* and *C'*. At the top a bell is placed connected to batteries *B*. The gage is graduated in feet and inches and is so marked that the reading corresponds with the height of water in the reservoir.

When the reservoir is full the spring *I* on the block makes contact with *C* at the top, completing the circuit and ringing the bell, and at the bottom a similar contact is made when the water is low. The wiring is concealed behind the gage board, and a switch can be used to cut out the bell.

The gage is located in the most convenient place and wired so that the bell may be where the operators are most likely to hear it.

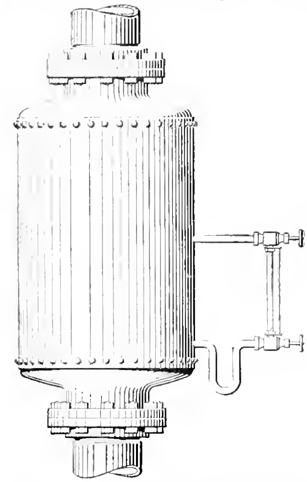
To Prevent Gage-Glasses Breaking

Anyone troubled with separator glasses breaking should make a drop or trap in the bottom connection so as to form a water seal. This will stop the flow of steam



Water Seal in Gage Connection

in the glass. The drop needs to be only from 3 to 6 in. The illustration shows the application of the idea.

Clay Center, Ohio.

Steam Pressures and Piston Speed

The editorial on page 548 of the Apr. 20 issue very properly called the attention of the operating engineer to the increased hazard in engine operation today, as compared with twenty years ago, due to the increase in the steam pressures used. I had thought to criticize this editorial, because it did not take account of the fact that during the time steam pressures have been mounting higher and higher the demand for closer regulation for electric-light engines has increased, and in order to meet this demand for closer governing the weight of the flywheel has steadily increased.

The increased weight of flywheels has acted, of course, to retard the speeding up of the engine when the governor lost control, and this, in some measure, has acted to counteract the effect of the higher steam pressure tending to hasten the approach of the bursting speed in case of accident. I hesitated about sending such a criticism in, because it requires considerable temerity to take issue with an editor and I was not so sure that I was altogether right, not holding a first-class engineer's license; but since I have seen the remarks on this same editorial by Mr. Williams on page 585 of the Apr. 27 issue, I am willing to take a chance.

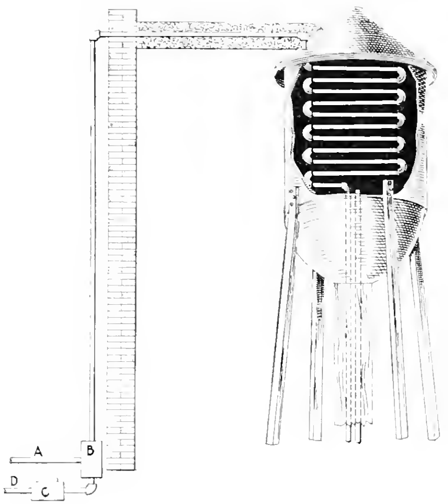
How a change in engine design during the last 25 years so that a working piston speed of 600 ft. per min. has been made 900 ft. per min.—or if made 9000 ft. per min.—could have such effect on the safety of flywheel operation as pointed out in Mr. Williams' article, is more than I can understand. Calling attention to the high piston speed of the modern engine as a factor contributing to flywheel accidents seems about on a par with figuring the explosive energy in a boiler from the number of pounds of coal burned per square foot of grate surface. Will not Mr. Williams enlighten us further on how high piston speed affects the safety of the flywheel?

A. K. JONES.

Melrose, Mass.

Steam Coil in Water Tank

The illustration shows a large water-supply tank. It is exposed, that is, it is erected outside and elevated 60 ft. from the ground; the water is pumped by motor or windmill from a river some distance away. The pipes to and from the tank are run underground in a waterproof



STEAM CONNECTIONS TO THE WATER TANK

box. The pipe *A* carries the exhaust from three duplex steam pumps, one of which is always working and sometimes all three are in service. A separator *B* that removes water and oil from the steam is provided, and another, *C*, which removes the oil from the condensate, so the clean water flows along pipe *D* and discharges into the hotwell; the oil is discharged into a filter. The exhaust riser runs to the tank, where it enters a coil surrounded by the tank water.

Where the pipe passes from the building to the tank it is covered for protection from frost and cold. The steam in the coil keeps the water in the tank from freezing. The water is used for domestic service as well as for the power plant, therefore the exhaust steam could not be discharged directly into it. The water in the pipes or tank has not frozen, although the outside temperature has been as low as 30 deg. F. below zero. A relief valve was attached to the exhaust pipe near the pumps to provide for any possibility of a stoppage in the coil or elsewhere.

Ballade of the Stokers

The following clipping from the *Cleveland Plain Dealer*, I believe, expresses the true inward feeling of the stoker in a moment of resentment. You may care to use it.

Our muscles ache from stretch and strain,
 Our eyes are sore with salty sweat;
Our blistered skins are gnawed with pain,
 Our souls, the Devil claims for debt.
 Before us there a gage is set—
The only oriflamme we know!
 Above, they fight the foe we've met—
Who gives a damn for us below?

The great guns boom across the main,
 The Steam Boss comes with curse and threat.
We stuff the hot, red maws in vain
 Another pound of steam to get!
 With senses taut, we toil and fret
And wonder how our fortunes go
 Above, we know they battle yet—
Who gives a damn for us below?

A crash—a roar—and cries profane!
 We slip, we sprawl—our floors are wet!
The bulkheads close, and we—remain!
 The Steam Boss lights a cigarette.
 The hot steam scalds, the waves abet—
We choke—we die—we have no show
 To save the rest! But where's regret?
Who gives a damn for us below?

Prince! And you of the epaulet!
 The world on you will praise bestow,
From Admiral to young Cadet.
 (Who gives a damn for us below?).—Planchette.

WILLIAM D. TAYLOR.

Lorain, Ohio.

Boiler Inspections

In a recent issue it is stated that boiler inspectors do not always report defects, to which statement I agree. We have state inspection here, but it seems as if the main thing is to get the inspection fee. I have been inspecting boilers for some time for various companies and have followed both the state and insurance-company inspection in various plants.

In one plant in New Mexico I was sent to inspect three horizontal-tubular boilers carrying 150 lb. pressure that had been inspected about fifteen days before. The following defects were found: A handwheel was gone on a water-gage cock; three wheels missing on the gage-glass cocks; brickwork on all the boilers in bad shape; a 6-in. globe valve had a hole in the body, over which a piece of packing was clamped to stop the leak; the pressure gages had not been tested for three years; some flues were leaking on all of the boilers at the back head, and two of the boilers had small bags on the fire sheet; in one boiler two braces were broken and they all needed scaling. I recommended that the plant be closed until repairs were made, and the superintendent nearly had a fit.

Another plant contained water-tube boilers that had been giving trouble from pitting tubes. The engineer claimed to have been an inspector and resented my making an inspection, but as I was boiler foreman I made one at the next washout. The tubes were clean owing to using a cleaner. When the manhole was removed on the steam drum, the steam line was found leaking so badly past the valve that the line had to be cut and a blind gasket put in to keep the steam out.

The drum was badly scaled, seven riser tubes were plugged and the rest were dirty. The risers were cleaned and a new set of tubes recommended, also that all leaks in the steam line and valves be repaired before the boiler was returned to service.

It is time that the United States Government controlled the inspection of all boilers or enacted some law that will make it a criminal offense to report a boiler in good condition unless it is so.

L. B. MOORELAND.

Denver, Colo.

Charging Small Storage Batteries

In charging a small storage battery the common method is to use a bank of lamps for regulating the current, as shown in Fig. 1. By this means the current passing through the battery is roughly determined by the number and size of lamps used. The simplest way to determine the correct battery connection is to connect the wires first one way, and then the other, and note which way the lamps burn the dimmest; the dimmest is the correct way. Another simple method is to put the ends of the wires into a cup of water containing a little salt, acid or sal ammoniac; the wire around which the most bubbles are seen is the negative and should be connected to the negative side of the battery.

The foregoing method is very wasteful of electrical energy. Suppose a three-cell battery is to be charged from a 110-volt circuit; the battery will take only a little over six volts and the difference must be taken up by the lamps. Therefore, less than 7 per cent. of the energy expended is actually used in charging the battery.

To avoid this loss the writer devised the method shown in Fig. 2, where L and L' represent the wires leading

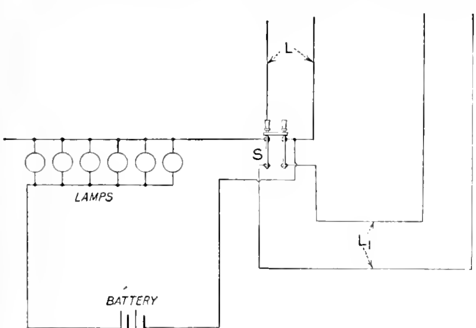

FIG. 1. USUAL METHOD OF CHARGING BATTERY

from the exciter to the main field of an alternator and S is the usual double-pole switch on the exciter circuit of the switchboard. One of these wires is disconnected from the switch S and is connected to one side (2) of a two-point switch, the common point (1) of which is connected to switch S at P. From terminal 2 on the two-point switch a wire leads to one side of the battery and the other side is connected to the remaining point (3) of the switch through an ammeter. A rheostat is connected as shown so that the current flowing through the battery can be regulated. The meter must be connected so as to measure only the current flowing through the battery.

When the two-point switch is connected from point 1 to point 2 the battery is out of circuit and should have one of its wires disconnected to prevent it from discharging through the rheostat. The battery should never be connected in circuit when the exciter is not running, for then it will either discharge through the rheostat or through the exciter, depending on which way the two-point switch is thrown.

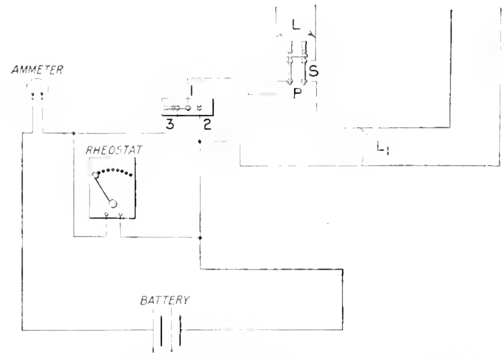

FIG. 2. CHARGING BATTERY IN SERIES WITH GENERATOR FIELD

When not charging, the two-point switch is turned to connect from 1 to 2. To put the battery in circuit, first connect the wires to it and then turn the switch to connect from 1 to 3. If the connections are right the voltage on the machine being excited will fall slightly as the voltage of the battery is deducted from that of the exciter, but if the connections are wrong the voltage of the machine will be raised slightly, as the voltage of the battery will be added to that of the exciter. This is the only test for polarity required. The battery should always be disconnected before shutting down the machine charging it, as otherwise its current will be discharged through the exciter armature and the polarity of the machine may be reversed.

When charging batteries by this method the only energy wasted is the little taken by the rheostat. This will depend on the current required for charging as compared with that passing through the exciter circuit. If the exciter circuit does not carry as much as is called for to charge the battery, the latter will have to be left in circuit longer; that is, it will have to be charged at a lower rate.

G. E. MILES.

Denver, Colo.

Electrically Controlled Damper Regulator

In Mr. Carples' comments on my letter that appeared under the above heading in POWER, Apr. 13, page 517, he says he believes it would be difficult to determine the quantity of air required to burn a certain kind and quality of coal per square foot of grate per hour. He further says I do not explain how this is determined. It is quite easy to determine, when one is getting the best possible flue-gas analysis daily, and the coal runs uniform, as it does.

Mr. Carples is quite right in his contention that the quantity of air required changes with the quality and kind of coal and must be redetermined when these factors change. It is well known that the average CO_2 can be kept at a higher percentage under close draft regulation than when allowed a wide fluctuation, and that under close regulation the efficiency of a boiler will be high.

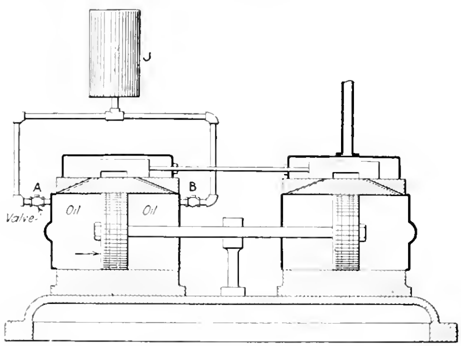
There is no balanced-draft system that I ever heard of that operates without blowers. What my letter makes clear is that we accomplish results nearly equal to those obtained by balanced-draft systems and without the use of blowers or the cost of power to operate them. I hope this is clear to Mr. Carples.

HENRY W. GEARE.

New York City.

Supply for Oil-Cushion Cylinder

On large hoisting engines and others which are reversed frequently the links are shifted by an independent steam-cylinder equipment. In order to avoid too quick and destructive motion of the piston, another cylinder filled with oil is fitted with a piston and D-valve and connected, to oppose the steam piston's motion by acting



CUSHIONING DEVICE FOR REVERSING ENGINE

on a cushion of oil. The illustration shows the general arrangement.

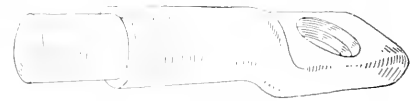
If the oil does not entirely fill the cylinder there is sure to be a jerky motion at the beginning of the stroke somewhat similar to that of a direct-acting pump which is getting air with the water it is pumping. To make sure that the cylinder was filled at all times, I connected a large oil cup *J* to the oil-cushion cylinder by means of small pipe and check valves *A* and *B*, as shown. The action is as follows: When the piston moves in the direction of the arrow, check valve *A* opens, if there is a partial vacuum created, and admits a little oil. At the same time check *B* is closed, so that there is no escape of oil through it. In the other direction the action is reversed, and the oil cylinder is kept full at all times.

G. D. DEARBORN.

New York City

Home-Made Lugs

While making some changes on a direct-current switchboard some time ago, we ran out of lugs, or terminals, and as it would take two days to get them from the nearest supply house, we decided to make them out of half-inch brass pipe annealed by heating to a dull red and ducking in water. We then sawed off several pieces



TERMINAL LUG MADE OF PIPE

about 2½ in. long and drove a piece of ⅝-in. round iron in one end about 1 in. The other end was then put in a big vise about 1¼ in. and flattened down. The iron was then removed and the hole drilled in the flat part, which was then finished up with a file. The lugs proved to be just as strong as the cast ones and, being of brass, were also good conductors. This saved us two days' delay.

J. GERBER.

Dansville, N. Y.

Paper-Mill Power Plants

I have been a reader of POWER for a long time, but do not remember reading any articles about the paper mills. I am now in charge of a plant consisting of 3300 hp. in steam and 1400 kw. generated by water power, furnishing power for making sulphite fiber and paper. Perhaps I am over-zealous in my line of business, but I should like to hear from others working along the same lines, and perhaps we might compare notes and help one another Only one who has worked at it can know the varied experiences encountered in the pulp- and paper-mill work

Steam is used for everything, from thawing frozen pulp to blowing out screen plates, and when things are going along fine, suddenly a 6-in. pipe line is opened into a digester, or two or three steam jets into the beaters, which will keep a man guessing how his coal report will look in the morning.

Let's make ourselves heard.

W. H. HOLMES.

Lincoln, N. H.

Examination Questions

I am sending a list of questions (from memory) which were recently asked in an examination for the position of third-class engineer, hoping they may help others.

1. What causes scale, and how is it prevented?
2. What is a water column, and is it always dependable?
3. What is a fusible plug, and what is it used for?
4. Describe a heating system, and show how condensation is returned to the boiler.
5. Name several causes for an engine pounding and the remedy for each.
6. How is an engine governed? Describe a governor.
7. Describe a feed-water heater, and give two reasons why water should be heated before entering a boiler.
8. What parts of an elevator should be inspected daily?
9. What care should be used in starting a new boiler?
10. (a) Sketch a round pipe strap. What is the vent for? (b) How is a 4-in. soil pipe calked?

RAYMOND J. CAREY.

Fitchburg, Mass.

Inquiries of General Interest

Short-Stroke of Pump—What will cause a duplex pump to reverse before completing the stroke?

C. W. O.

The pump will short-stroke if the lost motion of the steam valve is not enough to delay reversing of the steam valve until the piston has completed its stroke.

Changing from Noncondensing to Condensing—What difference should be made in the setting of the valves of a compound engine to run condensing in place of noncondensing?

M. D.

For running condensing the principal change required in the valve setting would be to secure earlier closing of the exhaust valves of the low-pressure cylinder, so as to obtain the same cushioning effect from compression of exhaust steam of lower pressure.

Flash and Burning Points of Oils—What is the difference between the flash point and the burning point of an oil?

J. R.

The flash point is the lowest temperature at which the oil discharges vapors that ignite with a flash when a lighted taper or match is passed at intervals of a few seconds over the surface of the oil, while the burning point is the temperature which the oil must attain for the vapors to burn continuously over the whole surface.

Advantage of Narrower Belt—Where the narrower belt is sufficient for transmission of the power, what saving of power would be obtained by substituting a 3-in. single leather belt in place of a 4-in. single leather belt for transmission of power from an electric motor?

P. C.

For the same total belt tension there would be no saving of power except that lost in bending the wider belt around the pulleys. With belts in good condition, the power thus lost is so small that the saving from use of the narrower belt would be inappreciable.

Why Smaller Discharge Pipe Worked Better—For pumping water over a hill a pump with a 4-in. discharge pipe would not do the work, but upon replacing the pipe with one 2½ in. diameter, a satisfactory amount of water was delivered. Why should delivery be better by use of the smaller discharge pipe?

E. A. W.

It is probable that at a time when the larger pipe was in use a greater rate of discharge was permitted from the lower end than was being supplied by the pump, and that siphonage caused the discharge line to become airbound at the crest of the hill.

Kinking of Boiler Flue—What would cause one flue of a return-tubular boiler to become warped, or kinked out of line, more than others in the same horizontal row?

F. K.

If the flue was under stresses of cold bends, such as it might have received from rough handling or from straightening the flue before it was set in the boiler, the stresses present would draw it more out of line with each repeated heating and cooling and permanent distortions would be produced to a greater extent when the cooling was sudden, as by admission of much cold air through the fire-door for the purpose of checking a hot fire.

States Having Workmen's Compensation Acts—In what states have workmen's compensation acts been passed?

S. K. C.

To this date Workmen's Compensation Acts have been adopted by 30 states, as follows: Arizona, California, Colorado, Connecticut, Illinois, Indiana, Iowa, Kansas, Louisiana, Maine, Maryland, Massachusetts, Michigan, Minnesota, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New York, Ohio, Oklahoma, Oregon, Rhode Island, Texas, Vermont, Washington, West Virginia, Wisconsin and Wyoming. In addition to these an act was passed by the State of Kentucky, but was declared unconstitutional.

Standards of Hardness of Water—What is the basis upon which the degree of hardness of water is designated?

J. B. R.

Hardness of water is usually designated according to one of the following standards of hardness:

French—Milligrams of calcium carbonate in 100 grams of water or parts per 100,000 of water.

German—Milligrams of lime in 100 grams of water, or parts per 100,000 of water.

English—Grains of calcium carbonate per Imperial gallon of 70,000 grains.

American—Grains of calcium carbonate per U. S. gallon of 58,381 grains.

Power Required for Operation of Pump—For raising water to an elevated tank, what horsepower will be required to operate a 7x10-in. pump making 95 strokes per minute with a suction lift of 8 ft. and working against a pressure of 70 lb. per sq.in., allowing for 15-per cent. slippage and 22 per cent. of the power lost in friction?

K. C.

With 15-per cent. slippage the effective length of stroke of the pump would be 85 per cent. of 10 in., or 8.5 in. A suction lift of 8 ft. would be equivalent to overcoming pressure of the atmosphere of

$$8 \times 0.434 = 3.47 \text{ lb. per sq.in.}$$

which, together with the discharge pressure, would amount to

$$3.47 + 70 = 73.47 \text{ lb. per sq.in.}$$

pressure overcome by the piston. The area of piston being

$$7 \times 7 \times 0.7854 = 38.4846 \text{ sq.in.}$$

the work performed in lifting the water would be

$$38.4846 \times 73.47 \times \frac{8.5}{12} \times 95 = 190{,}264.73 \text{ ft.-lb. per min.}$$

or at the rate of

$$190{,}264.73 \div 33{,}000 = 5.76 \text{ hp.}$$

With 22 per cent. of the applied power lost in friction, the power required for operation of the pump would be

$$\frac{5.76}{1.00 - 0.22} = 7.38 \text{ hp.}$$

Torsional Deflection of Iron Shaft—What would be the torsional deflection of a vertical iron shaft 10 in. diameter and 150 ft. long, running 200 r.p.m. and transmitting 1350 hp.?

G. H. R.

The angle of torsion is given in degrees by the formula,

$$A = \frac{583.6 \text{ P a l}}{d^4 G}$$

in which

l = Length of shaft (inches),

d = Diameter (inches),

P = Force (pounds) applied at the extremity of a lever arm = a in inches,

Pa = Twisting moment,

G = Modulus of torsional elasticity, which for an iron shaft would be equal to about 10,000,000.

Transmitting 1350 hp. at 200 r.p.m., the foot-pounds would be

$$\frac{1350 \times 33{,}000}{200} = 222{,}750 \text{ ft.-lb. per revolution,}$$

and the twisting moment, Pa, in inch-pounds would be

$$\frac{222{,}750 \times 12}{2\pi} = 425{,}420$$

As l, the length of shaft, is 150 ft. = 1800 in., and d, the diameter, 10 in. ,then by substitution the formula becomes,

$$A = \frac{583.6 \times 425{,}420 \times 1800}{10^4 \times 10{,}000{,}000} = 4.47 \text{ deg.}$$

which on the circumference of a 10-in. diameter shaft would measure

$$4.47 \times \frac{10 \times 3.1416}{360} = 0.39 \text{ in., or about } \frac{3}{8} + \frac{1}{64} \text{ in.}$$

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Missouri N. A. S. E. State Convention

Members of the National Association of Stationary Engineers in Missouri held their annual state convention May 19-21 at the Planters Hotel in St. Louis. With the 40 delegates and a number of visiting engineers from the vicinity, the attendance was up to normal. At the opening session, Wednesday morning, Associate City Counselor Charles H. Davies, in behalf of Mayor Kiel, welcomed the delegates to the city. In the response Fred W. Raven, national secretary, summarized briefly the aims and policies of the organization and the benefits to be derived from the practical education available to the members. Referring to Missouri's well-known motto, he suggested that the "me" be changed to "them." In other words, the members should show others the benefits to be derived from, and get them into, the organization. First of all, more interest must be taken in the work. Missouri has been drifting, and if she is to keep pace with her progressive neighbor, Kansas, there is urgent need of good work in the state. More enthusiasm, individual effort and the election of active officials were the things most needed.

J. H. Van Arsdale, past-national vice-president, reminded the engineers that they were assembled for the purpose of collectively seeing what could be done for the benefit of the organization. It stood for education, and many benefits could be derived from membership if advantage were only taken of opportunities available. Although national officers were doing all they could to improve the official paper there was need of the assistance of the engineer. The latter was not doing justice to the paper when he failed to credit its advertising pages as the source of inquiries for power-plant products. State President Daggett responded, urging a full attendance in the exhibit hall. The convention was then formally opened and the usual committees appointed.

MISSOURI N. A. S. E. DELEGATES ASSEMBLED AT ST. LOUIS

Routine business occupied the afternoon session. In the evening a get-together banquet proved a great success. Afterward, the diners retired to the exhibit hall and joined in favorite selections from the official songbook.

Much of the Thursday morning session was taken up by a discussion on the needs of the state organization. The advisability of discontinuing the convention, holding it at less frequent intervals or perhaps combining with Kansas, was considered. That general opinion favored continuance along the usual lines was evidenced on Friday when Kansas City was chosen as the convention city for 1916.

Thursday afternoon was featured by an inspection trip through the Anheuser-Busch Brewery and the manufacturing plant of the Busch-Sulzer Bros. Diesel Engine Co. In the evening an illustrated lecture by E. A. Garrett on the product of the latter company drew a large attendance.

On Friday morning news of the death of C. H. Huntington, president of St. Louis No. 2, was received with many manifestations of sorrow. The convention drew up suitable resolutions and authorized a presentation of flowers. Only necessary business was completed and all entertainment features on the program, such as a vaudeville entertainment listed for that evening, were eliminated. The following officers were elected and installed: L. Kjerluff, president; Charles Parkinson, vice-president; Rice Nance, secretary; F. H. Munsberg, treasurer; F. Middleton, conductor; Jacob Newpert, doorkeeper; Fred Key, trustee; S. J. Hunt, deputy, and L. Kjerluff, assistant deputy.

The companies represented in the unusually good exhibition and those who contributed follow:

The V. D. Anderson Co.
Arrow Boiler Compound Co.
Baumes-McDevitt Machinery Co.
A. Leschen & Sons Rope Co.
The Lunkenheimer Co.
James P. Marsh & Co.
George F. Matthews & Co.
Bennett-Dreyer-Buss Belting Co.
Big Muddy Coal & Iron Co.
C. J. & F. E. Briner.
Broderick-Bascom Rope Co.
Busch-Sulzer Bros.-Diesel Engine Co.
Clement-Restein Co.
Commercial Electrical Supply Co.
Crandall Packing Co.
Crane Co.
Dearborn Chemical Co.
Donk Bros. Coal & Coke Co.
The Edward Valve & Mfg. Co.
Walter L. Flower Co.
The Garlock Packing Co.
Greene, Tweed & Co.
Hawkeye Compound Co.
Heine Safety Boiler Co.
Price Hill.
Home Rubber Co.
H. W. Johns-Manville Co.
Kayser Tanning Co.
Keystone Lubricating Co.
Kupferle Bros. Mfg. Co.
Modern Engineering Co.
Morse Engineering Co.
Mound City Oil & Supply Co.
Mount Olive & Staunton Coal Co.
"National Engineer"
New York Belting & Packing Co.
Otis Elevator Co.
The P.-K. Engineers.
The Peerless Rubber Co.
Pierce Oil Corporation.

F. C. Schwaner & Co.
Spencer Turbine Cleaner Co.
Standard Oil Co.
Western Boiler Compound & Chemical Co.
Western Valve Co.

Massachusetts Licensing Act Passed

Governor Walsh of Massachusetts signed an act on May 17 (Chapter 259) relative to the licensing of engineers and firemen, following extended discussion of this subject by the present Legislature. The act retains the supervision exercised by the boiler-inspection department of the district police over steam boilers and engines, licenses, examinations, etc. Its definitions of classes of licenses are of chief interest.

The act provides a nine-horsepower limitation on the size of boilers and engines that may be operated without a license, with the well-known exception of boilers and engines of locomotives, motor vehicles, residences and agricultural power units. Under its terms, to be eligible for examination for a first-class fireman's license, a person must have been employed as a steam engineer or fireman in charge of operating boilers for at least a year, or must have held and used a second-class fireman's license for not less than six months. To be eligible for examination for a third-class engineer's license, a person must have been employed as a steam engineer or fireman in charge of operating boilers for not less than one and one-half years, or must have held and used a first-class fireman's license for at least one year.

To be eligible for examination for a second-class engineer's license a person must have been employed as a steam engineer in charge of a plant having at least one engine of over 150 hp. for not less than two years, or he must have held and used a third-class engineer's license either as an engineer, assistant engineer or fireman for not less than one year, or have held and used a special license to operate a first-class plant for not less than two years; except that any person who has served three years as apprentice to the machinist or boiler-making trade in stationary, marine or locomotive engine or boiler works and who has been employed for one year in connection with the operation of a steam plant, or any person graduated as a mechanical engineer from a duly recognized school of technology, who has been employed for one year in connection with the operation of a steam plant, shall be eligible for examination for a second-class engineer's license. A person must have been employed for not less than three years as a steam engineer in charge of a plant having at least one engine of over 150 hp., or he must have held and used a second-class engineer's license in a second-class or first-class plant for not less than one and one-half years.

Licenses shall be distributed as follows:

Engineer's licenses: First-class, to have charge of and operate any steam plant; second-class, to have charge of and operate boilers or engines, no one of which shall exceed 150 hp., or to operate a first-class plant under the engineer in direct charge; third-class, to have charge of and operate boilers not exceeding 150 hp. in the aggregate, or engines not exceeding 50 hp. each, or to operate a second-class plant under the engineer in direct charge; fourth-class, to have charge of and operate hoisting and portable engines and boilers; portable class, to have charge of and to operate boilers and portable engines except hoisting and steam fire engines; steam fire engineer's class, to have charge of and to operate steam fire engines and boilers.

Firemen's licenses: Extra first-class, to have charge of and operate any boiler plant; first-class, to have charge of and to operate any boiler where the safety valve is set to blow at a pressure not exceeding 25 lb. per sq.in., or to operate high-pressure boilers under the engineer or fireman in direct charge thereof; second-class, to operate any boiler under the engineer or fireman in direct charge thereof. A person holding an extra first-class or first-class fireman's license may operate a third-class plant under the engineer in direct charge of it.

Special license: A person who desires to have charge of and operate a particular steam plant may be examined for such a license, but no engine of over 150 hp. is to be operated by such a person except where the main power plant is run by water power exclusively during the major part of the time and has auxiliary steam power for use during periods of low water.

Coming Pennsylvania State N. A. S. E. Convention

The annual convention of the Pennsylvania N. A. S. E. will meet at Pittsburgh, June 18 and 19. Headquarters will be at the Monongahela House, where all sessions are to be held. State President J. D. Rostron, of Chester, Penn., will preside. The other state officers are: P. O. Johnson, Philadelphia, vice-president; R. B. Ambrose, Pittsburgh, secretary, and D. E. Seeley, Dubois, treasurer. The committee in charge of the local arrangements for the convention is made up from the membership of the three Pittsburgh associations. This committee, of which George A. Bu Miller is chairman and L. S. Evans (care Lawrence Paint Co., Pittsburgh), is secretary, is preparing an elaborate entertainment and inspection program.

PENNSYLVANIA N. A. S. E. OFFICIALS

Jas. D. Rostron, State President (center); P. O. Johnson, State Vice-President (left); and R. B. Ambrose, State Secretary (right)

New Jersey N. A. S. E. Convention

The state convention of the New Jersey National Association of Stationary Engineers will be held in Masonic Hall, Warren and State St., Trenton, June 3 to 6, inclusive. Delegates' headquarters will be at the Trenton House, opposite the exhibit hall. A large attendance is expected on account of Trenton being a central location.

J. F. Lightford, president of Trenton No. 4, N. A. S. E., is chairman of the executive committee; William Hirst, vice-chairman; William W. Law, treasurer; E. A. Corbett, secretary.

New Johns Hopkins Buildings Dedicated

After the general exercises dedicating the new engineering building and power plant of the Johns Hopkins University, at Homewood, Baltimore, Md., an inspection tour through the engineering laboratories and power station was arranged for the evening of May 21. A short talk was given by the heads of the various departments, explaining the main features of the work under their charge, closing with a few general remarks by the newly installed president, Frank Johnson Goodnow, lately constitutional advisor to the Chinese Government. Instruction in mechanical engineering is in charge of Prof. Carl Clapp Thomas, M. E.; that in civil engineering is directed by Prof. Charles Joseph Tilden, S. B., and in charge of the department of electrical engineering is Prof. John Boswell Whitehead, Ph.D.

The power-station equipment is used as far as possible for both instructive experiments and supplying heat and electric current for the buildings. The steam and electric distributing systems are in light, roomy tunnels, which also afford convenient passageways from building to building.

In the power station are four B. & W. type water-tube boilers, each having 2640 sq.ft. of heating surface and carrying 125 lb. pressure. They are equipped with automatic feed-water control, high- and low-water alarm, and in the brick setting there are openings for thermometers, draft gages, CO_2 recorders. Under two boilers there are underfeed (Taylor) stokers and under the other two overfeed (Roney) stokers. The air supply from the fan to the stokers is measured by a Thomas recording gas meter, designed by Professor Thomas, and an accurate record may be made of the air supply to check with the flue-gas analysis.

The brick chimney, 160 ft. high and 7 ft. in diameter, has openings at various points (and convenient staging or balconies) from which gas samples may be obtained, and also the temperature and velocity determined.

By using Orsat flue-gas apparatus, of which there are two side by side, one a German type and the other American, the composition of the flue gas may be determined and the degree of efficiency of the furnace operation indicated. A Pintsch CO_2 recorder, which is a new and interesting development, takes samples of gas from the breeching just below the damper. It passes through a dry excelsior purifier, then enters a cooling coil that is jacketed by the water used to operate the ejector. This brings the gas to a constant temperature. It next passes through a small precision gas meter containing light mineral oil and then through an absorber, where the CO_2 is removed. The absorbing agent is slaked lime mixed with sawdust to keep it porous. This can be readily renewed once a week at very small cost. After leaving the absorber the gas passes through another cooling coil to remove the heat generated by the absorption of the CO_2 and is then directed through a second precision gas meter. The siphon ejector is placed after the second meter. The first meter measures all the gas; the second measures a lesser quantity by the amount of CO_2 absorbed, and therefore runs slower. A differential gear and mechanism transmutes this speed difference into vertical pen motion and makes a record on the chart. The pen is released and makes a dot on the chart for every cubic foot passing, its relative position indicating the percentage of CO_2. The coal- and ash-handling systems are so arranged that during tests accurate weights may be taken.

From the boilers the steam may be led through an independently fired superheater to the engines or by a direct line in a saturated state, so as to demonstrate the effect of superheat on the efficiency and steam consumption in the engines under various conditions of operation.

In the main engine room there are three units: A Harrisburg four-valve reciprocating engine rated at 150 hp. at 200 r.p.m., directly connected to a Westinghouse 100-kw., 250-volt generator. A Kerr (Economy) turbine, connected to an Allis-Chalmers 100-kw. generator; and a Westinghouse turbine set. All of these are so piped that the exhaust steam may be used for heating the buildings or may be directed to a Wheeler surface condenser having 300 sq.ft. of cooling surface capable of condensing 2500 lb. of steam per hour with cooling water at 70 deg. The condensation may be led to the weir tanks and measured. The cooling water also is measured by a venturi meter.

In another part of the building a Nash producer-gas engine rated at 14 hp. is supplied by a Smith suction gas producer using anthracite coal, which gives the student an idea of the general requirements of such apparatus.

A Diesel-type crude-oil engine loaned by the Allis-Chalmers Manufacturing Co. is used for experimental purposes. It is equipped with special attachments for testing and is capable of using almost any kind of clean liquid fuel.

On the floor above, a Buckeyemobile engine, directly connected to a 75-kw. generator, represents the latest development in a self-contained steam unit of remarkable efficiency. Various other equipment connected with the heating and ventilating operation, and meters, oil testers, calorimeters, etc., give the student a comprehensive insight into actual power-plant management and, together with extensive laboratory equipment, make it possible for the instructor to demonstrate the latest practice in engineering.

PERSONALS

Walter R. Johnson is no longer associated with the Harrison (Cochrane) Safety Boiler Works. He was formerly Southern representative, with headquarters at Atlanta, Ga.

H. D. McCaskey has been designated as statistician in charge of the Division of Mineral Resources, U. S. Geological Survey, succeeding Edward W. Parker, resigned, as noted elsewhere. Mr. McCaskey was a mining engineer in the Philippine Mining Bureau from 1900 to 1906, and has been with the Geological Survey since 1907. He will also continue his work upon the metallic resources of the United States.

Edward W. Parker, statistician in charge of the Division of Mineral Resources, U. S. Geological Survey, and for many years the Government coal statistician, leaves the Government service July 1 to accept a responsible position with the anthracite mining interests. Director George Otis Smith, of the Survey, has gone on record as expressing his regret at this termination of Mr. Parker's long and efficient service, which, in addition to the work mentioned, has comprised a study of coal testing and conservation and the publication in the engineering press of many papers on coal mining and production.

ENGINEERING AFFAIRS

The Worcester Polytechnic Institute will celebrate its fiftieth anniversary June 6-10. The dedication of a new gymnasium, a special meeting of the American Society of Mechanical Engineers to be held at the works of the Norton Co., and the annual commencement exercises are among the events scheduled. President Wilson, who was the commencement orator twenty-five years ago, has expressed a desire to be present, and it is hoped that the pressure of public business may permit his attendance. Gen. George W. Goethals has already accepted an invitation to be present.

NEW EQUIPMENT

ATLANTIC COAST STATES

Bids will be received until June 1 by the Children's Institution Department, Boston, Mass., for a 15-kw. direct-connected engine and generator at Rainsford Island. John O'Hare is Comr.

The town of Milford, Mass., is considering the purchase of the plant of the Milford Electric Light & Power Co. William Plattner, Attleboro, has been retained to appraise the value.

At a recent town meeting in Sterling, Mass., an appropriation of $5900 was made for extending the transmission lines of the municipal electric-lighting system as follows: Camp grounds at Sterling Junction, $2600; Rowley Hill district, $2000, and to the Chocksett district, $1300. H. W. Rugg is Mgr. and Supt. of the municipal plant.

Bids will be received until June 1 by C. B. J. Snyder, Supt. of School Buildings, Park Ave. and 59th St., New York, N. Y., for additions, alterations and repairs to the electrical equipment in Public Schools 25, 31, 44, 62, 177 and 188, Borough of Manhattan.

It is reported that the Crucible Steel Co. of America, Harrison, N. J., will build a new power station on Cumberland St. in connection with the extensions to its plant.

The Atlas Finishing Co., Homestead, N. J. (West Hoboken post office), plans to build a one-story power house.

The Toms River & Island Heights Electric Light & Power Co., Toms River, N. J., will soon install one 125-hp. Coatesville boiler in its plant. C. A. Brant is Secy. and Mgr.

The Borough Council of St. Clair, Penn., is considering plans for improving the municipal electric-light plant. J. J. Hughes is Mgr. of the plant.

The City Council of Cumberland, Md., is reported to be considering improvements to the municipal electric-lighting system at an estimated cost of $15,000. A high-speed steam turbine, directly connected, will be installed, and the present street-lamps will be replaced by new ones. James P. Gaffney is City Engr.

SOUTHERN STATES

According to press reports, the North Carolina Electrical Power Co., Asheville, N. C., plans to build a steam-driven auxiliary electric plant on the French Broad River to cost about $150,000. Generating equipment for 4000 hp. will be installed this year. W. T. Weaver, Asheville, is Pres. and Mgr.

At a recent election the citizens of Waynesville, N. C., voted in favor of issuing $25,000 in bonds to be used for the installation of a municipal electric-light plant.

Bonds in the sum of $10,000 have been voted by the citizens of Gleason, Tenn., for the construction of a municipal electric-light plant.

The Lancaster Electric Light Plant, Lancaster, Ky., will increase the equipment of its plant to provide 24-hr. service for the town. Alex Walker is interested.

CENTRAL STATES

Press reports state that the City Council of Oberlin, Ohio, is considering the installation of a municipal electric-light plant and water-works system.

It is reported that the new Alhambra Theater, Sandusky, Ohio, will be equipped with an independent electric-light and power plant. The equipment will include a 90-hp. Bruce-McBeth engine and a 50-kw. generator, directly connected.

It is reported that the Western Drop Forge Co., Marion, Ind., will increase its power plant by the addition of 700 hp.

WEST OF THE MISSISSIPPI

Bids will be received until June 7 by the Town of Alta Vista, Iowa, for the construction of an electric transmission line and a distribution system for the town. F. Rabe is Town Clk.

The town of Charter Oak, Iowa, has sold bonds, the proceeds of which will be used for the installation of a municipal electric-light plant.

A special election will be held in Lake City, Iowa, to vote on the question of granting a 25-year franchise to the Central Iowa Light & Power Co., Boone, to furnish electricity for lamps and motors in Lake City.

The City Council of Wilton Junction, Iowa, has rejected the offer made by the Davenport & Muscatine Ry. Co., Davenport, to build a transmission line to Wilton Junction, and will rebuild the municipal electric plant. George Bannock is Mayor.

Preliminary plans are being prepared for the installation of a municipal electric-lighting system for the town of Muscotah, Kan.

It is reported that the Texas Southern Electric Co., Victoria, Tex., has purchased the electric-light and ice factory of the City Ice & Electric Co., Del Rio, Tex. The reported purchase price is $90,000. The new owners will improve the property.

Bids will be received until June 3 by Wilson & Cutting, Engrs., 325 Electric Bldg., Butte, Mont., for the installation of an electric-heating system (indirect with fan) in the High School at Burley, Idaho. The building contains 40 rooms.

The plant of the Morton Electric Co., Morton, Wash., owned by F. M. Broadbent, has been sold to C. O. Smith of Pe Ell, Wash., at approximately $20,000. The plant will be enlarged and improved at once.

It is reported that the West Virginia Mining Co., operating the Lone Surprise mine at Republic, Wash., will install a 200-hp. compressor, a new Diesel engine and an electric hoist.

POWER

Vol. 41 NEW YORK, JUNE 8, 1915 No. 23

Candid Chats

The Power of Ambition

Do you want to be more successful, earn more money, occupy a better position in life? You can do it. Your life is in your making. Be you what you may, you can rise to a height limited only by your ambition and your energy.

You say you are now putting in the better part of the day in a hot and stuffy power plant. That should not deter you. You are AMBITIOUS. Can't you feel an invisible something forcing you upward, almost against your conscious will, continually urging you onward and onward? You know that to attain a higher position, you will have to make yourself more valuable to your employer and to the world. One way to do this is to study good books; subscribe to the best technical magazines; so that you may keep informed of the latest progress in your business.

BE YOU *what you may, you can rise to a height limited only by your ambition and energy.*

Your limit is not the Chief Engineer's desk. It is but a step from that to an executive position. Once you start working in earnest, you will be surprised at THE POWER OF AMBITION.

Every circumstance will be a spur and an incentive to greater effort; if adverse, it will only make you clench your teeth and fight the harder. But first you must fix in your mind what object you are going to attain; choose a definite goal, so that you can concentrate all your efforts toward it.

In this fight for advancement, it is very much as in actual warfare — once the general discovers where the enemy lies hidden, he can muster all his forces to overcome them, without having to spread them over a large area with the consequent weakening of his power.

Be sure to set your mark high enough. "Hitch your wagon to a star." And above all, don't allow yourself to become discouraged at the first obstacle you meet.

Any weakling can lie down and quit, but it takes a MAN to be up and at it when he encounters an obstruction in his path to success. Just as the athlete becomes stronger by continued physical exertion, so you will become stronger in character by overcoming the obstacles confronting you.

Now then, FIRE UP! See what you can do!

(Contributed by Herman Block, Brooklyn, N. Y.)

Power Plant of New Lumber Exchange Building

By Thomas Wilson

SYNOPSIS—A direct-current plant with 600-kw. generating capacity and 800 hp. in Scotch marine boilers. Engines equipped with poppet valves operated by eccentrics on a layshaft. Small steam piping and large receiver separators a feature. An excellent switchboard on which vertical circuit-breakers replace the usual switches and fuses on feeder panels. Gravity ventilation for engine and boiler rooms.

On May 2, 1914, the work of tearing down the old Roanoke Building at the corner of Madison and La Salle St., Chicago, was started, and at the present writing the Lumber Exchange Building, which has taken its place, is practically complete. The latter structure is a 16-story office building, 217 ft. tall from sidewalk to cornice, erected by the L. J. McCormick estate. The steelwork was designed for 20 stories, and the supporting risers have been carried through the roof, so that if desired an extension may be easily made at any time. Below the sidewalk there is a basement and two sub-basements containing the engine and boiler rooms, the floor of the latter being 45 ft. below the street level. The two levels for the power plant were necessary, as the adjacent building rests on a floating foundation, within 30 ft. of which deep excavation was not permitted. The frontage on La Salle St. is 135 ft. and on Madison St. 101 ft. At the inner corner a 47x75-ft. light-shaft above the third floor reduces the outline to an L shape. The building is of substantial construction throughout and, with its artistic terra cotta exterior, presents a handsome appearance.

To supply this building with heat, light, and power for the electric elevators is the purpose of the power plant located in the sub-basements. This plant contains a number of interesting features such as are indicated in the synopsis. Generally speaking, it is substantial and uptodate in every respect. For the services for which it is intended the plant has been laid out to operate at high economy, and a special effort has been made to hold the labor and maintenance items to a minimum.

It has been estimated that the load will run close to 300 kw. during the heating season and up to 200 kw. in the summer months. Consequently, units of these capacities and four boilers rated at 200 hp. each were installed. At any one time two of these boilers will easily supply sufficient steam for the generating units and there will be two in reserve. Exhaust steam will be used for heating, and to furnish a sufficient supply during nights and holidays a specially designed 100-kw. turbo-generator with a high water rate will carry the load.

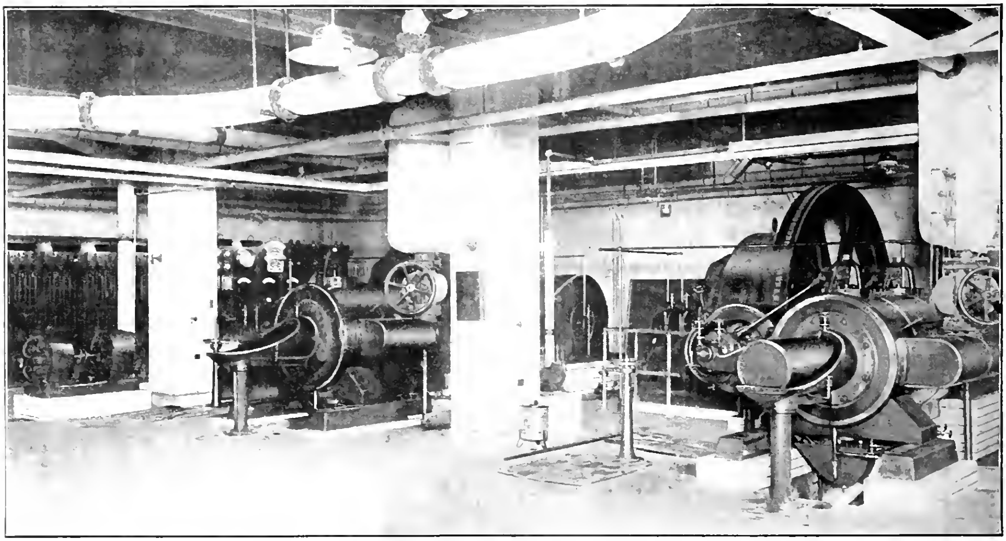

Fig. 1. Engine Room of Lumber Exchange Building

Boiler Installation

After due consideration of the magnitude and variable character of the load, it was decided to install units of 200-hp. capacity. These boilers are of the Scotch marine dry-back type, 96 in. in diameter and 16 ft. long. By means of a sheet-iron thimble lined with firebrick each boiler is connected with a dutch-oven furnace equipped with a top-feed stoker. Eventually, the air supply for the furnace will be drawn around this thimble and introduced into a closed ashpit. The stoker is provided with crushing rolls at the bottom of the magazines, which not only crush the coal, but also force it onto the grates. The latter are V-shaped and are inclined at an angle of 45 deg. The actual grate surface is 53 sq.ft. and 50 per cent. of this is air space. To the 1595 sq.ft. of heating surface in the boiler, the grate area bears a ratio of 30.1 to 1. This is considerably lower than commonly allowed, but the boilers are rated on 8 sq.ft. of surface per horsepower and the large air space in the grate permits a high rate of combustion.

The boilers are designed for 200 lb. pressure, but are operated at 160 lb. gage. They are covered with magnesia block, and with a handhole on each side and one on the top of the boiler, are easily accessible so that cleaning may be effected in a comparatively short time. There is diameter, but a 4-in. lining all the way up reduces the bore to 5 ft. 4 in. A powerful draft is thus available, and the proper intensity over the fire is obtained by damper control. Differential draft gages with four connections—one to the ashpit, one over the fire, one at the rear of the boiler and one to the uptake—make it possible to read the draft at the particular points just mentioned or the drop in draft through the furnace and boiler. The smoke flue, which is immediately in front of the boiler and runs over the rear ends of the furnaces, is of tapering section. It has one right-angled turn and at the stack its area is 27 sq.ft. This may be compared to 22 sq.ft., the free area of the stack, and to a connected grate surface of 212 sq.ft.

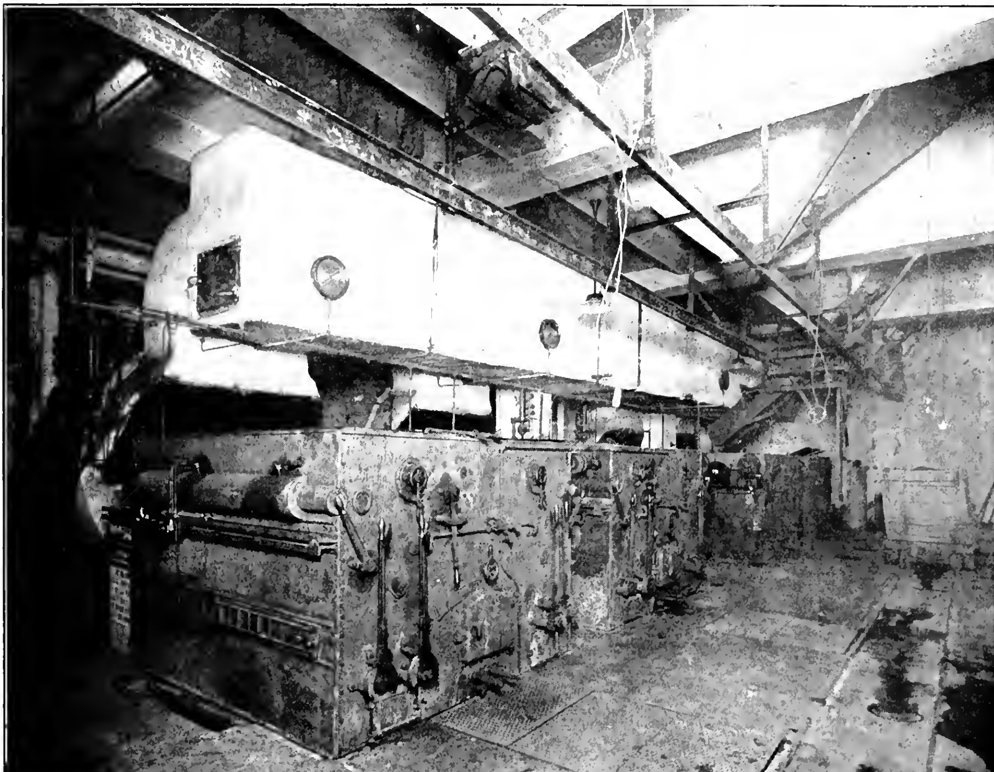

Fig. 2. Boiler Installation with One of Tunnel Cars at the Right

little loss from radiation. The boilers will hold their heat well over night and by the omission of the usual brick setting air infiltration is obviated. High economy should be obtained, and with a furnace which can be hand-fired if necessary, reliable and continuous service may be expected. It is planned to run two boilers during the day and bank one at night. By forcing, one boiler might handle the load, but two are carried on the line to guard against a possible interruption of the service. A point worthy of consideration is that all repair parts that these boilers may need can be conveyed to the boiler room through the elevator shaft.

Natural draft is supplied by a steel stack rising about 300 ft. above the boiler-room floor. The shell is 6 ft. in To the last figure the breeching area bears a ratio of 1 to 8, but as it is not expected that more than two boilers will be operated at any one time, the ratio actually becomes 1 to 4, which is close to standard practice.

Feed water may be drawn from the heater or the city mains and is forced to the boilers by either one of two simplex pumps. To guard against interruption of the feed, the supply lines to the boilers are in duplicate and are cross-connected so that parts of either line may be cut out of service if desired. Provision has also been made for weighing tanks to be used in testing the boilers or as a check on the V-notch meter.

Illinois screenings is used as fuel. It may be delivered by wagon or through Chicago's underground freight tunnel. There are four chutes from La Salle St., each discharging to a 50-ton reinforced-concrete bunker, one for each boiler. When the coal is delivered through the tunnel, the cars are run in on the boiler-room floor and dumped into a hopper beside the track. From this hopper a screw conveyor forces the coal to a bucket elevator, which at the top of the boiler room turns at right angles and delivers the coal to any one of the four bunkers. In the horizontal run the buckets scrape the coal along a

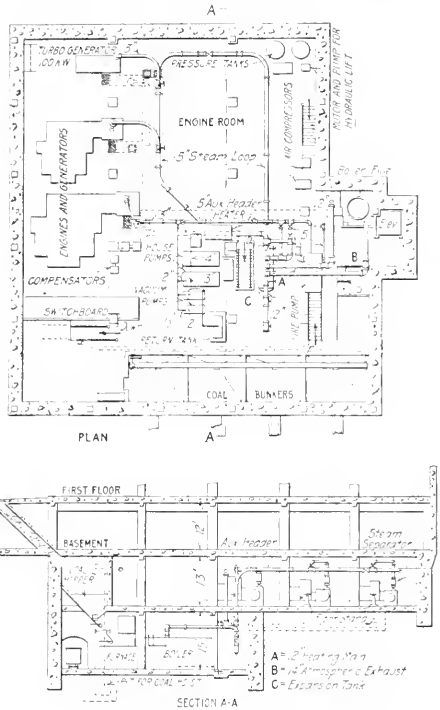

Fig. 3. Plan of Engine Room and Elevation through Plant

trough and through gates in the bottom of this trough, which are operated by handwheels in the engine room, and discharge it to any one of the bunkers. A track scale weighs the coal on its way to the magazines of the stoker. Ashes are shoveled directly into the tunnel cars, which at stated intervals are removed from the plant.

To prevent spoiling the fires in the boiler furnaces, a rubbish burner has been provided. This is a hot-water boiler with a coal grate below and a tube grate above for the paper and other waste from the building. Water for house service passes through this boiler and absorbs the heat from the waste material. Additional heat is supplied by closed heaters in the engine room, provided with exhaust-steam connections and temperature regulators.

From the third floor down all sewage must be raised to the street. For this purpose a duplex motor-driven sewage ejector has been provided in the boiler room. To care for an excessive quantity of water, a turbine-driven centrifugal pump with a 10-in. suction and 5-in. discharge, has been installed. The sewage must be elevated about 40 ft.

In the selection of the generating units, economy and regulation were the first considerations. With an electric-elevator load the variations are excessive and close regulation is necessary to prevent the fluctuations showing in the lights. Poppet four-valve engines were chosen as the prime movers for the two larger units. The valves are of the balanced type and are positively operated by cams oscillated by eccentrics on a layshaft. Between the two eccentrics an inertia governor mounted on the layshaft controls the speed. On its way to the inlet valves the steam passes over the ends of the cylinder, tending to reduce initial condensation and increase the economy of the engine.

For these units, which are of 300- and 200-kw. capacity respectively, the guaranteed steam consumption at full load is 20.8 lb. per i.hp.-hr., but from results obtained from engines of the same type a lower rate is expected. The generators are two-wire, 240-volt machines specially provided with extra large air gaps and heavy series windings to care for the heavy inrushes of current caused by the electric-elevator load. Compensators provide for three-wire distribution on the lighting. The engines are equipped with an automatic oiling system with an overhead tank and drainage from the bearings to a filter in the boiler room. Cylinder lubrication is effected by three-feed pumps driven from the layshaft. One feed goes to the throttle and one to each end of the cylinder. A reducing motion attached to a standard on the guide barrel and driven by the crosshead is a permanent fixture of the engine.

During the summer months it is the intention to run the smaller engine unit. In the heating season the large

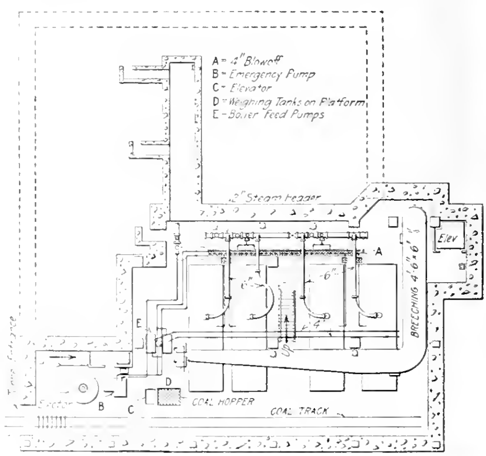

Fig. 4. Plan of Boiler Room below the Engine Room

unit will carry the load. From preliminary estimates it was figured that during the day there would be sufficient exhaust steam for heating, as in addition to the engines there are a number of steam-driven pumps. At night, however, and on holidays the load will be light, and rather than supply the live steam which would be necessary for heating through a reducing valve, it was deemed advisable to utilize a turbo-generator with a water rate purposely made high by the addition of nozzles so that sufficient exhaust steam would be available for heating. In other words, the turbine will act as a reducing valve and at the same time generate all of the current that is needed.

The unit consists of a 150-hp. single-stage turbine directly driving a 100-kw., 240-volt, direct-current generator at a speed of 2200 r.p.m. It was built especially to meet the requirements of the particular class of service existing in this plant. The governing device is so designed as to give practically constant speed under all conditions of load. At this writing the turbine has not been installed. A fuller description of this unit will be given when the results of the acceptance tests are available.

Piping Arrangement

From the accompanying line drawings the piping arrangement will be evident. Six-inch boiler leads connect with a 12-in. header at the rear of the boilers. Risers lead up to a 5-in. loop in the engine room and to an auxiliary header supplying the boiler-feed, fire, house and vacuum pumps. From this header there are also reducing-valve connections to the expansion tank, so that live steam may be supplied to the heating system when the turbine unit is not operating. If a large amount of live steam is required, the 5-in. reducing valve will be used. For a small quantity to supplement the exhaust-steam supply, a 1½-in. reducing valve has been provided. This relieves the larger valve and prevents the wire-drawing that would occur with a small quantity of steam passing through. The 5-in. loop now supplies the smaller engine and the turbine and is also intended for a 150-ton refrigerating machine which may be installed at some time in the future. All condensation from the loop and the auxiliary header returns directly to the main header in the boiler room, and from here it is trapped to the heater.

The remarkable feature about the piping is the small leads supplying the generating units. A 3-in. pipe supplies the 300-kw. machine, and the lead to the smaller engine is only 2½ in. in diameter. A 25-per cent. overload on the engines will require a steam velocity of about 8000 ft. per min. in these pipes. As standards go, this velocity might be considered excessive, but as the pipes are used in conjunction with receiver separators four times the volumes of the cylinders and large throttle valves, not the slightest trouble has resulted during the short time the plant has been in operation. The loop from which the small engine draws its supply is suspended from rings in the ceiling by means of turnbuckle hangers. It is not even anchored, and yet there is no evidence of vibration due to the cutoff of the engine. The reasons for this small piping are, of course, less radiation, less condensation and a lower initial cost for piping and fittings. As the engine throttles are 8 and 7 in. respectively, the supply of steam is not curtailed, and any inequalities in pressure which might result with the usual installation are smoothed out by the large separators.

Through a tunnel under the engine-room floor the exhaust piping passes out into the boiler room, thence up to the heater, which is on the engine-room floor, and on to the expansion tank and the hot-water heaters for house service. The relief valve to atmosphere is set for a back pressure of 2 lb.

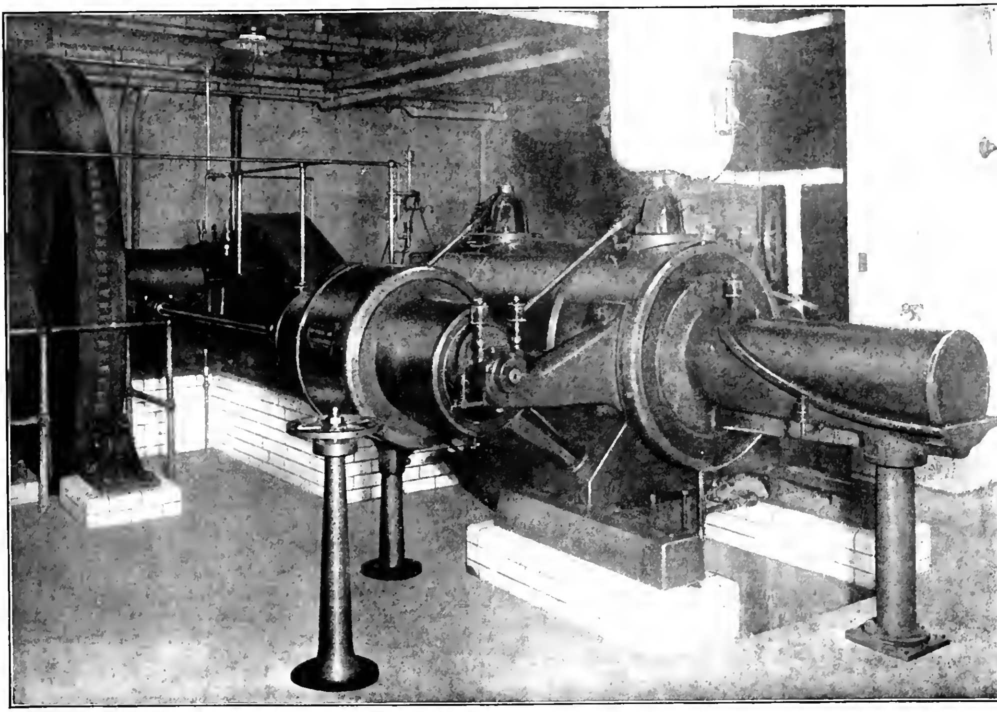

Fig. 5. One of the Poppet Four-Valve Engines

A feature of interest is the separation of the V-notch meter and the feed-water heater. The connections are so arranged that either may be cut out of service without affecting the other or both may operate independently; that is, the meter may measure the water to one boiler which is perhaps running on test, while the water for the other boilers is drawn directly from the heater. Piping connections have also been made so that the returns from the heating system or from any or all traps can be measured separately. Ordinarily, of course, the water passes from the heater to the meter, and with this independent arrangement the exact quantity is recorded just as it flows to the boiler. When the meter is installed in the heater, the flow over the V-notch may be greater or less momentarily than the amount of water fed to the boilers. The flow over the weir is the amount recorded on the chart, so that instantaneous readings and the actual boiler feed may not check, although either system over a period of time will record the same amount.

Another feature, not as common as it should be, is the provision of a small auxiliary pump to relieve the fire pump. Any slight unbalancing of pressure is cared for by the small pump. The fire pump is maintained ready for instant duty and is automatically cut into service when the capacity of its auxiliary is exceeded.

Heating and Ventilation

To heat the building, 21,108 sq.ft. of direct radiation has been provided. It is served by a vacuum system of the Van Auken type, with overhead distribution. Everything above the main floor is taken care of by a 10-in. riser that distributes downward from the attic on the seventh floor. A 5-in. pipe supplies the main floor and the basement.

Ventilation for the basement and the toilets is provided, and effected by motor-driven exhaust fans. The engine and boiler rooms depend on the pull of the stack for their supply of fresh air. Cold air from above is drawn down through the elevator shafts and stairways and in this particular case also through two ducts leading to gratings in the sidewalk. Fresh air passes across the engine and boiler rooms on its way to the furnaces, so that the rooms are maintained at a comfortable temperature. The stack has been erected in a square casing, with considerable clearance between the walls and the shell. Consequently, there is a free passage for the air from the boiler room to the roof, so that the ventilation is continuous whether the dampers to the furnaces are open or closed. The same system has been applied to the McCormick Building with wonderful success. The engine and boiler rooms are exceptionally cool. The air currents were studied by means of silk flags hung from wires stretched across the room. In this way the openings for air admission were properly located and any necessity for deflectors to send the air to all parts of the room was made evident. The same procedure must be followed in the new building under discussion. The air currents common to the building must be established, and proper methods adopted to produce uniform distribution and satisfactory ventilation.

To heat the hallways the same principle was applied, but this time utilizing the pull of the building. Vento coils are placed within inclosures off the hallways, and through grills fresh air from the street is drawn over the heating surface into the hallways. This relieves the dif-

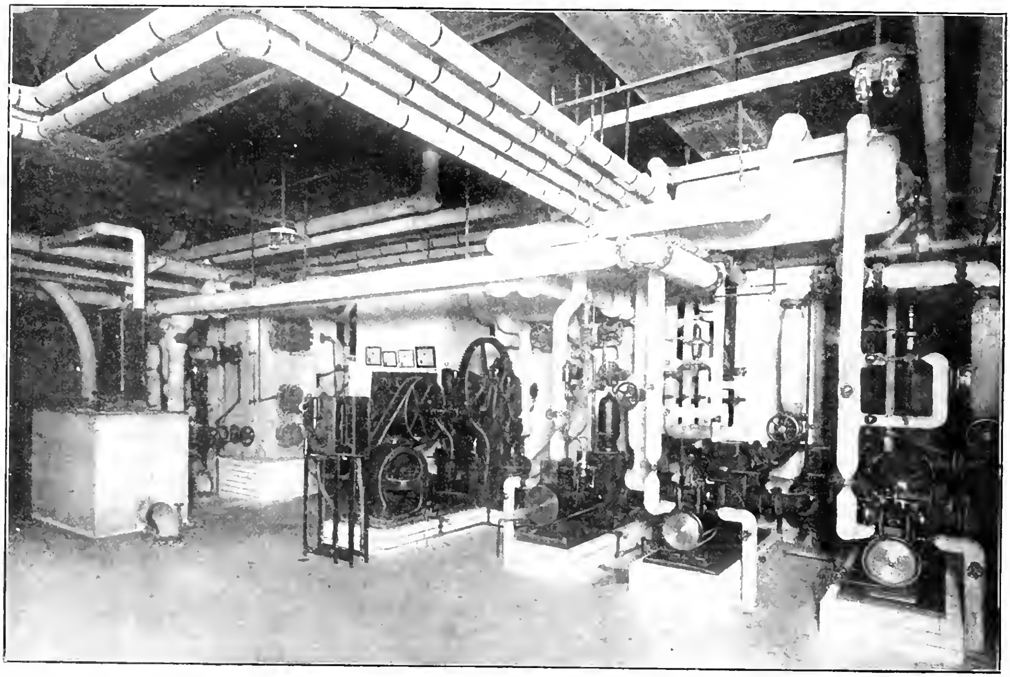

Fig. 6. Vacuum and House Pumps, Open Heater and V-Notch Meter

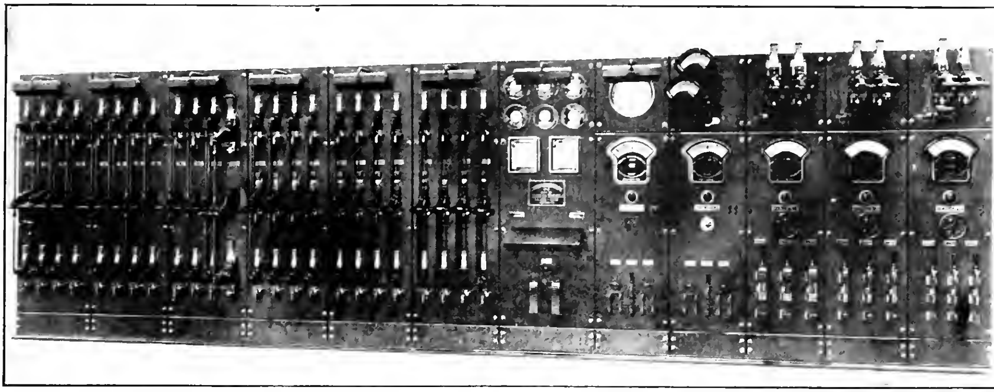

FIG. 7. FRONT VIEW OF SWITCHBOARD, SHOWING VERTICAL-TYPE CIRCUIT-BREAKERS

ference in pressure between the interior and the exterior of the building, and when the doors are opened no great quantity of cold air is drawn in. The hall is maintained at a satisfactory temperature, and in this regard the usual difficulties are eliminated.

ELEVATOR DETAILS

The elevators for the building are of the 1 to 1 gearless traction type. Five are passenger cars having a capacity of 2500 lb. at a speed of 550 ft. per min. The sixth elevator is for freight service. Its capacity and normal speed are the same, but heavy lifts may be effected at slow speed by the use of an extra 6000-lb. counterweight. All of the cars are driven by 220-volt, 31-hp. motors having a rated speed of 58.5 r.p.m. The cars have interlocking doors that must be closed to within 4 in. before motion is possible. There is also a special board for recording the stops and signals.

For service between the main floor and the basement there is a 1000-lb. hydraulic lift, operating on a water pressure of 125 lb. The equipment, consisting of pressure tanks, a motor-driven pump and a small air compressor belted to the pump shaft, is located in the engine room. Near-by is a small air compressor, which is motor-

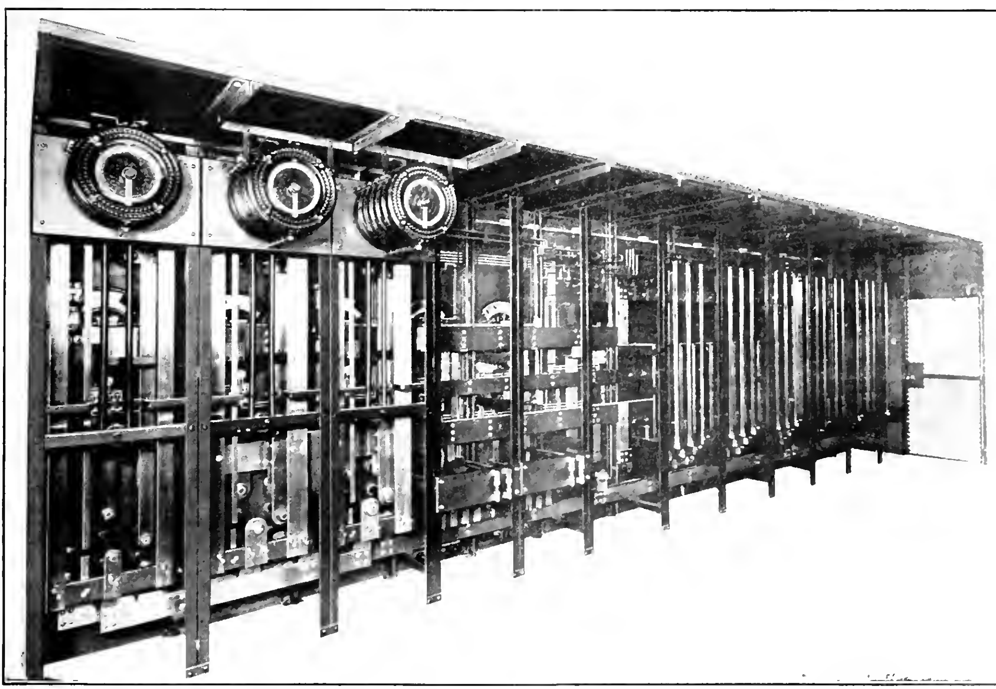

FIG. 8. REAR VIEW OF SWITCHBOARD, SHOWING SIMPLICITY OF COPPER WORK BEHIND FEEDER PANELS

driven and supplies air at 100 lb. pressure for blowing the dust from the switchboard, generators and other equipment of the plant.

Switchboard Equipment

The switchboard is an excellent example of a modern installation. It is equipped with the latest instruments and lighted by means of reflectors above the panels, but the feature which distinguishes it from the ordinary is the use of vertical-type circuit-breakers on the feeder circuits. These breakers are connected directly to the busbars so that intermediate connections and fuses are eliminated. This results in an unusually simple arrangement back of the board and effects a considerable saving in copper. The circuit-breakers are of the interlocking type, nonclosing on overloads, and as the busses may be run close to the board, studs of standard length are used.

For lighting, the distribution is three-wire and the power circuits are two-wire. As a consequence two- and three-pole circuit-breakers are employed, but for the sake of uniformity the positive poles at the top, the negative poles at the bottom and the operating handles at the center have all been placed in line. The generator panels are equipped with overload, no-voltage and time-limit release-type circuit-breakers in which the poles are arranged horizontally. The three busses are carried directly across the board to the lighting panels and independent positive and negative busses extend all the way across to the power panels. The two sets of busses are brought together by means of a suitable tie-switch. It is thus possible to carry the power and lighting loads on separate machines or on one machine, as desired. The lower stud of each breaker is connected to a bus. The upper stud is carried back of the bus, and a bar connection extends directly down to the terminal board. It may be noticed that all of the feeders terminate on panels at the bottom of the switchboard and that no flexible copper leads are used save those for the instruments. It is evident that the copper work is all straight-run and the arrangement unusually simple.

Frank H. Getchell, electrical engineer for Holabird & Roche, architects for the building, is the designer of the switchboard and the remainder of the electrical equipment. The mechanical equipment of the plant and building was laid out by John B. Blake, mechanical engineer for the same company, under the supervision of M. T. Kinman, chief engineer of the McCormick estate. C. G. Harding is the chief operating engineer in charge of the plant.

PRINCIPAL EQUIPMENT OF LUMBER EXCHANGE BUILDING PLANT

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
4	Boilers	Scotch-marine	200-hp.	Generate steam...	160 lb. press., natural draft stokers........	Springfield Boiler & Manufacturing Co.

*Weston ammeters and voltmeters, Sangamo wattmeters, Esterline graphic ammeter and voltmeter

B.t.u. to Calories—To convert B.t.u. per pound to calories per kilogram, divide the number of B.t.u. by 1.8; to convert calories per kilogram to B.t.u. per pound, multiply the calories by 1.8.

Pressure Drop in Steam Lines is comparable with line drop in electric distribution systems, which is known to be energy lost, but the desired terminal voltage is obtained and the drop compensated for by a slight increase of voltage at the source or apparatus designed to use the lower voltage. Feeders or steam lines large enough to cause no drop are not feasible; the amount of drop to be permitted is the variable quantity. The greater radiation loss from excessively large steam lines has no counterpart in the electric-distribution analogy.

Core Loss in Series Motor

By T. M. Robie

SYNOPSIS—The article describes a method of finding the core loss of a series motor by test with the aid of a motor-dynamometer.

The losses in a motor or generator are: The field loss *F*, due to the heat generated in the field windings by the field current; the armature loss *A*, due to the heat generated in the armature windings; the loss in the brushes; stray power loss *S*, which includes eddy current and hysteresis losses, chiefly in the armature core; and losses due to friction in the bearings, at the brushes, and windage, or air friction.

The heat losses can be calculated from the equation,

$$\text{watts lost} = I^2R$$

where *R* is the resistance of the part under consideration and *I* the current flowing in that part. The resistance should be that at running temperature.

Stray power loss cannot be accurately calculated by any simple data and is usually determined by experiment. In this article the author will give a simple and reasonably accurate means of finding the core loss in a series motor. It is necessary to know all the losses mentioned in order to find the efficiency of a motor or generator. Core-loss tests are made by the manufacturers on one machine for

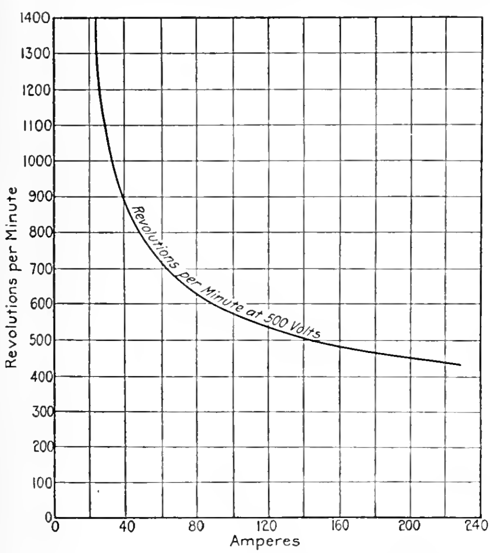

Fig. 1. Speed Curve for 500-Volt Series Motor

each type and class, and hold, with but slight variations, for all machines of the same size and design. While it is usually impractical to make these tests outside a laboratory, still it is interesting to know how they are carried out. Following is the method employed by one of the largest manufacturers of electrical machinery in this country:

The motor or generator under test is mounted on the test stand and is connected by means of a sleeve coupling to a similar motor which runs as a generator and furnishes the load. Holding the motor voltage constant, the load is varied from about 30 to 175 per cent. of normal, and the corresponding speeds are carefully observed.

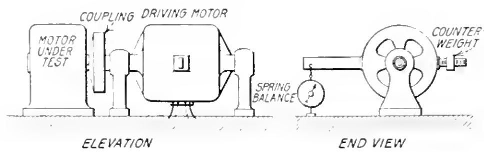

Fig. 2. Showing Driving Motor and Bearings which Allow Frame to Turn About Its Axis

From these data a speed curve is obtained having revolutions per minute as ordinates and current, or load, as abscissas; such a curve is shown in Fig. 1.

The motor is next disconnected from the position mentioned and is connected to a motor dynamometer, as shown in Fig. 2. The motor of the latter is mounted on ball bearings so that the frame is free to turn as well as the armature. A lever arm is attached to the side of the frame, and from this a spring-balance is suspended, the other end of the balance being fastened to the floor. This spring-balance furnishes the force necessary to keep the frame from revolving. The machine under test is then run as a separately excited generator operating at zero load.

About five speeds are selected from the speed curve, and runs are made at each, using five different field excitations for each speed. At the lower speeds the field current on the generator will, of course, have to be higher than at high speeds. Having decided upon the speeds and corresponding field excitations, the field of the motor under test is completely demagnetized by means of a reversing switch installed for that purpose, and the driving motor is started at the lowest speed decided upon. The set is now run until the reading upon the spring-balance is constant. This first reading takes care of all friction losses in the driving motor as well as the motor under test.

The maximum field current is now thrown on and, keeping the speed constant at the first value, the pull on the spring-balance is noted. The four other values of field current are applied consecutively and the corresponding spring-balance readings recorded. The fields are then demagnetized as before by momentarily reversing the field current and a second friction reading is taken, which should check exactly with the first. This process is simply repeated for the higher speeds and their correspondingly lower field currents.

The watts loss in the armature can now be calculated. The net pull on the spring-balance, that is, the reading with the field excited minus that with the demagnetized field, is a measure of the watts lost. The length of the arm from the spring-balance to the center line of the motor shaft can be measured, and the other values in the equation

$$Watts = \frac{2 \pi l n W}{33,000} \times 746$$

are known, where

l = Length of the lever arm in feet;

n = Revolutions per minute of the driving motor;

W = Net pull on the scales in pounds.

From the data thus obtained five curves may be drawn, one for each speed, having watts for ordinates and field current for abscissas. These should be drawn on the same curve sheet as was used for the speed curve; see Fig. 3.

The core-loss curve may now be readily drawn in. Suppose it is desired to find the point where the core-loss

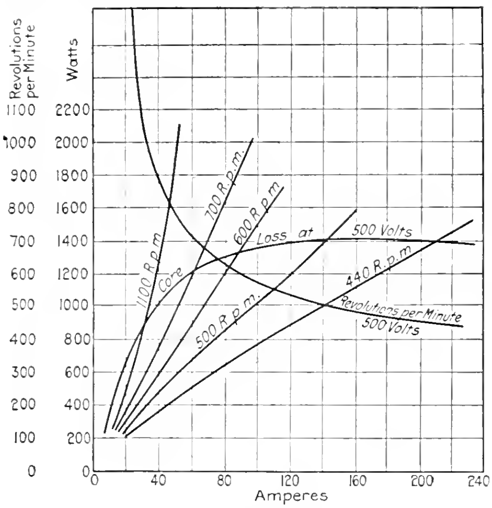

Fig. 3. Core-Loss and Speed Curves

curve crosses the 500-r.p.m. curve. Find the field current corresponding to 500 r.p.m. from the speed curve; this is about 140 amp. The point where this field current crosses the 500 r.p.m. curve will be one point on the core-loss curve.

A somewhat quicker way, but not as accurate, is to find the field current corresponding to a given speed and then run the motor under test at this speed and field excitation. The pull on the spring-balance is recorded as before and the watts lost calculated. This will give a point on the core-loss curve corresponding to the field current used; other points may be obtained in a similar manner.

The first method is the more accurate inasmuch as any error will quickly show in the core-loss curves taken at constant speed.

As will be seen, the core loss of a series motor varies greatly with load. With a shunt machine, on the other hand, it is practically constant irrespective of load.

The advantage of the method described lies in the fact that the electrical calculations are reduced to a minimum. It is not necessary to know the input to the driving motor or to know what losses there are in it.

The curves here shown are taken from a 50-hp. 500-volt G. E. railway motor.

JUST FOR FUN

As Usual, No Mystery When Found Out

On arriving at the plant in response to a distress call from the night man, I inquired what was wrong. He placed his hand gingerly on the low-pressure valve-chest cover and informed me it was hot. It was quite evident from the smell in the room that something was hot. He then told me that the engine had not been running evenly, but he could locate no other "trouble."

Upon examination I found the pedestal bearing hot and the bronze bearing gripping, causing the engine to slow down and then race. The oil drain-cock had been accidentally opened while cleaning the engine, and although the machine had been running over an hour, the so-called engineer had not discovered the lack of oil, but instead was looking for "something mysterious."—*F. E. Wood, Whitinsville, Mass.*

Absurdity Not Always Funny

I read with some amusement the letter by Mr. Newbury in the issue of Mar. 2, under the column headed "Just for Fun," wherein he refers to the blower salesman's remarks. While the statement was absurd, it does not sound quite so funny to one who has had the following experience.

A blower was sold, and the manufacturer was advised shortly afterward that the plant operator could not run the blower because it blew the gases out into the boiler room. Upon investigation he found that the man operating the plant insisted upon opening the blower valve to its full extent, regardless of the amount of air required. As the blower was installed with a fair margin of extra capacity, it was not ordinarily necessary to operate it at its full rate. Still, the fireman thought he ought by all means to do so, even if he spoiled the fire and filled the boiler room with gas. The main thing in his mind was to operate at full speed.

Is this experience any less funny than the other?—*T. L. Hoyt, New York City.*

As Good as Ever

In the palmy days of the Mississippi River shipping, the captain of one of the crack racing boats, the "Natchez," I think, was preparing to sail up the river from New Orleans, and finding that a rival boat was to sail about the same time, took occasion to impress upon his colored fireman the importance of having a good head of steam at starting time.

A few minutes before time to depart the captain strolled over in front of the boilers and was surprised to note that the steam gage showed exactly zero.

Naturally he wanted to know why in "hellenblazes" and several other things the fireman hadn't got up steam, to which the colored gentleman replied: "Dat's all right, Cap'n, dat thing's done been around once."

The above is a "wheeze" for which the writer can not vouch, on account of its not being true; still, it may interest such readers as have not heard it before. But if the steam gages had the stop pin taken out or were made so they *could* go around the second time we would be willing to believe the story, judging from some known incidents.—*L. A. States, Gastonia, N. C.*

Horsepower Constants for G. E. Type F Steam-Flow Meter

By Hubert E. Collins

SYNOPSIS—This article contains horsepower tables to be used with the G. E. steam-flow meter with several sizes of steam pipes. The tables are not corrected for moisture or for any other inner mechanism than a No. 6.

Chart readings taken from the G. E. Type F steam-flow meter must be computed by the method laid down in the instruction book No. Y 328, Sept., 1913, which also contains diagram No. 11, with the formula as shown herewith.

Meters not having the integrating attachment require considerable computation to figure the daily output registered. In order that the average of a day's run can be arrived at, the chart reading should be figured at least every half-hour. To get the rate of flow at any half-hour period requires four computations. If the factory has a number of meters, the work is considerable.

The accompanying tables are figured for a No. 6 inner mechanism General Electric Type F steam-flow meter for which the constant K_{cp} on the chart is 1.000. To use the tables with any other inner mechanism, multiply the reading from the table by the constant K_{cp} for that one.

These tables do not take into consideration the moisture of the steam or superheat, and any reading from them must be corrected for one of these. This means that it is necessary to multiply by constant K_1.

To illustrate the calculation of one of these figures in the table, let us figure the rated boiler horsepower passing through a 12-in. pipe at 100-lb. pressure, the chart reading being 2.

Then

$$K_2 = 0.835;$$
$$K_3 = 15{,}750;$$
$$K_{cp} = 1.000.$$

$15{,}750 \times 0.835 = 13{,}151$ *lb. of steam per hour rate*

$$\frac{13{,}151}{30} = 438 \text{ boiler horsepower}$$

TABLE 1. HORSEPOWER CONSTANTS FOR "TYPE F." G.E. STEAM-FLOW METER

With these constants table No. 1 is figured. This table gives the horsepower for the given pipe sizes and steam pressures for a reading of 1 on the meter chart. When using this table, multiply the chart reading by the constant corresponding to the pipe sizes and gage pressure. Then correct for moisture or superheat. If another inner mechanism than a No. 6 is used, correct for that, as already stated.

The integrating attachment to one of these meters does away with the necessity of calculating the steam flow at stated periods and averaging the result, or adding them to get the total. The device gives the total chart reading, which is multiplied by the result of the calculations given with Diagram No. 11.

With the integrating device the following formula is given for Type F meter with nozzle plug:

$$\textit{Total flow in lb.} = \frac{\textit{net dial reading} \times 4.7 \times K_1 \times K_2 \times K_3 \times K_4 \times K_{cp}}{\textit{revolutions of chart in 24 hr.}}$$

The numeral 4.7 stands for the integrating dial constant which is given on the nameplate.

To use these tables the formula is as follows:

$$\textit{Total horsepower} = \frac{\textit{net dial reading} \times \textit{constant} \times \textit{horsepower from Table 1}}{\textit{revolutions of chart in 24 hr.}}$$

To change to number of pounds of steam, multiply the above by 30.

If other than No. 6 inner mechanism is used, multiply the above by the constant given in Diagram 11 for the proper mechanism.

Correct for moisture or superheat.

For example, let us assume the following: The steam-pipe diameter is 12 in.; the average steam pressure at 100 lb. equals 438 hp. (Table 1); the integrating-dial reading for 24 hr. is 30; the dial constant is 4.7; and the reading of the meter chart in revolutions is 1. Then

$$\frac{30 \times 4.7 \times 438}{1} = 61{,}758 \textit{ total horsepower}$$

Where the integrating device is not in use, the Tables 2, 3, 4, 5, 6 and 7 are of especial use. With these the horsepower for any chart reading and given pressure can be read direct; each table is for a given pipe size.

Converter Station of Aluminum Company of America

SYNOPSIS—The equipment includes nine 2500-kw. rotary converters, outdoor transformers and high-tension switches and special control and protective apparatus.

The installation of nine 2500-kw. 60-cycle rotary converters at the Little Tennessee Plant of the Aluminum Company of America at Maryville, Tenn., in addition to constituting one of the largest 60-cycle rotary-converter installations in the world, presents a number of interesting features in the arrangement of the controlling and protective equipment. Energy is brought to the station by the Tennessee Power Co. over a single-circuit transmission line 70 miles in length, consisting of 400,000-circ.mil stranded aluminum cables, carried on steel towers 55 ft. in height, the lines being hung from suspension insulators. Temporarily, a transmission voltage of 66,000 is used, which later will be boosted to 110,000 volts.

Two banks of three 3650-kv.-a. 110,000/66,000-volt outdoor-type single-phase transformers are used to step down to the converter voltage, four six-phase machines

Fig. 1. Interior View of Station, Showing Converters and Control Panels

operating from independent secondaries on each bank, with provision for operating one spare unit from any set of secondaries of either bank. Automatic overload protection is provided by three-pole outdoor oil circuit-breakers equipped with outdoor condenser-type terminals and ring-type current transformers. The breakers are solenoid operated, and are controlled from the control desk located in the station. The breakers are isolated from the transmission line by means of three-pole outdoor disconnecting switches which are mechanically controlled by a handle installed in the station. One of these switches is shown in Fig. 2 between the supports of the transmission tower. The outdoor lightning arrester of the electrolytic type, shown at the left, provides protection against lightning.

The low-tension leads from the transformers are carried directly through the station wall and the six-phase connections are made beneath the floor. The aluminum-strap bus arrangement shown along the right-hand station wall in Fig. 1 provides the necessary connections for transferring the spare converter to any set of secondaries of either bank of step-down transformers.

The converters are ordinarily started from the 500-volt direct-current side, although two are arranged so that alternating-current starting motors may be used. Owing to the size of the machines and their large overload capacity, the switching equipment for both the alternating- and the direct-current ends is somewhat unusual in character. For the control of the alternating-current ends of the converters, 2500-amp., three-pole, solenoid-operated automatic carbon circuit-breakers are used, and for the direct-current ends the control consists of two 5000-amp., single-pole, solenoid-operated automatic carbon circuit-breakers for each machine. The alternating- and the direct-current panels are located adjacent to each ma-

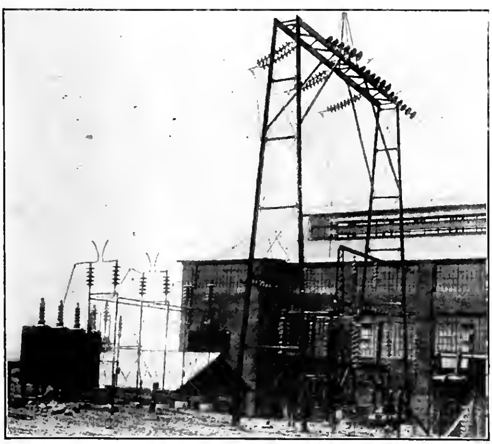

Fig. 2. Outdoor Switches and Lightning Arresters

chine, thus reducing to a minimum the length of the main connections. Low-voltage protection is provided on the alternating-current panels, and protection against reversal of direct current is secured by reverse-current relays.

The output of the converters, which is used in the manufacture of aluminum, is distributed through a 20,000-amp. single-pole solenoid-operated automatic carbon circuit-breaker, and two 10,000-amp. single-pole solenoid-operated automatic carbon circuit-breakers, mounted directly against the left-hand wall; see Fig. 1. The panels for the control of the direct-current ends are also on this side.

The details of the brush construction of the 20,000-amp. breaker are shown in Fig. 3. The main brush consists of six unit brushes of laminated copper so spaced as to secure the benefit of maximum ventilating effect.

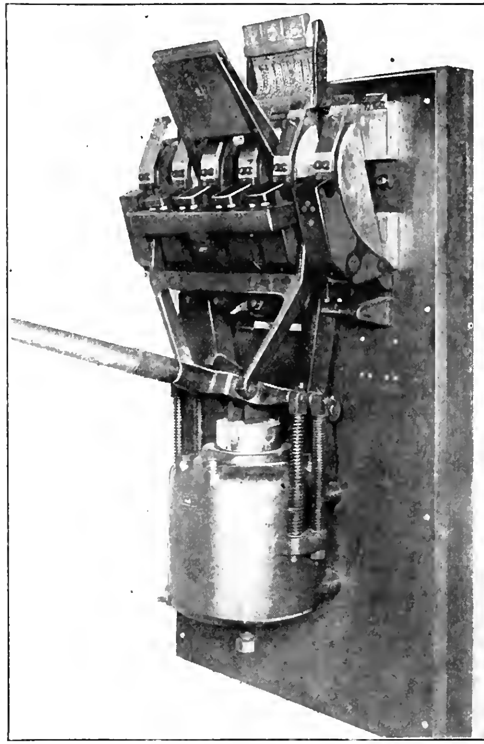

Fig. 3. 20,000-Amp. Circuit-Breaker

Auxiliary arc-interrupting contacts are located above the main brush and on the lower portion of the carbon contacts, which make the final break. Laminated studs are used for all breakers, and a single solenoid is used for operating each breaker, regardless of the number of poles, making possible a very simple and direct-acting operating mechanism.

The metering and controlling equipment for the alternating- and the direct-current sides of the converters, as well as for the high-tension side of the step-down transformers, is installed upon the control desk located in the balcony.

Current for operating the solenoids of the switching equipment and for the station lighting is provided by a motor-generator set consisting of a 60-kv.-a., 125-250 volt, three-phase generator driven by a 500-volt direct-current motor.

The electrical equipment for the station was manufactured by the Westinghouse Electric & Manufacturing Co. under the direction of William Hoopes, electrical engineer of the Aluminum Company of America.

Inconspicuous Losses in Refrigerating Plants

By Peter Neff

SYNOPSIS—You can see steam leaks and smell ammonia leaks, but you can neither see nor smell those heat losses by transmission through the walls that confine the heat units. The article suggests how these leaks may mean considerable loss in a short time.

Anyone can see a steam leak or smell an ammonia leak and know that a loss is going on, but many are often unaware of those silent, unnoticeable losses that go on continually, due to heat transmission, and while these cannot be entirely prevented, they can and should be minimized.

A plant may have good cold water and an efficient ammonia condenser, making it possible to get the liquid ammonia away from the condenser at, we will say, a temperature of 60 deg. Then this ammonia is conveyed through pipes to a receiver, perhaps located in a hot engine room, with the result that the ammonia goes to the feed valve possibly nearer 80 than 60 deg.

What do these 20 deg. mean? Suppose the plant is of 100 tons' refrigerating capacity and is circulating about 40 lb. of ammonia per minute, these 20 deg. mean about 800 heat units per minute unnecessarily added to the load. Two hundred heat units per minute is equivalent to a ton of refrigeration per day, so that this loss amounts to approximately four tons of refrigeration per day. It may be argued that this is not much in a 100-ton plant. But the loss represents money. The greater part might be saved by spending a few dollars on insulation, at least covering the receiver.

See that the ammonia leaves the condenser at as near as possible the temperature of the water available and that it does not rise in temperature before reaching the feed valves.

This brings up the question of the use of thermometers about a refrigerating plant, a subject the writer will take up at some future time. Suffice it for now to say, one might as well try to run an electric plant efficiently without voltmeters or ammeters as to attempt to operate a refrigerating plant without thermometers.

The suction line leading to the compressor is much neglected; sometimes it bears evidence of an attempt at insulation, but the last state is often worse than the first. Most engineers know of the loss due to the exposed steam piping, but frequently do not apply this knowledge to the suction line.

To relate an instance of how this matter is sometimes viewed, the writer found in a plant, a 4-in. ammonia suction line running partly in close proximity to steam condensers and thence through the hottest part of the engine room before reaching the compressor; obviously this line had been put there intentionally. Upon inquiry, this statement was given in answer: "You heat the gas in the compressor, therefore it is desirable to heat it as much as possible beforehand and save work by the machine." An hour was spent in a vain attempt to convince the operator of his error, but he had only pity for me and my ignorence. Happily, such instances are rare.

Suppose the suction line offers 100 sq.ft. of exposed surface, and assume a heat transmission of 10 units per hour per degree difference. It is no uncommon thing to find the suction line exposed to a room temperature of 80 deg., while the ammonia gas leaving the place of evaporation is at zero.

We may fairly assume an average difference of 60 deg., or 60,000 heat units per hour, which is equivalent to five tons of refrigeration per day. This is not all, for while the refrigeration load has been increased, the capacity of the compressor has been cut down.

It is well known that refrigeration is accomplished primarily by the heat absorbed in changing the liquid ammonia into a gas and that this gas is at first in what is termed a saturated condition where a given volume has a maximum weight. It is also well known that if this gas be heated it will expand and the weight in a given volume will be reduced. As the compressor offers a constant volume for the reception of the gas, it follows that the greater the density of the gas, the greater will be the weight handled by the compressor. So it is obvious that it is desirable to get the gas to the compressor without superheating it.

We have supposed that superheating of the gas has taken place, owing to the exposed suction line, so that in reality there has been an attempt to cool the engine room or outdoors, wherever the suction line has been run, which was neither desired nor intended, but which has required an expenditure of energy that represents a money loss.

In the supposed case the 40 lb. of ammonia per minute, when in the form of a saturated gas at zero degrees, occupied approximately 367 cu.ft. If, now, this gas is raised in temperature to only 50 deg., we find that the gas that had formerly occupied the space of 367 cu.ft. will now occupy 416 cu.ft. If the compressor is to handle the same weight of ammonia, which it must do to produce the same amount of refrigeration, its speed must be increased 13½ per cent.

The plant may be, as far as visible observation can tell, working well, everything apparently in perfect order, not a leak of steam or ammonia and yet there may be some such losses going on.

While, perhaps, the increased number of revolutions does not, owing to the friction load, increase the horsepower proportionately, it nearly does so, and almost any engineer may calculate what this loss means in fuel cost.

The engineer who wants to build up a reputation and to make himself valuable to the concern which employs him will, in addition to keeping his plant free from those defects that are obvious to anyone, be on the lookout for those losses not apparent on the surface. It is this care that makes some men so much more successful than others.

There are many other losses going on, but the examples given illustrate the importance of looking into the heat-transmission losses

Tests on the Diagonal Strength of Boiler Plate

By J. W. F. Macdonald*

On Apr. 10 tensile tests were conducted at the Watertown (Mass.) Arsenal on 21 specimens of boiler plate. The object of the tests was to determine the minimum distance between rows at which the joint fails through the net section along the line of rivets in one row, rather than along the zigzag diagonal lines. The test specimens

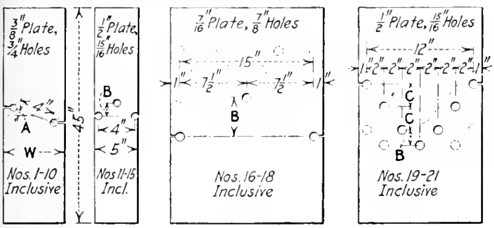

FIG. 1 FIG. 2 FIG. 3 FIG. 4

Specimens on Which Tests Were Made

were prepared by the International Engineering Works, Ltd., Framingham, Mass., from material furnished by the Lukens Iron & Steel Co., Coatesville, Penn. Following is the mill test report for the steel used:

Slab No.	9968 G	9968 J	9968 H
Physical properties—			
Width, in.	1.725	1.915	1.816
Thickness, in.	0.380	0.447	0.515
Area, sq.in.	0.655	0.856	0.935
Elastic limit—			
Lb. per sq.in.	36,660	38,090	36,160
Tensile strength—			
Lb. per sq.in.	59,680	59,340	57,760
Elongation—			
Per cent. in 8 in.	30.0	28.0	29.5
Reduction in area, per cent.	60.3	60.7	57.2
Chemical properties, per cent.—			
Carbon	0.17	0.17	0.18
Manganese	0.36	0.36	0.44
Sulphur	0.023	0.023	0.030
Phosphorus	0.018	0.018	0.012

The first ten specimens had a section 4 in. wide and 3/8 in. thick between hole centers. The lines through this section were placed at an angle *A* (see Fig. 1) to the line normal to stress, varying from 0 to 90 deg. in 10-deg. increments. The purpose of this series of ten was to obtain data for a curve giving the strength of the material for the different angles. From this curve the proportion of metal necessary along the diagonal lines could be found directly.

Specimens Nos. 11 to 21 inclusive were arranged with varying proportions between the net amount of material along the diagonal lines and that straight across between the two holes in the same line. Nos. 11, 12, 13, 14 and 15 (Fig. 2) had a 4-in. pitch and represented typical spacing in the inner rows of riveted joints. Nos. 16, 17 and 18 (Fig. 3) represented the rivet holes in the two outer rows of the ordinary type of quadruple butt joint with an outer pitch of 15 inches. In No. 16 there is actually less material along the diagonal lines between the two outer rows than there is directly between rivets in the outer row, a condition given no consideration in the rules for calculating such joints. Nos. 19, 20 and 21 (Fig. 4) represented the rivet holes inside the calking edge of the sawtooth type of quadruple butt joint with an outer pitch of 12 inches.

Where the same thickness of plate was used, test specimens were all cut from the same slab, in order to have conditions as uniform as possible. The actual results in the first ten specimens show remarkable uniformity, particularly with reference to the elastic limit indicated by the first scaling of the plate and drop of the beam. The results of tests made on these specimens follow:

No.	Angle A (See Fig. 1), Deg.	Width (W) Specimen, In.	Section Between Holes, Sq.In.	Elastic Limit in Lb. Total	Elastic Limit in Lb. Per Sq.In.	Ultimate Strength in Lb. Total	Ultimate Strength in Lb. Per Sq.In.	Relative Ultimate Strength Per Cent.
1	0	7	1.52	62,200	40,900	96,400	63,400	100
2	10	7	1.56	57,100	36,600	92,700	59,400	93.6
3	20	7	1.52	51,100	33,600	87,400	57,500	90.7
4	30	7	1.52	45,000	29,600	81,000	53,300	84.0
5	40	8	1.56	40,500	26,000	78,100	50,100	79.0
6	50	9	1.56	37,500	24,000	74,900	48,000	75.7
7	60	10	1.56	32,800	21,000	71,000	45,500	71.7
8	70	10	1.56	29,200	18,800	70,500	45,200	71.2
9	80	11	1.52	27,900	18,400	71,900	47,300	74.6
10	90	11	1.52	26,900	17,700	63,100	41,500	65.5

Curves Nos. 1 and 2 were plotted with the ultimate strength and elastic limits as ordinates and different angles as abscissas. These curves show that the ultimate strength decreased almost uniformly with the increased angle from direct tension to direct shear.

Specimen No. 11, in which the areas diagonally and straight across were equal, and No. 16, in which the latter was slightly greater, failed diagonally through the three holes, as was expected. Specimen No. 13 was stronger than would be indicated from the results found in the first ten specimens, the ultimate failure being straight across. With a riveted connection, where the holes were forced to retain their full width and the metal was prevented from flowing to the extent it did, as shown by the elongation of the holes along the line of stress and their contraction transversely, the results would probably

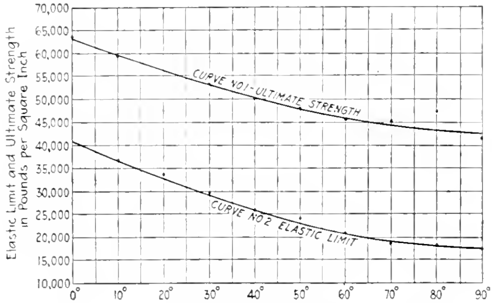
*Chief draftsman, International Engineering Works, Ltd., Framingham, Mass.

have agreed more closely with those obtained with the first ten specimens. Again, in these specimens the material was given more opportunity to stretch where its continuity was not wholly broken than if the stress was transferred from one plate to the other by rivets.

Specimen No. 13 was watched with especial interest, as the proportions conformed to those required as a minimum by the Canadian Rules, and also by the recent A. S. M. E. Code. Specimens Nos. 14 and 15 broke directly across, the third hole showing less deformation as the proportion of material increased diagonally.

It would be interesting in the line of further investigating of this condition to have the five specimens 11 to 15 inclusive prepared with exactly the same spacing of holes, only in the form of a butt joint with double strap, the double shearing strength of rivets being sufficient to insure a plate failure.

Specimen No. 16 broke through the three holes at an ultimate load far below the strength according to the methods of calculation used in the various boiler rules. This failure shows a rather astonishing condition in the ordinary type of quadruple butt joint. The condition has apparently existed for years without being given much consideration. In designing these joints the practice has been to find the weakest part by calculating eight possible methods of failure. Yet, what is the use of such calculations if the actual method of failure has not been considered at all? No matter if the ultimate strength by the real method of failure may be only very slightly below the calculated strength, so long as the condition exists at all, to be consistent a proper investigation should be made. It is a significant fact that this type of joint is not recognized by the various Canadian Rules, which we believe are patterned after the Code of the British Board of Trade.



Results Obtained with First Ten Specimens

Another feature noted in these tests was that in several of the samples which failed straight across the elastic limit indicated by the scaling of the plate was first shown along the diagonal lines, which under the conditions would perhaps be the proper criterion for judging the weakest section.

Another important point to be noted was that in the narrow specimens Nos. 12, 13, 14 and 15, with a 4-in. pitch, the ultimate strength came fully up to that which might be expected from the mill-test report, but as the specimens grew wider they fell far below. In specimens Nos. 19, 20 and 21, the calculated strength as compared with the solid plate should be 92.1 per cent., but actually was only 87.3 per cent., 87.5 per cent. and 89.5 per cent.; and in specimens Nos. 16, 17 and 18, where the strength should be 94.1 per cent. of the solid plate, it actually was only 81.0, 84.6 and 83.1 per cent. These results bear out exactly the statement made with reference to wide pitches by James E. Howard in his paper read last December before the Society of Naval Architects and Marine Engineers.

In this question of the proper back pitch, or distance between rows, the design should have some excess strength in favor of the material diagonally and not be merely a balance. Really, this part of the proportioning of any joint is a feature of the design preliminary to the proper calculation by the usual methods. In considering the different possible methods of failure, if no direct calculations are made for the strength diagonally, the proportions should be such that there is no possibility of the joint failing in that manner; or in other words, whatever the method of failure may be, it should be among those for which direct calculations are made.

These tests, which will perhaps open the way for further research along this line, tend to arouse suspicions as to our high efficiencies. If the 94 per cent. and more of the strength of the solid plate are not dependable figures, we may again be falling back on our old friend the "factor of safety" to make up the difference between actual and assumed conditions.

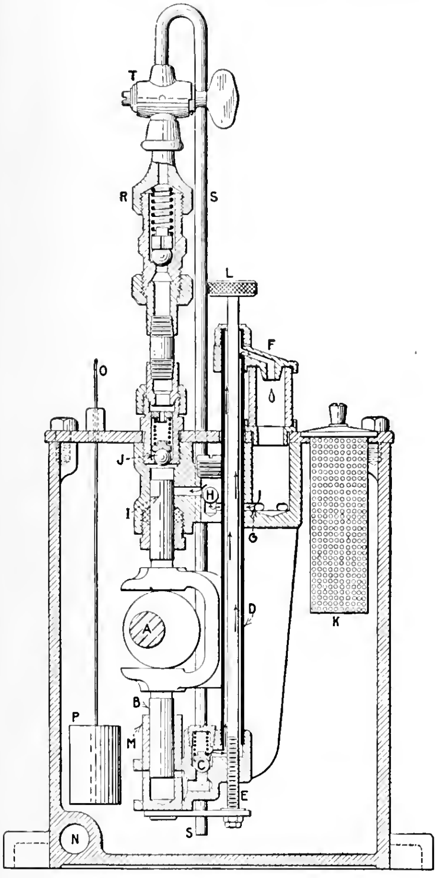
Phenix Oil and Graphite Cylinder Lubricator

Quite recently the Richardson-Phenix Co., of Milwaukee, Wis., has placed on the market an oil and graphite lubricator provided with an agitator that continually discharges puffs of air into the oil reservoir. This keeps the graphite uniformly mixed with the oil and obviates the trouble usually experienced when attempting to feed graphite to the cylinders of steam-using equipment. Referring to the accompanying illustration, the lever operating the lubricator is given a reciprocating motion from some external source such as the valve gear of the engine. By means of a ratchet which has four go-ahead and two retaining pawls, the lever arm causes shaft *A* to revolve in one direction, rotating the cam and causing the yoke to reciprocate vertically for each feed.

Upon the upper stroke of piston *B* the oil and graphite mixture is drawn into cylinder *M*. On the downward stroke of the piston the mixture is forced up through the check valve *C* and tube *D*, thence down through the opening *F* and the sight-feed glass to chamber *G*. From the bottom of the chamber the mixture is drawn up past check valve *H* by the downward stroke of the piston *I*. On its upward stroke the piston forces the mixture through check valve *J*, out into the feed line to the terminal check valve. In the illustration a section through the agitator nozzle is shown, but the oil and graphite feed is exactly the same. The terminal check valve is inserted in the steam pipe above the throttle or into the steam-inlet passage to the valve, and the incoming steam picks up the graphite and oil from the atomizer nozzle.

To fill the lubricator, oil is poured into strainer *K*. The quantity of oil and graphite fed for each stroke of the pump *B* is regulated by means of an adjusting nut *L*. To the lower end of the adjusting rod is attached a metal strip carrying the cylinder *M*. Turning the nut in a right-hand direction lowers the rod and sleeve so that on its downward stroke the plunger *B* does not go to the end of the cylinder. Thus, a portion of the oil remains in the cylinder and only a small quantity is forced up through the sight-feed. Turning the nut in the opposite direction raises the sleeve to its highest point and increases the feed to the maximum.

To keep the oil warm when the lubricator is used in cold places, a cored opening *N* has been provided, so that a



SECTION THROUGH OIL AND GRAPHITE CYLINDER LUBRICATOR

steam line can be connected if desired. A gage-glass shows the level of the mixture in the reservoir, and as some kinds of graphite are liable to form a deposit on the glass, a float-operated indicator is also provided. This consists of a rod *O* operated by a float *P*.

The agitator unit is exactly the same as the mixture feeding pump except that only enough of the mixture is pumped by the lower plunger *B* to provide a seal for the top plunger *I* which handles air drawn in through a vent in the top cover of the sight-feed glass. The air is compressed beneath the check valve *R* to a pressure of about 300 lb.; when the resistance of the spring is overcome, the air is discharged with a puff through pipe *S* to the bottom of the oil tank. These frequent discharges keep the graphite uniformly distributed throughout the oil. A three-way cock *T* is inserted over the check valve, so that it may be determined whether or not the agitator is working properly.

By turning the handle to the horizontal position a by-pass to atmosphere is opened, so that the discharge can be observed and the air pressure tested. On the agitator feeds the top of the adjusting rod *E* is slotted and the thumb-nut eliminated. The rod may be turned by a screw-driver and when the proper adjustment has been obtained, it is held in place by a locknut.

Norwegian Waterfall Concessions

At a cabinet council in Christiania, on Apr. 16, it was decided to bring in a bill to restrict further the existing laws of 1909 and 1911 in respect to waterfall concessions in Norway. The right of the state to regulate watersheds is confirmed in principle. Where public convenience is not interfered with and the regulated power does not exceed 500 hp. and is distant 12½ miles from another fall, no concession is necessary. Concessions will, as at present, be granted by the King, though with the proviso that where the regulated power exceeds 10,000 hp., or where considerable interests are involved, the terms of the concession must be submitted to the Storthing (parliament) for discussion. The existing maximum period of 80 years for a concession is reduced to 60 years, though in special cases, and with the sanction of the Storthing, it can be extended to 70 years.

The present clause giving to Norwegian citizens and Norwegian joint-stock companies an unlimited period of concession is struck out, but is maintained in respect of Norwegian communes. At the termination of the concessional period the state can demand the transfer to it of the undertaking, with its lands, buildings, etc., without any compensation whatever. As regards concessions for a shorter period than 50 years, an amount can be fixed for the redemption by the state of the whole or a portion of the constructional work, based on the original cost of the lands, buildings and plant, according to its technical value, less amortization.

At the end of 40 years from the date of the concession the state is entitled to take over the entire proposition at its original construction cost and the plant at its technical value. This right may, if it be more convenient to the state, be postponed to periods of 10 years subsequent to the 40 years mentioned.

An important provision is an increase in the maximum royalty to the state per horsepower from 26c., as at present, to 52c., plus 26c. to the commune, or 78c. in all; though in special cases the total to state and commune can be increased to $1.04 per horsepower. There are, moreover, obligatory clauses relating to the supply to the state and commune of power at fixed prices and the use for the public of bridges and roads constructed by the party receiving the concession.

The proposed bill, the drastic restrictions of which are directed against foreign exploitation, is viewed with much disfavor by the progressive element in Norway. It is feared that its provisions with wages at the continental level, the 8-hour a day pending, and taxes at the breaking point will do away with the notion abroad that Norwegian waterpower is cheap.

EXPLANATORY NOTES

1. Standard and Extra Heavy Reducing Elbows carry same dimensions center to face as regular Elbows of largest straight size.
2. Standard and Extra Heavy Tees, Crosses and Laterals, reducing on run only, carry same dimensions face to face as largest straight size.
3. If Flanged Fittings for lower working pressure than 125 lbs. are made, they shall conform in all dimensions except thickness of shell, to this standard and shall have the guaranteed working pressure cast on each fitting. Flanges for these fittings must be standard dimensions.
4. Where long turn fittings are specified, it has reference only to Elbows which are made in two center to face dimensions and to be known as Elbows and Long Turn Elbows, the latter being used only when so specified.
5. All standard weight fittings must be guaranteed for 125 lbs. working pressure and extra heavy fittings for 250 lbs. working pressure, and each fitting must have some mark cast on it indicating the maker and guaranteed working steam pressure.
6. All extra heavy fittings and flanges to have a raised surface 1/16" high inside of bolt holes for gaskets. Thickness of flanges and center to face dimensions of fittings include this raised surface.

   Standard weight fittings and flanges to be plain faced.

   Bolt holes to be 1/8" larger in diameter than bolts.

   Bolt holes to straddle center lines.
7. Size of all fittings scheduled indicates inside diameter of ports.
8. Square head bolts with hexagonal nuts are recommended.
9. Double Branch Elbows, Side Outlet Elbows and Side Outlet Tees, whether straight or reducing sizes, carry same dimensions center to face and face to face as regular tees and elbows.
10. Bull Head Tees or Tees increasing on outlet, will have same center to face and face to face dimensions as a straight fitting of the size of the outlet.
11. Tees, Crosses and Laterals 16 inches and smaller, reducing on the outlet, use the same dimensions as straight sizes of the larger port.

    Sizes 18 inches and larger, reducing on the outlet, are made in two lengths depending on the size of the outlet as given in the table of dimensions.
12. For fittings reducing on the run only a long body pattern will always be used.

    Y's are special and made to suit conditions.

    Double Branch Elbows are not made reducing on the run.
13. Steel Flanges, Fittings and Valves are recommended for Superheated Steam.

This schedule, superseding all previous issues, was adopted Mar. 20, 1914, by a Joint Committee of the National Association of Master Steam and Hot Water Fitters, the American Society of Mechanical Engineers and the Committee of Manufacturers on Standardization of Fittings and Valves, and became effective Jan. 1, 1915. All dimensions are in inches. Copies of the original chart, of which this is a reproduction, on heavy paper, 24x36 in., can be secured for $1 by addressing the National Association of Master Steam and Hot Water Fitters, 260 Broadway, New York City.

Editorials

Classification of Technical Literature

On another page is reported the organization by some twenty national technical and scientific societies of a Joint Committee on Classification of Technical Literature. As its name indicates, its purpose is to propose a standard method of classifying technical literature so that filing may be facilitated and the valuable things which are being forgotten and practically buried in the back numbers of periodicals or other sources of information may be kept easily available.

The problem before this committee is three-fold. First, to arrange a complete classification of subjects in the wide fields of technology and applied science. Second, to select or develop a notation or system of indexing for the subjects classified. Third, to set before the publishers of technical journals and books, and societies that print technical and scientific transactions and proceedings, the value of adopting the accepted classification and notation.

From the deliberations of this committee will undoubtedly come suggestions as to ways in which the papers can coöperate. It goes without saying that Power will be glad to do its part in any such way, and undoubtedly all others will be similarly disposed, for it will be to their interest to have the value of their issues made more enduring.

Power is not insensible either of the honor of having its editor chosen as the first chairman of the committee.

Side Lights on Hydro-Electric Plant Service

To many engineers, service in a hydro-electric generating station means almost exile. They dread the prospect of spending years in a plant situated, as they often are, many miles from a city, in a rough or mountainous district. Others see in it opportunities for maintaining a little country home and a pocket-sized farm as a "side line," but fear that the work itself will lack interest because of the absence of steam equipment, the few men required to handle the installation in normal service, and the apparent simplicity of the operating routine. They feel that the opportunity to grow may be denied the water-power plant operator—that a job of this kind may be good enough for an elderly man who fancies solitude and enjoys grubbing in a garden and counting eggs, but that it cannot appeal much to an engineer with real "pep" in his makeup.

For some men this point of view is so ingrained that it would unquestionably be a false move to accept a position in a station of this kind. It is, no doubt, partly a matter of taste whether an engineer will find satisfaction in a steam plant in the town or in a water-power station many miles from the allurements of city life. But, granted the importance of applying the personal equation to hydro-electric plant service in remote localities, it is worth realizing that this kind of work may possess both interest and opportunity if a man takes advantage of his chances. The casual visitor to a hydro-electric plant in the wilderness goes away with the impression that there is comparatively little apart from routine work for the operating staff to do. It seems to the layman merely a question of opening the gates and letting the water run through, and the wheels do the rest. Beyond oiling the governors, keeping an eye on the lubrication of main-unit and exciter bearings, putting down the half-hourly instrument readings on the log sheet and watching out for possible damage from thunder storms, life appears to be one glad, sweet song. Wages are moderate, to be sure, but the little farm does the rest, thinks the visitor, and seldom does anything arise to disturb the poise of the operating shifts.

Brethren of the water-power service know better. They appreciate that under normal conditions, with everything running smoothly, the days sometimes do seem a bit long, but the wise ones in this work find fully as much to learn as do their steam-plant brothers in the town. It is true that the design of a hydro-electric station generally "stays put" and that capital errors in layout can be corrected only at relatively high cost. In its general arrangements such a plant is a pretty rigid affair, but this does not mean that skill is not necessary to operate it efficiently. Waterwheels and generators have their economical range of output no less than steam-driven machines, and conservation of storage facilities is as important in many plants as the careful use of fuel in steam stations. The relations of weather conditions to stream flow, the changes in effective head on the wheels, accuracy with which the governing equipment operates, effect of wear in turbine blades and passages upon water consumption, prevention of ice formation within wheels, proper handling of sluice gates, and the study of voltage regulation—all challenge the interest of the engineer of inquiring mind. The opportunity for the installation of home-made apparatus in the auxiliary branches of water-power plant service is large, notably in connection with the remote control of head-gates, the prevention of leakage, recording of river, reservoir and tail-race elevations, economical repairs, and improved lighting and small power applications. When a hydro-electric plant operates in parallel with one or more other stations, the possibilities of utilizing water efficiently become even more interesting and important. The reduction of waste has not received the attention it should in some stations, while in others it has gone to such refinements as the installation of special meters for water-flow records, the subdivision of local lighting and power circuits, the inclosure of operators' quarters in electrically heated spaces of limited size, use of the more efficient types of lamps, and recirculation of transformer cooling water.

In emergencies the operator's skill is taxed to maintain continuous service, no less than in steam stations. The isolation of line troubles is almost a specialty in itself.

The man with a leaning toward investigation will find plenty to occupy himself with if he confines his attention for a time to the good points and shortcomings of alternating-current relays in relation to trouble detection and segregation on the system at large. The study of lightning protection is another big subject, worthy of unusual ability, and we repeat the profound interest always associated with the subject of waterwheel governors. As a factor in securing an all-round experience in power production, the water-driven station will be in the running for a long time to come. Its isolation but gives the keen student of this branch of engineering better opportunity to master this part of his profession. Few indeed are the cases where the mails will not bring the benefits of the technical press just as well as in the city. The laws of power production are universal in scope, and if the operator refuses to yield to the temptation to live a routine life and sticks to his purpose to become an expert on the work with which he is engaged, location becomes of secondary concern for the time being and opportunity absorbs him to a degree but little realized by the fellow who thinks that water-power service is narrowing to ambition.

State Aids Kansas Engineers

The commendably generous offer made by the Kansas State Agricultural College to assist in the educational program of the National Association of Stationary Engineers of that state will most likely be accepted. State and municipal educational institutions of an engineering or technical character might well consider following Kansas' lead.

The college offers to direct a course of study under the auspices of the State association, each subordinate association to have at least three lectures a season by a representative of the college. Special lectures on subjects allied with power-plant operation will also be given. The college aims to send out questions and references to each association. Every sixth lesson will be in the nature of an examination, the results of which will be reported to the college. The associations are expected to pay for only the traveling expenses of the lecturers; this outlay to be met by special assessment. It is the intention to begin the course July first.

The National Educational Committee of the association supports a program similar to that offered by the Kansas Agricultural College. It would seem that both programs could be carried out to the advantage of all concerned.

Cleanliness in Refrigeration Plants

To the mind of the layman cleanliness implies absence of dirt. To the engineer it means, or should mean, absence of anything foreign to the machine or apparatus or its functioning. As someone has said, "Dirt is matter out of place."

The refrigeration plant is a place of transmissions. Not the noisy, evident processes heard and seen in turbine or engine rooms or in shaft alleys or belt races, but the quiet, invisible transmission of heat through metal walls. You cannot see it. Sometimes in some places the hand, sensitive as it is to temperature differences, cannot inform even approximately how effectively this transmission, which is so vitally necessary to the plant's efficiency, is going on.

Elaborate, extensive and expensive tests have been conducted to reduce to accurate figures the losses due to scale in boilers, because scale is an undesirable insulator between heat and the water that should absorb it—because it is dirt; because it is foreign.

The refrigeration plant is a great rendezvous of similar foreign substance or substances having similar effects. If the condensers are scaled the heat-laden ammonia cannot get rid of its heat as it should, and it starts on its heat-absorbing journey handicapped and partly incapacitated. If this were all it would not be so bad; but when this ammonia arrives at the working place, at the cooler and the coils, the same coils may be so insulated with ice or scale, or both—and both are foreign, both may be considered dirt, because they are matter in the wrong place—that the half-able ammonia cannot even do what it is willing to do. The compressor water-jackets, the absorber, the generator, the precooler, the cooling tower—all may be likewise coated with dirt. Even the noncondensible gases may be considered as dirt and are worse than scale or ice, because they circulate.

The whole system must be as clean as a freshly laundered shirt if it is to work well. How to keep it clean and working well is the engineer's job. He is the laundryman as well as the maker of the shirt, which in this case happens to be refrigeration. The articles now appearing in POWER tell him in that good old shop-talk way how to do it best. They are useful articles, these; and we hope to have more of them.

Motor Records Again

Engineers in charge of industrial power plants are more and more being made responsible for the quality of motor service rendered on the premises. Even where the establishment carries one or two electricians on its payroll, the chief engineer is likely to be blamed for motor troubles, and the anticipation and prevention of these deserve some attention. Motors of the induction type, if built by reputable concerns, will stand a large amount of abuse, it is true, but the furnishing of efficient service is today demanded almost as much as regular operation, and superficial knowledge of what the local motors are doing is a pitfall into which the steam engineer in executive charge of this branch of the installation should not allow himself to fall.

The larger the plant, the more justifiable it is to keep accurate records of the repair items on individual machines, the performance of different makes, any tendencies toward heating of bearings or moving parts, and the repeated need of adjustment of air-gap conditions, alignment of bearings, or commutator difficulties, where direct-current motors are used. The value of card-index test records of loads carried has been emphasized in these columns; of equal importance is the maintenance of a high power factor in alternating-current installations. Protracted underloading of individual motors leads to overheating of generators from excessive idle current, and the study of manual versus solenoid control for motors on machine tools is one of large interest.

Correspondence

Depth of Stuffing-Box

The writer has had the same trouble with an outside-packed pump as described by C. E. Sherman in the issue of Apr. 6, 1915, page 481. In my case it was overcome by fitting a dummy packing of lignum-vitæ two inches deep and filling the stuffing-box with soft packing. This means of packing removed all trouble and considerably reduced the friction losses.

For low pressures white-metal shavings, with a turn of soft packing before and after, will give good results.

E. R. PEARCE.

Rochdale, England.

Isometric Drawings

Most power-plant engineers can make pencil sketches of the general appearance of parts of machinery, showing the dimensions and thus conveying the desired information to others. Most men would probably draw freehand two or three views on the back of a report sheet and write in such information as they thought the drawing failed to give. A sketch in isometric perspective, or sort of a bird's-eye view, necessitates but one view and is easy to make, yet engineers generally think it beyond their ability. Such a sketch shows the parts in their true relation best and is really easier to draw.

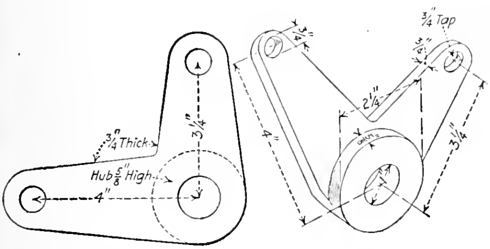

FIG. 1. FIG. 2.
ADVANTAGES OF ISOMETRIC SKETCHES

In a number of cases repair parts made from drawings capable of being misinterpreted have resulted in expensive mistakes. One instance will illustrate. A Corliss engine broke one of the bell cranks. The engineer took the gear apart and sent a helper in with a sketch of the broken piece, Fig. 1. I could see that he had laid the broken crank on the paper and drawn a line around it, and then put on such dimensions and notes as he thought were necessary. The hub was shown dotted and there was a chance for a misunderstanding as to which side the hub should be on, so I phoned to him for the old casting. For some reason he refused to part with it and told me to make it "just as it says on that paper—and be quick about it," for he had to start up at 6 : 30 o'clock.

It was forged out, finished and delivered after working hours. Next morning there was a phone call for another crank made with the hub on the other side, "where it belongs." The second crank was made as shown in Fig. 2, but there was trouble when the bill for two cranks was presented. Fortunately, we had retained the engineer's drawing and the first crank.

The bill was not paid until a competent person had passed on the correctness of the work. Of course, the intentions were all right, but the mistake was in showing the hub by dotted lines, indicating a lower or invisible surface according to the rules of drawing. The engineer had not known this and had committed the error.

A little time spent in practice will make anyone fairly proficient in sketching. It is interesting and is helpful even when correct three-view drawings are at hand.

DONALD A. HAMPSON.

Middletown, N. Y.

Clean New Steam Lines

Although steam has been used commercially for one hundred years or more and steam regulating and economizing devices have been constantly increasing, many engineers are still ignorant as to certain vital points. The greatest trouble we find is that a large percentage of engineers (and this refers to the educated men as well as the ones in overalls) will connect up an entirely new line and blow dirt, grease, white lead, red lead, iron turnings and dirt generally through separators, reducing valves and steam traps and all other devices.

Cannot you start a campaign of education along these lines? We advise wherever we have an opportunity to do so that the lines be blown through for at least forty-eight hours before connecting up the devices. Of course this wastes a lot of steam, but it is paid for a hundred times over in the avoidance of subsequent trouble.

Cleveland, Ohio.

Explosions in Boiler Furnace*

I have read the discussion on this subject for the reason, chiefly, that we have had similar trouble, although so far no damage has been done. Mr. De Blois in the Apr. 30 issue states that his boilers are equipped with underfeed stokers. [These are of the Jones type.—EDITOR.] We have four boilers, horizontal water-tube, equipped with underfeed stokers (Taylor), and on several occasions there have been explosions which occurred while the fire was being worked. I have studied the conditions and believe the trouble is caused in the following manner:

The arrangement of this furnace is such that the coal is pushed into a trough, or retort, by the slow-moving plungers. It is then worked forward and upward by the plunger and incoming coal. When the coal first enters the retort it is fine and closely packed and sometimes

*See "Power," Apr. 30, p. 553; May 11, pp. 651, 652 and 653, and May 25, p. 719.

quite damp, as we wet the coal in the bunker to keep the dust down.

The air holes in the tuyeres are above this trough and about at the level where coking takes place as the coal is moved forward in the furnace. With ordinary crushed bituminous coal, usually quite fine, the greater part of the volatile hydrocarbons are driven off at about this point in the furnace and pass through the incandescent fuel bed above to the combustion chamber. After a few hours' firing a clinker will form on the tuyere plates, which partly obstructs the air passages through the tuyeres and which must be broken up and removed with the slice-bar. This is done through the small side doors. Sometimes it can be done without disturbing the green coal below the tuyeres, and at these times there have been no explosions. But at other times the upper part of the fire, or the incandescent fuel bed, is so broken or so light after getting the clinkers out that it is necessary to break the bed of green coal to level the fire. This liberates a large quantity of rich gas which is below the level of the air openings and has not a good chance to mix with the air coming through the tuyere holes. As this gas rises it comes directly across the path of the high-velocity incoming air and forms a large volume of gas that is explosive and does explode when ignited by the incandescent coke and hot side walls of the furnace. In some cases the flames, usually accompanied by a shower of sparks which I think are particles of coal dust that have been ignited, have shot out of the small doors and into the fireman's face. When the fresh coal was quite wet this explosion was sometimes strong enough to blow open the side doors. The reason that wet fuel causes a more violent explosion is, I think, because the coal is packed more closely and does not allow the gas to escape readily until the fuel is broken up with the bar.

The air pressure in the wind-box at the time these explosions occur is usually about 1.8 to 2.5 in. of water. The boiler damper is usually wide open, and the draft over the fire is maintained at about 0.2 to 0.3 in. of water in the front pass.

Mr. De Blois asks for suggestions as to how to prevent these explosions. I do not know how his furnace is constructed or how the fan is controlled, but in our case the speed of the fan engine, which also drives the stokers, is controlled by a damper regulator which, instead of being connected to the dampers, is connected to a butterfly valve in the steam line to the engine. When the pressure drops about 1 lb. the engine speeds up to about 450 r.p.m. This creates considerable air pressure in the tuyeres, as the steam pressure is usually a little low at this time, and when the green coal is moved with the slice-bar a large volume of explosive gas is liberated.

As a remedy for this trouble I would suggest two changes in the operation, either of which will bring about similar results. First, before the fires are worked with the bar in cleaning or leveling, close the gate in the air-supply pipes, which the fireman will probably not do unless specially instructed. Second, change the methods of control of the fan so that the air pressure will be constant and will change only as the load changes, or in other words, make the air pressure proportional to the load carried by the boilers. The first change will prevent sufficient air from entering the furnace at the time when the rich gas is being driven off to cause an explosion, the gas escaping to the stack. The doors are so small that only a small volume of air can enter at this point, and the air that can filter in through the setting at this low draft pressure is negligible so far as explosions are concerned. The second change would give an even air pressure at all times and might prevent a proper mixture of explosive gas. It also has the advantage of giving a uniform rate of combustion with only the minimum amount of excess air, a condition which makes for economy.

I have never known an explosion to occur except when the front doors were open, but this is the time when the coal is being disturbed, and the air probably comes through the tuyeres instead of through these doors.

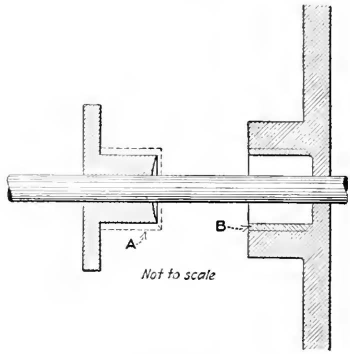
Hyattsville, Md.

Changed Proportions of Stuffing-Box

After having a great deal of trouble with the packing on one of my engine rods, I overcame it as follows:



Stuffing-Box Bushed

The rod was 2 in. and the packing 7/8 in., which is too large for a rod of that size, so I made a bushing 1/4 in. thick and drove it into the stuffing-box, as at *B*, turned 5/16 in. off the gland at *A* and used 5/8-in. packing, which works to perfection. This engine makes a 60-day run of 24 hours without a stop, with a piston speed of 400 ft. There has been no trouble with the packing during the last 45 days.

M. J. Merrell.

St. Louis, Mo.

Grouting under Heavy Machinery*

With small engines—those weighing six or seven tons—six wedges, 2 in. wide, 8 in. long and 1/4 in. thick at the point by 5/8 in. at the butt, are quite sufficient if distributed one at each corner and one in the middle of the frame at each side and all removed as soon as the grout has set. When the engine has been leveled up with a 5/8-in. space left for grouting, a dam of clay or mortar should be built around the bed so as to let the grout stand two inches up the side of the bed. The grout should be two parts clean, sharp sand and one of cement.

*See previous discussion, Mar. 2, p. 310; Apr. 6, p. 482; May 4, p. 620.

mixed to the consistency of thick buttermilk and run in (the bolt holes having first been surrounded with clay). Mr. Wilson speaks of borings and ammonia; this is all right for small jobs, but hardly feasible with a big machine.

The old-fashioned way of bedding down to a stone bed was good, as the stones were very little affected by oil, whereas many foundations have been ruined by oil getting between the bed and engine.

Care should be taken to remove all traces of oil before pouring the grout and it should not be allowed to set too quickly. This may be retarded in a hot room by covering the exposed parts with burlap which should be kept wet. Always make sure that there is a free escape for the air from the inside of the box beds, otherwise the grout will not flow evenly to all parts.

E. R. PEARCE.

Rochdale, England.

In the issue of Apr. 4, p. 620, J. E. Poche advocates using iron wedges in leveling up machinery preparatory to grouting in. Wedges of this kind serve very well for leveling up, but should not be left in as he recommends, as the base of the machine will rest on the wedges and not on the concrete. We tried it once and had to dig the grouting out and do the job over, because of the engine sliding on the iron wedges. I prefer wedges of hardwood for this work.

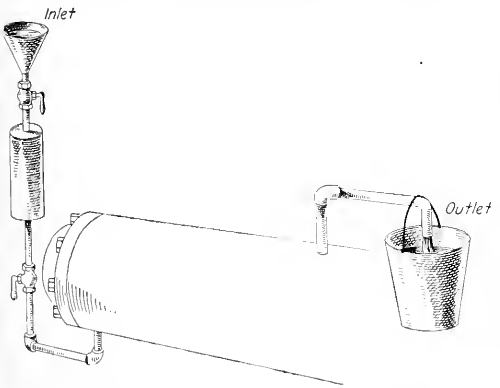
Removing Scale from Inside of Water Jacket

The cooling water, which contained a large amount of sulphate of lime, for an air compressor (12¼x18¼x12 in.), had been throttled, and it raised the temperature of



ACID PIPED INTO WATER JACKET TO REMOVE SCALE

water so that it deposited inside of the cylinder jacket a hard scale which we could not get at to remove with tools. I used muriatic acid piped through as shown in the illustration, and it worked fine. It took ten gallons at 60c. per gallon to do the job.

To operate, close the lower valve and fill the reservoir with acid, then close the upper and open the lower valve. The acid forces its way through and disintegrates the scale in the jacket. I used the acid over again as long as it had any strength.

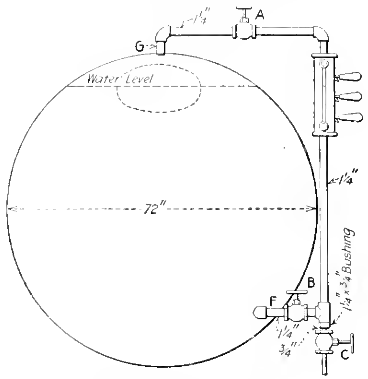
Queer Action in a Water Column

I hesitate to tell the following experience with a 72 ft. by 17 ft. 6 in. horizontal return-tubular boiler, for I would not believe it myself until I had actually seen it.

The boiler had been out of service for a few days for cleaning and repairs. When it was ready again the



WATER COLUMN AS CONNECTED

fireman replaced the manheads and started to fill it with water. (It has been the custom at this plant when filling a boiler to leave all connection closed till an air pressure of about 20 or 30 pounds has been reached; then, if either manhead gasket is defective it will show it at this pressure and can be changed without having to pull the fire.) When the fireman returned to this boiler he found the water showing at the top of the water-glass. He immediately shut off the water-feed valve and opened the blowoff to drain out the water to the proper level for firing up. But he had no sooner opened the blowoff valve than the water disappeared in the gage-glass and did not return. He then closed the blowoff and opened the feed-water valve, and the water immediately rose to the top of the glass again. He repeated this performance several times, with the same result each time, and then called in the foreman who also obtained the same results. He then shut both the blowoff and the feed valves and opened valve *C* (valves *A* and *B* being already open), and there was a strong suction of air into the boiler. Valve *B* was next closed, with valves *A* and *C* open, and water rushed out with considerable force. Valve *A* was then closed, with *B* and *C* open, and the water immediately stopped running, but there was no suction. On opening valve *A*, however, with valves *B* and *C* open, the suction commenced again and the water could be seen rushing upward through the gage-glass.

These valve changes were made many times, with the same results. With valves *A* and *B* open and *C* closed, the water sometimes showed at one height in the glass and sometimes at another. It finally came to rest at a point a little below the third gage-cock, but the suction continued when valves A, B and C were opened, and water rushed out when valve B was closed, with A and C open, as before.

It was finally decided to take out the rear manhead to see the actual location of the water level. Before doing this, however, valves A, B and C were again opened and the suction was as strong as ever. Valve C was closed and the water level, after some fluctuation, came to rest in the glass a little below the third gage-cock. The rear manhead was then loosened, but instead of falling in as was expected, there seemed to be a heavy pressure holding it in place. It required several sharp blows with a heavy bar to loosen the head. When it was finally driven in air and water spurted out as if from heavy pressure. The water level was found to be about as the level in the glass had last shown it.

The boiler was then emptied and all the pipe connections of the water column removed and examined. The lower horizontal pipe marked F was partly closed with scale, but still had a free opening of ample area, and the rest of the pipe and the water column itself were perfectly clear.

Now, if anyone can satisfactorily explain how vacuum and pressure can exist in the same boiler at the same time I would like to see the explanation published in POWER. Also, why and how did the water siphon out of the boiler in a continuous stream when valve B was closed with A and C open? Pipe G did not extend through the shell of the boiler more than ½ in., and the water level was eight or ten inches below it.

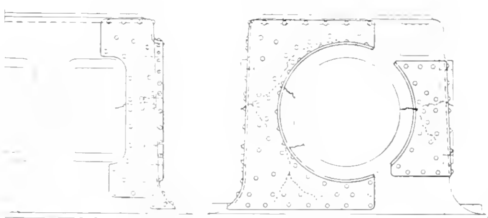
Gillespie, Ill.

Repairing Gas-Engine Housing

On one of the three-cylinder vertical 200-hp. gas engines in the local electric-light plant the housing was broken as shown by the heavy dotted lines in the illustration. The fracture began at the end bearing seat and continued around the corners and along both sides, terminating at the manholes in each side. On one side of the end



SHOWING HOW PLATE WAS RIVETED TO HOUSING

vertical center line the break extended upward and downward until there was practically no support for the bearing and shaft and part of the weight of the revolving part of the generator.

The builders of the engine advised that the least time in which they could furnish a new casting completely machined would be three weeks, which meant a serious delay for the lighting company.

A local firm guaranteed that it could repair the housing in three days from the time of delivery at its works. The offer was accepted, and a very substantial job was accomplished. The repair plates are $\frac{9}{16}$-in. boiler plate formed to fit the casting as shown, and special care was exercised to make a good fit around the circular flange at the bearing seat. Where possible the plates were secured to this flange with ¾-in. machine screws fitting in reamed holes that penetrate sufficiently into the casing flange to insure a true surface for the end face of the bearing. In the other parts ¾-in. rivets were used, and around the corners these extended through, with heads against the fillets on the inside of the housing.

On the whole this repair job, while a big one, is entirely satisfactory, and besides saving much time, proved cheaper than a new housing.

Franklin, Penn. M. E. GRIFFIN.

Priming Centrifugal Pumps

Having read the several letters in recent issues of POWER* relative to priming centrifugal pumps, I submit the following description of a method that I used successfully on a three-stage pump. This was connected to 21 drilled wells and discharged into a standpipe about 160 ft. above the pump. The wells were divided, ten on one and eleven on the other side of the pump, with a check valve in each lead.

An old belt-driven air compressor was used as a vacuum pump, and the suction was connected between the wells and the check valves. The suction pipe was run up through the chimney, which gave it a total height of 40 ft., so that the pump would not draw water into the cylinder. The pump suction pipe between the check valves and pump was filled with water and the air pump started. After the air was exhausted from the suction pipe, the centrifugal pump was started.

Marshfield, Wis. LOUIS B. CARL.

The letters on this subject appearing in recent issues of POWER are interesting and instructive.

About two years ago I installed four centrifugal pumps, each of which had a suction lift from 12 to 16 ft. The suction pipes were from 4 to 10 in. in diameter and the discharge pipes 4 to 8 in. Two of the pumps were used for pumping sewage and two for clear water. The speed was from 1250 to 1500 r.p.m., the discharge lift from 30 to 70 ft. Each suction pipe had a foot valve (they could not be kept tight on the sewage pumps) and a strainer at the inlet end. There never was any trouble in priming these pumps. The facilities for priming consisted of a 2-in. pipe connected to a tank 30 ft. above the pumps. The tank was always kept full of water.

A 1-in. branch pipe from the 2-in. line was run to each pump and a 1-in. straight-way valve put in each branch.

All the pumps had water-sealed shafts and were direct-connected to alternating-current motors from 35 to 125 hp. The valve on each discharge pipe was opened only after speeding up the pumps. From two to four minutes was the time required to prime. A vacuum gage was at-

*"Power," Mar. 2, p. 294; Apr. 6, p. 481; Apr. 20, p. 550; May 4, p. 615

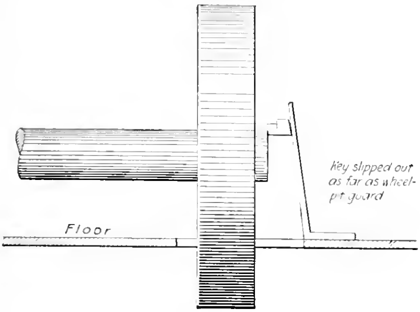
tached to each suction pipe and a pressure gage to each delivery pipe between the pump and the delivery pipe valve.

James E. Noble.

Toronto, Ont.

An Accident Prevented

The illustration shows how a sheet-iron wheel-pit guard prevented a flywheel from slipping off the shaft and probably causing serious damage. The diameter of the wheel is only 30 in., but it is in such a position that had it slipped off it would have wrecked the main unit of the isolated plant. One of the attendants noticed that the wheel was not running true, and it was found that the key was very loose and a new one had to be made.



Key Held in Place by Guard

Providence, R. I.

Comment on Turbine Lecture

I have read C. H. Bromley's lecture on steam turbines in the May 11 issue. In the latter part he offers suggestions on starting and running a turbine, and it does not appear to be clear what type of machine he had in mind.

To pick out one or two statements: "Now close the drains of the stages. The gear may then be oiled. The main turbine may vibrate considerably while being brought up to speed" . . . "to get the rotor above the 'critical speed,' when the vibration will ordinarily cease."

Mr. Bromley's opening remarks undoubtedly refer to a multi-stage turbine; in fact, one might gather that he has particular reference to a Curtis vertical machine. He then appears to refer to a De Laval single-stage impulse turbine in the same breath, as it were, for no multi-stage units are built with shafts which run above their critical speeds; in fact, to my knowledge this characteristic is peculiar to the original single-stage impulse De Laval, with its flexible shaft. I might also add that if the gears which Mr. Bromley mentions did not receive oil immediately they started to revolve, instead of after the load was thrown on, the heat generated would soon cause abrasion of the teeth.

He refers also to clearances between the blade teeth and the casing. As every turbine man knows, the radial clearances for an impulse turbine can be much greater than for a reaction, due to there being no pressure difference between the two sides of any one wheel, whereas with the reaction type these must be reduced to the smallest practical amount. There are also other statements on which comment might be made, such as, "sometimes an elevated tank is used for supplying oil at starting and stopping." The gravity system, comprising the elevated tank with cooling coils and filter placed below, is in general use.

R. N. Austin.

Toronto, Ont., Can.

I was much interested in Mr. Bromley's lecture on the steam turbine, appearing in the May 11 issue of Power, particularly in his instructions for starting.

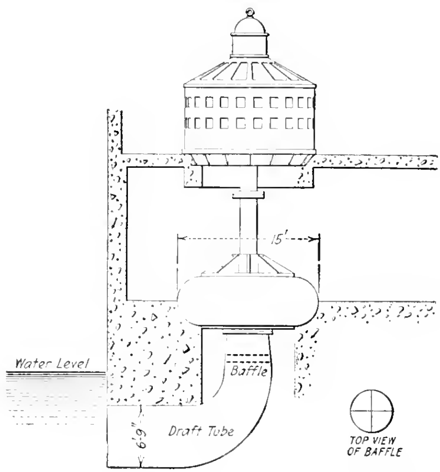
He says the turbine may vibrate considerably while being brought up to speed and that the admission of a little more steam quickly to get the rotor above the "critical speed" will ordinarily cause the vibration to cease. Although his instructions seem to apply to the Curtis turbine, this point is also true of the Westinghouse machine. If, however, the turbine is started about fifteen or twenty minutes before it is needed for the load and slowly brought up to speed, the vibration at the "critical speed" will be reduced to a minimum and in some cases done away with altogether.

John Tooker.

Richmond Hill, N. Y.

Draft-Tube Water-Hammer

Recently, there was installed in our plant, a 15,000-hp. waterwheel driving an alternator. The plant operates under 375-ft. head and the unit runs at 375 r.p.m., the pressure at the waterwheel being 158 lb. When operating at $\frac{5}{10}$ gate opening, it was found that water-hammer occurred in the draft tube, causing the pressure in the pipe line to rise 25 lb. and starting leaks in the 7-ft. wooden-pipe line.



Baffle in Draft Tube Stopped Water-Hammer

The theory of the engineer was that, owing to the construction of the draft tube, the velocity of water at that particular gate opening was such that the whirling motion through the wheel set up a counter-current in the center of the draft tube, causing the water to come back into the wheel and raising the pressure. The vacuum gage in the draft tube varied from 15-in. vacuum to 5-lb. back pressure under this condition of water-hammer.

The engineer stated that a baffle placed in the draft tube to break up this whirling motion would cure the trouble, and a piece of boiler plate 1 in. thick and 18 in. wide was then placed therein, as shown in the accompanying sketch.

This cured the difficulty and since then no trouble has been experienced.

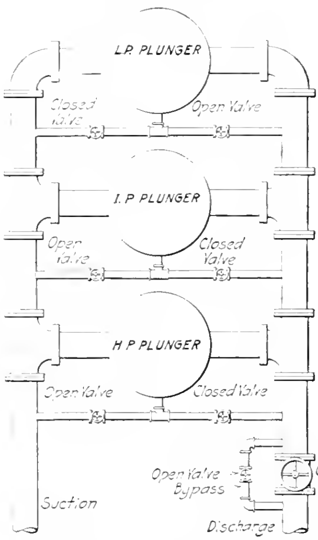
J. B. Crane.

Duluth, Minn.

Moving Pumping Engines by Water Pressure

Handling pumping engines of the large sizes calls for a method of procedure peculiar to itself. They must be moved a small distance at a time and also held securely in position.

Multiple-expansion pumping engines are not usually built with reversing gears, and it is customary to move



Pipe Connections for Water Pressure

them forward or backward a small amount with water pressure. I submit the simple illustration of the pipe connections to the plungers and valve chambers of a twenty-million gallon pump.

The engine is of the vertical triple-expansion type. The three cranks are set at 120 deg. apart. We have access to a 100-lb. water pressure which is brought to bear under the plunger whose crank happens to be in position to be raised. This moves the entire engine. By the manipulation of a set of bypasses the discharge area, plunger chamber and suction area are thrown open to water pressure and release as desired.

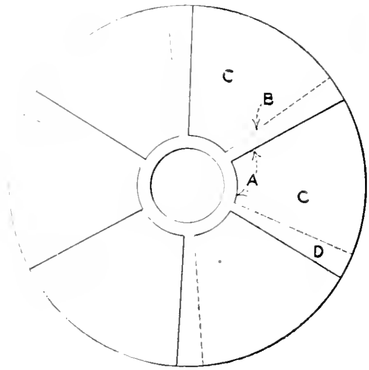
Edward T. Binns.

Philadelphia, Penn.

Increasing the Flow of Water

An appliance for increasing the amount of water that will flow through the outlet of a shallow tank when the depth of the water does not exceed three times the diameter of the outlet may be easily made in the following manner:

Cut a sheet-metal disk of suitable thickness four times the diameter of the outlet, and a hole in the center of



Disk over Tank Outlet

the disk the size of the outlet. Lay out the flange in six equal parts (see illustration). Cut the disk on the full lines marked *A* and bend on dotted lines *B*, bringing the planes *C* to a vertical position and at right angles to *D*, thus forming six wings. Place the appliance directly over the outlet, using the plane *D* as the base. The plane *C* eliminates the whirling motion of the water and allows it to run out in a steady stream.

E. A. Buchanan.

Coffeyville, Kansas.

"Unusual Opportunity" for the Fireman

When it comes to versatility for the fireman we certainly have to hand it to North Carolina. In this state he can assume such rôles as best meet any and all occasions, playing the part of fireman, scrubman, bath artist, etc., with full permission of the law. In fact the law helps him to it, as shown by the following interesting extract from the State Public General Laws of 1911, and now operative:

Section 1 (Chapter 156). That the fireman of the Supreme Court building shall be appointed by the chief justice and associate justices of the Supreme Court, and when not engaged in his duties as fireman shall act as assistant janitor of the Supreme Court, and shall assist in the cleaning and care of the Supreme Court and perform such other duties as may be designated by the said justices of the Supreme Court.

This law, granting these great privileges, is the noble work of the General Assembly. How many members of that honorable body ever visited a boiler-room to learn what firing really meant?

L. R. W. Allison.

Newark, N. J.

Inquiries of General Interest

Long-Range Cutoff for Corliss Engine—How can long range of cutoff be secured with a Corliss engine?

J. C. H.

By supplying the engine with a separate eccentric for operation of the steam valves.

Submerged Piston vs. Straightway Pump—What is the difference between a submerged piston and straightway pump?

W. C. O.

Submerged piston pumps are like the ordinary duplex feed pump with both suction and discharge valves above the water pistons, the latter being submerged, while in the straightway pattern the suction valves are below and the discharge valves above the water pistons.

Terminal Pressure—What is meant by terminal pressure?

S. H. J.

Terminal pressure is the pressure that would be in the cylinder at the end of the stroke of the piston if the exhaust valve did not open until the stroke was completed. On a steam-engine indicator diagram the terminal pressure may be found by extending the expansion curve to the end of the diagram. The theoretical terminal pressure is found by dividing the pressure at cutoff by the ratio of expansion.

Piston Displacement—What is meant by the term "piston displacement"?

C. A. G.

Piston displacement is the space, usually reckoned in cubic inches, through which the piston sweeps in a single stroke. It is found by multiplying the area of the piston, in square inches, by the stroke in inches. The displacement of a pump piston would be the number of cubic inches of water discharged by one stroke, if there were no leakage or slippage.

Spouting Velocity of Liquid—What is the "spouting velocity of a liquid?

S. H. H.

The velocity with which a liquid under pressure issues from an orifice, and unless otherwise qualified, the term is used to signify the theoretical velocity that would be due to the head or pressure of the liquid at the entrance of the orifice, as given by the formula,

$$v = \sqrt{2gh}$$

in which

v = Velocity in feet per second;

$2g = 64.32$;

h = Head in feet, equivalent to the pressure.

Absolute Pressure for Inches of Vacuum—What would be the absolute pressure with 26 in. of vacuum and 29.5-in. barometer?

M. W. C.

Inches of vacuum signifies pressure in inches of mercury column below the pressure of the atmosphere; hence, with a barometer reading of 29.5 in., 26 in. of vacuum would represent an absolute pressure of

$$29.5 - 26 = 3.5 \text{ in. of mercury.}$$

At ordinary temperatures each inch of mercury may be taken as equal to 0.491 lb. per sq.in., therefore the absolute pressure would be

$$3.5 \times 0.491 = 1.7185 \text{ lb. per sq.in.}$$

Stacks Mounted on Boiler Settings—What are the advantages or disadvantages of having independent steel stacks set directly over the front smoke connections of return-tubular boilers?

W. L. B.

Stacks erected in that manner have the advantages of affording direct and independent draft and a saving of ground or floor space required for independent bases and foundations. They have the disadvantages of requiring special supports and also of usually requiring reinforcement of the front ends of the boiler settings to prevent the settings from being racked by wind movement of the stack. They also present difficulties in providing protection of the front end of the boiler and setting from damage by rain water carried down inside or outside of the stack.

Designation of Superheated Steam—How is the amount of superheating of steam designated and how is it usually determined?

S. W.

Superheating is designated in degrees of superheat, meaning the number of degrees by which the actual temperature of the steam exceeds the temperature of the boiling point corresponding to the pressure which is under consideration. For practical purposes the number of degrees of superheat present is usually determined by ascertaining the actual temperature of the steam by a thermometer and deducting the temperature of saturated steam for the given pressure, as found from the steam table. Thus, if the gage pressure of the steam is 150 lb. per sq.in. and a thermometer inserted in it shows that its temperature is 470 deg. F., then, as the temperature of saturated steam for the pressure is about 366 deg. F., there would be

$$470 - 366 = 104 \text{ deg. of superheat.}$$

Relative Economies of Evaporation—If, with an average temperature of feed water of 44.4 deg. F., a boiler evaporates 36,315 lb. of water into dry saturated steam at an average gage pressure of 110.4 lb. per sq.in., using 5326 lb. of coal, what would be the relative economy with an evaporation of 39,000 lb. of water from a feed temperature of 45 deg. F. into dry saturated steam at an average gage pressure of 107.6 lb. per sq.in. and using 5600 lb. of coal, the kind of coal, duration of trials and other conditions being the same?

M. T. J.

In the first instance the actual evaporation would be 36,315 ÷ 5326 = 6.818 lb. of water per pound of coal. A pound (weight) of steam at 110.4 lb. gage pressure or about 125 lb. absolute contains 1190.3 B.t.u. above 32 deg. F., and as each pounds of feed water at 44 deg. F. contains 44.4 — 32 = 12.4 B.t.u. above 32 deg. F., the heat received by each pound of water evaporated would be

$$1190.3 - 12.4 = 1177.9 \text{ B.t.u.}$$

As the heat required for evaporation of a pound of water from and at 212 deg. F. is 970.4 B.t.u., the factor of evaporation would be

$$1177.9 \div 970.4 = 1.2138$$

so that the evaporation of 6.818 lb. of water per pound of coal would, under the conditions, be equivalent to the evaporation of

$$6.818 \times 1.2138 = 8.2757 \text{ lb.}$$

of water from and at 212 deg. F. per pound of coal.

In the second instance the actual evaporation would be 39,000 ÷ 5600 = 6.964 lb. of water per pound of coal. As the gage pressure of 107.6 lb. per sq.in. would be equal to about 122 lb. absolute, each pound (weight) of steam would contain 1189.8 B.t.u. above 32 deg. F. With feed water at 45 deg. F. each pound evaporated into steam would receive

$$1189.8 - (45 - 32) = 1176.8 \text{ B.t.u.}$$

the factor of evaporation would be

$$1176.8 \div 970.4 = 1.2132$$

and there would be an evaporation equivalent to

$$6.964 \times 1.2132 = 8.4487 \text{ lb. of water per pound of coal.}$$

Therefore, in the second instance there would be

$$\frac{8.4487 - 8.2757}{8.2757} \times 100 = 2.09 \text{ per cent.}$$

more water evaporated per pound of coal, and for evaporation of the same quantity of water the percentage less of coal would be

$$\left(\frac{1}{8.2757} - \frac{1}{8.4487}\right) \times 100 \times 8.2757 = \text{nearly } 2.05 \text{ per cent.}$$

Such small variations of conditions would be required to make the evaporative economies equal that, for all practical purposes, the results may be regarded as identical.

[Correspondents sending us inquiries should sign their communications with full names and post-office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

License Legislation in the United States*

By A. A. Potter†

Thirty-four states have no state laws at present and no proposed state legislation for licensing stationary engineers. They are: Alabama, Arizona, Arkansas, Colorado, Connecticut, Florida, Georgia, Idaho, Iowa, Kentucky, Louisiana, Maine, Maryland, Michigan, Mississippi, Missouri, Nebraska, New Hampshire, New Mexico, New York, North Carolina, North Dakota, Tennessee, Utah, Vermont, Virginia, Washington, West Virginia, Wisconsin and Wyoming.

Nine states—California, Delaware, Illinois, Indiana, Kansas, Minnesota, Pennsylvania, Rhode Island and Texas—had laws pending in 1915. Charles H. Wirmel, chairman of the N. A. S. E. License Committee, asserted that a state law is pending in Washington. I have been unable to secure from the secretary of state at Washington any confirmation that such a law is before their legislature.

In Indiana an attempt has been made several times to have a state license law passed, but without success. The manufacturers, farmers, and even many of the operating engineers fought the bills introduced.

Several unsuccessful efforts were made to enact a state law in Missouri, but nothing was brought up at the 1915 session of the legislature. The State of New Hampshire has certain laws regarding engineers operating steamboats.

North Dakota, in Sec. 8994 of the 1905 Revised Codes, holds the engineer or other person having charge of steam boilers and engines responsible and guilty of a misdemeanor for accidents whereby human life is endangered.

The states having city laws include Alabama, California, Colorado, Connecticut, Indiana, Iowa, Illinois, Louisiana, Maryland, Michigan, Nebraska, New Jersey, New York, Pennsylvania, Tennessee, Washington and Wisconsin. These laws were given in detail in the "Report of the License Committee of the N. A. S. E." in 1906.

The act of the general assembly of the State of Louisiana empowers municipalities of over 50,000 inhabitants, through their local councils, to regulate the use of stationary and portable steam boilers, and to constitute and appoint a board of examiners of stationary and portable steam-boiler engineers for the carrying out of this purpose . . . empowers said municipalities to require persons operating steam boilers . . . , to have in their possession and posted in conspicuous places in the engine room where employed as such, certificates of authority . . . This act further requires owners to have none but certified engineers, having proper certificates and renewals thereof.

Missouri has at present the following law: "No person is authorized to manage, control or take charge of or act as engineer of any steam boiler, engine or apparatus, who has not the requisite knowledge or ability to manage the same with safety to the lives and property of the inhabitants of such cities. Any incorporated association of qualified local steam engineers in any city is authorized to appoint an examining committee for the granting of certificates of qualifications." Provision is also made that no charge exceeding one dollar is to be made for any certificate.

The State of Maine has certain laws pertaining to school buildings, churches or other public buildings when heated by a steam plant located in, under or near such building.

EXISTING AND PROPOSED LAWS

Examiners—The state license laws are under the jurisdiction of the boiler-inspection department of the District Police in Massachusetts. In Montana the state boiler inspectors attend to the licensing of engineers. In Nevada the boards of county examiners regulate the operation of stationary and hoisting engines. The state laws of Nevada are not very extensive or definite, but aid in protecting life and property. The district examiners, who are under the Industrial Commission of Ohio, examine applicants for licenses, while in New Jersey this power is vested in a bureau of the Department of Labor, known as the "Steam Engine and Boiler Operators' License Bureau." In Minnesota 53 inspectors are appointed by the governor and these examine engineers, issue licenses and inspect boilers. This system makes it possible to build up quite a political patronage. A new bill has been introduced into both branches of the Minnesota legislature this year which is indorsed by the Minnesota State Association of the N. A. S. E., the main features of which will be brought out later.

Among the states having proposed state license laws in 1915, California, Illinois and Pennsylvania have an examining board consisting of one chief engineer and several assistant examiners. In Indiana an examining board is appointed by the governor, but this board is under the supervision of the chief inspector of the State Bureau of Inspection, who is ex-officio the president of the examining board. In California the examining board is appointed by the commissioners of the Bureau of Labor Statistics. In Minnesota and Texas one examiner is appointed for each congressional district. The contents of the bills for Delaware and Rhode Island could not be secured. The proposed state law of Kansas vested the licensing power in an "Engineers License Committee."

In the majority of states a person to be eligible as examiner must have ten to fifteen years of practical experience.

License Required—Those exempted from license requirements include operators of locomotives, motor road vehicles, boilers in private residences, boilers and engines under the jurisdiction of the Government of the United States, boilers carrying not more than 15 lb. pressure, boilers and engines (stationary and traction) when used for agricultural purposes exclusively.

In Illinois and New Jersey the exemptions include boilers carrying not more than 10 lb. pressure and in Illinois only heating plants which serve 50,000 sq.ft. radiation or less. In California boilers less than 4 hp. and also those used in logging camps or in pumping or boring wells for oil or water are exempted. The proposed bill of Indiana and Ohio exempts boilers used in the production of crude oil. In some states the existing or proposed laws exempt only such heating boilers as are provided with a device approved by examiners, limiting the pressure to 15 lb. Apartment houses to be exempt must have less than five flats. In several states fire-department engines are exempt.

The exemption limit for boilers and engines is 9 hp. in Massachusetts, 30 hp. in Ohio and Pennsylvania, and 250 hp. in Texas. In Texas this high limit is fixed in order to exempt all ginners, contractors and sawmills of the state. In Pennsylvania first- and second-class cities are exempt from the state license act, such cities having municipal license laws.

Classification of Licenses—Several of the proposed bills seem to be in favor of making no differentiation between grades or classes of engineers. California, Indiana, Illinois, Nevada, New Jersey and Pennsylvania have such bills in force or proposed. A large number of the cities of the first class have unclassified license laws, the opinion being that the license law is mainly for the protection of life and property.

The Massachusetts license law includes four different classes of engineers' licenses, three classes of firemen's licenses and a special license for particular plants.

The proposed law of Minnesota calls for four classes of engineers' licenses and also a special license for portable, traction or agricultural engines.

In Montana there are three classes of engineers' licenses and a traction-engine license. Firemen not under the direct charge of an engineer are required to have a third-class license.

Ohio classifies engineers' licenses into first, second and third grades. These licenses are granted partly upon the percentages received in the examination, as will be explained in the next section.

The Texas bill grades engineers into three classes—first, second, and special. The owner or lessee is held responsible for the engineer carrying a special license.

The proposed Kansas bill provided for two grades of engineers' licenses.

Requirements for Licenses—All proposed state bills make provision for issuing licenses to engineers engaged in the practice of their occupation at the time the licensing act takes effect.

In Massachusetts where the licenses are classified, to be eligible for a first-class fireman's license a person must have been employed as a steam engineer or fireman in charge of or operating boilers for not less than one year. The third-class engineer's license requires one and one-half years' ex-

*Paper presented before the Kansas State Convention of the National Association of Stationary Engineers at Wichita, on May 14, 1915.

†Dean of the Division of Engineering and Professor of Steam and Gas Engineering at the Kansas State Agricultural College.

perience, the second-class engineer's license two years' experience in a plant having at least one engine of over 50 horsepower. A person who has served an apprenticeship for three years to the machinist or boiler-making trade or is a graduate of a recognized engineering college, is eligible to take the second-class engineer's examination if he has been employed for one year in connection with the operation of a steam plant. Three years' experience in a power plant having at least one engine of 150 horsepower is the requirement for first-class license examination.

The proposed act of Minnesota requires five years' experience for first-class license, three years' experience for second-class, and one year's experience for third-class license.

In Montana the requirements are three years' experience for first-class license, two years' experience for second-class license, and one year's experience for third-class license.

In Ohio a first-class license is granted to applicants who have had three years' practical experience and who obtain a percentage of 85 or more in the examination. Two years' experience and a percentage rating of from 70 to 84 entitle the applicant to a second-class license, while the third-grade applicant must have one year's experience and an examination rating of from 60 to 69.

No definite requirements were outlined for the two grades of licenses in the proposed Kansas bill.

A clause should appear in bills or acts giving special authority to representatives or erecting engineers of any manufacturers of boilers or engines when employed in installing, testing, or operating boilers or engines.

Fees for Licenses—Illinois and Ohio, $2 for license and $2 for yearly renewal. California, Nevada and Texas charge $5 for license. Nevada has no renewal requirement, while California and Texas charge annual renewal fees of $2 and $5 respectively. The proposed law of Pennsylvania has $3 for license and $1 for renewal. In Montana the charges are: $7.50 for first-class license, $5 for second-class, $3 for third-class and special, and $1 for yearly renewal for all grades. The proposed Kansas law provided for $5 fee in the case of first-class license, $3 for second-class, and yearly renewal charges for the two classes $3 and $2 respectively.

The present Minnesota law allows the inspector to grant licenses for a fee of $1, which he pockets. The proposed law includes $2 for examination and $1 for annual renewal.

Appeal from Refusal of License—A person who is aggrieved by the action of an examiner in refusing or revoking a license has the right of appeal therefrom in all states except in Massachusetts, where the action of the examining board is final. In several states the applicant has the privilege of having one outside person during the examination or during the hearing of an appeal. This person is not allowed to take part, but can take notes if he so desires.

Posting of License—In the majority of states the act requires that the engineer's or the firemen's license be placed in a conspicuous position in the engine room of the plant operated by the holder of such license.

Operation without License—In Massachusetts a person without a license is allowed to operate a plant for one week, in Pennsylvania ten days and in Montana for a period of fifteen days, provided notice to that effect is sent to the inspector. In the majority of cases no provision is made authorizing operation without license.

Records of Operation—The Massachusetts law requires "a daily record of the boiler, its condition when under steam and all repairs made and work done on it" upon regular printed forms furnished by the boiler-inspection department.

Boiler Inspection—The states of Colorado, Connecticut, Massachusetts, Minnesota, Montana, Nevada, New York, Ohio, Pennsylvania and Wisconsin have boiler-inspection laws. In Colorado the governor appoints a chief and three deputy boiler inspectors who test every stationary boiler annually. The same is the case in Connecticut, where a boiler inspector is appointed from each congressional district.

In Massachusetts and in Ohio, besides the boiler-inspection department, which is responsible for the inspection of boilers, there is a "Board of Boiler Rules." The chief inspector of the boiler-inspection department is the chairman of the board of boiler rules, the other members being selected to represent the boiler-using interests, the boiler-manufacturing interests, the boiler-insurance interests and the operating engineers. The board of boiler rules formulates rules for constructing, inspecting, installing and testing of boilers.

Montana seems to have had boiler-inspection laws for many years. The 13th Biennial Report of the state boiler inspector shows that even in such a large and thinly populated state as Montana the boiler-inspection department has not only been self-sustaining, but has produced a revenue for the state, over all expenses, of nearly $16,000. The state has no record of a serious boiler explosion.

In New York the state fire marshal has charge of boiler inspection.

[This office has been discontinued and the duties of boiler inspection transferred to the factory inspector.—Editor.]

In Wisconsin boiler inspection is under the Industrial Commission, which has a standard code of rules for the construction, operation and inspection of boilers. This commission accepts inspections from qualified inspectors in cities of the first, second, and third class.

The fees for boiler inspection are, in the majority of states, $5 for external and internal inspection of each boiler and $2 when the boiler is only externally inspected under steam pressure. In Connecticut provision is made for inspecting steam boilers owned by farmers, once in two years for a fee of $2, provided such boilers do not exceed 5 hp. each. In Montana a charge of $10 is made for the inspection of a single boiler and $5 for each additional boiler.

The present law of Minnesota allows the inspectors to charge $3 for each boiler inspection and to keep such fees. The proposed law of Minnesota places a fee of $3 for the inspection of a single boiler and $2 for the inspection of each additional boiler.

In this connection the recent act before the 1915 Pennsylvania legislative session is of some interest. This act requires municipal inspection of steam and hot-water installations and provides for the examination, licensing and registration of persons, firms or corporations engaged in the business or work of steam and hot-water fitting.

DISPOSITION OF 1915 BILLS

It may be of interest to report the status of the bills proposed in 1915: The Kansas bill was killed in the committee. The Delaware, California, and Rhode Island bills were lost. The proposed license-law bill of Pennsylvania was declared unconstitutional by the attorney-general, principally on account of its exemptions. An act for the licensing of engineers in third-class cities of Pennsylvania passed through the committee and it is understood has a good chance of passing the House. In accordance with this bill, the city council appoints an examining board, consisting of two engineers who have had not less than six years' practical experience, to act in conjunction with the director of public safety. The proposed engineers' license and boiler-inspection law of Minnesota was defeated in the Senate on Feb. 18, after much hard and creditable work on the part of the Minnesota State Association of the N. A. S. E. No definite information could be secured regarding the ultimate fate of the bills proposed in Illinois, Indiana and Texas.

Powdered Coal

At the seventh annual convention of the International Railway Fuel Association, W. L. Robinson, supervisor of fuel consumption of the Baltimore & Ohio R.R., read an interesting paper outlining the advantages that might result from the use of powdered coal in locomotive furnaces. The cost of fuel for the 65,000 steam locomotives in use in the United States is from $250,000,000 to $275,000,000 per annum, and now represents about 25 per cent. of the total transportation-account expenses. The fuel used is principally bituminous coal, anthracite, fuel-oil, lignite and coke. While powdered coal has been used successfully and rather extensively for years in cement and metallurgical furnaces, its use for steam-making purposes has been limited, owing to the lack of practical development. Its possibilities, however, are great, and if the practical difficulties can be overcome, the saving for the various railroad companies throughout the country will be on a corresponding scale.

Coal in a finely divided or powdered state represents the most advanced method for producing perfect combustion. While a cubic inch of solid coal exposes only 6 sq.in. for absorption and liberation of heat, a cubic inch of powdered coal exposes from 20 to 25 sq.ft., which enables the more uniform gas production from the volatile matter in the coal and the more prompt and perfect intermingling of gas and air, thereby improving combustion and reducing smoke. Furthermore, there is no cooling of the fire by heavy intermittent charges of fresh coal, as is the case with hand or stoker firing on grates.

It has been generally thought that for the burning of solid fuels in powdered form in suspension, a bituminous coal of less than 30 per cent. volatile matter could not be used with satisfactory results. Mr. Robinson, however, had been informed that good results were being obtained in locomotive practice from semibituminous coal analyzing as low as 21 per cent. volatile and having 15 per cent. ash and moisture. To give the best general results and the least trouble from ash and slag, powdered coal should contain not more than 1 per cent. moisture and be of a uniform fineness, so that not less than 95 per cent. will pass through a 100-mesh, not less than 85 per cent through a 200-mesh, and not less than 70 per cent. through a 300-mesh screen.

COST OF POWDERING

The cost of preparing powdered coal will vary with the cost for the raw coal and its moisture content. However, a general average from available data covering periods of the past five to ten years at cement and metallurgical plants has made it possible to present the following conservative estimate, assuming the cost of the raw coal at from $1 to $2 per short ton, and that it will require crushing and have a moisture content of from 5 to 10 per cent. when placed in the drier:

Capacity of Plant in Short Tons per Hour	Average Total Cost for Preparation per Short Ton
2	From 25 to 50 cents
3	From 20 to 45 cents
4	From 16 to 40 cents
5	From 14 to 35 cents
10	From 12 to 30 cents
25	From 10 to 20 cents

The fuel required for drying the coal will average from 1 to 2 per cent. of the coal dried. The distribution of the total may be approximately stated as follows:

Fuel for drying	10 per cent.
Power for operation	30 per cent.
Labor	30 per cent.
Maintenance and supplies	25 per cent.
Interest, taxes, insurance and depreciation	5 per cent.
Total	100 per cent.

The cost of preparing powdered coal should be more than offset by the ability to utilize mine refuse and sweepings, run-of-mine, screenings and slack grades of coal that cannot be used to good advantage otherwise, and inferior grades of sub-bituminous coals, lignite and peat of relatively lower cost per ton than the readily salable commercial fuels.

Powdered coal may be burned by either of two generally defined methods—the long-flame method, constituting a progressive burning of the coal such as is employed in cement and openhearth furnaces, and the short-flame method, which is the latest development and is used in metallurgical and similar metal-heating work or under boilers where a similar furnace volume obtains. A combination of the long- and short-flame methods has been tried recently on a New York Central locomotive equipped for burning powdered coal.

LOCOMOTIVE MODIFICATIONS REQUIRED

For locomotive work the principal requirements are an inclosed fuel container, means for conveying the fuel to the feeders, means for commingling the fuel with air at the time of feeding, and afterward equipment for supplying the proper amount of air to produce a combustible mixture at the time the fuel and air finally enter the furnace, a suitable refractory-material furnace in the firebox, means for disposing of the slag, means for producing the proper draft through the furnace and boiler, means for harmonizing the draft and the combustion, suitable power for operating the fuel- and air-feeding mechanism, and automatic and hand control of the fuel and air regulation.

It is understood that the developed equipment for burning pulverized fuel can be readily applied to all existing modern types of steam locomotive without any changes in the boiler except to install arch brick supporting tubes, where fireboxes are not now equipped, and to remove the grates, ashpan and smokebox draft appliances. There is no equipment in the cab except the automatic hand control, which is placed in a position convenient to the fireman. The inclosed fuel container is suitable for either powdered coal or fuel oil and either kind of fuel can be used by changing the feeding equipment. The total weight of equipment applied will about equal that of the equipment removed. When not in operation the necessary draft through the boiler is obtained by the usual stack steam blower, and by exhaust steam from the cylinders when the locomotive is working. The supply of fuel is regulated according to the work the locomotive is performing, and when drifting or standing on sidings or at terminals, it can be entirely shut off. The exhaust-nozzle opening is about double the area of that used for grate firing.

Some of the advantages enumerated were the sustained boiler horsepower obtained from the use of powdered coal, the ability to increase the economical length of run, the firing of the boilers automatically with no hand-labor, the prevention of cinders, sparks, and smoke; the reduction in cylinder back-pressure due to the enlarged exhaust passages; saving in inspection, maintenance and operation through the elimination of grates, ashpans, dampers, etc.; a more uniform furnace temperature, reducing the liability of firebox and flue leakage; ability to make use of inferior qualities and grades of solid fuel; reduction of delay from cleaning or dumping fires; and a number of other factors which would tend to improve efficiency and lower the cost per car-mile.

DISCUSSION OF THE PAPER

The paper aroused a great deal of interest, and the subject was considered of enough importance to appoint a permanent committee to keep posted on developments in this field. In the discussion some of the difficulties experienced in burning powdered coal were brought to light. The principal objection and the most serious factor interfering with the continuous operation of the locomotive was the formation of large quantities of slag, which clings to the boiler plates, fills up the tubes and forms on the superheating surface. E. H. Stroud, a maker of powdered-coal equipment, who has had considerable experience in an experimental stationary plant equipped for burning powdered fuel, explained that there were several essential factors which must be given attention to burn this coal successfully. First, it is necessary to powder the coal to the proper fineness. This is vital, because instantaneous ignition within a few inches of the burner must be obtained. Unless complete combustion is obtained at once, slag will form. The furnace must get the proper amount of air, and to insure a correct mixture mechanical means to measure the coal and air are required. Slag was an objectionable feature, but there is no occasion to permit it to get as far as the boiler tubes. All of this could be precipitated in a chamber formed by a specially constructed arch at the rear of the firebox. It was his conviction that it paid to dry the coal. This could be done while it was being pulverized. The cost of pulverizing, including power, wear and tear and attendance, at a rate of 5 to 10 tons per hour, should not exceed 15c. per ton. Drying would add 4 to 6c. per ton. As to a capacity of individual units, burners could be made which would burn as low as 15 lb. per hour and as high as 5000 lb. per hr.

Joseph Harrington, who has recently become associated with the Powdered Coal Engineering & Equipment Co., of Chicago, discussed the question from the standpoint of smoke abatment. In Chicago and many other municipalities electrification has been urged because it eliminates smoke, soot, cinders, sparks and excessive noise. Within the City of Chicago alone the cost to electrify the railroads has been estimated at $190,000,000. It would appear that the same results can be obtained by the use of powdered coal, at a cost which would be insignificant in comparison. A uniform system would be maintained on the railroads and according to an estimate by Mr. Robinson, the use of powdered coal would result in a saving on various heat losses alone of 25 per cent. This does not include savings from the prevention of smoke, soot, cinders, sparks, ash-handling, the use of inferior grades of soft coal, elimination of smoke inspectors, which in Chicago alone costs the railroads $65,000 per annum, and the solution of other problems that enter into the production of steam power in locomotives.

Potential Hydro-Electric Development in Ontario, Canada

It is conservatively estimated that within a radius of fifty miles from Ottawa, there is available water power of approximately one million horsepower. The Ottawa River alone would supply 700,000, and its tributaries 300,000 horsepower. This estimate is based upon an average of water obtainable throughout the year from twelve to fourteen rivers. In this section are many great lakes that can be converted into immense reservoirs. A number of dams have been built on the upper reaches of the Ottawa River, insuring when fully completed a steady supply of water throughout the year.

Eminent authorities, when calculating the relative cost of hydro-electric and steam-generated energy, place the latter on the basis of $25 per horsepower year. Estimating the cost of the same power generated by water at $10 yearly, the saving effected for an output of one million horsepower would be fifteen million dollars. This power is all within a short distance of Ottawa, and therefore can be transmitted to that city very economically. The accompanying table was prepared by Holgate, McDougall and Ker, well-known civil and hydraulic engineers, acting as a special commission for the City of Ottawa. The data relate to existing installations within thirty miles of the city.

Name of Power Site	Distance (Miles) of Trans.	Hp. Output of Sub-station	Cost per Hp. per Year
Metropolitan Company	7	5,100	15.73
Metropolitan Company	7	11,050	13.89
Gatineau River	7	5,000	13.60
Gatineau River	7	10,000	8.80
Gatineau River	7	20,000	6.50
Lievre River	30	5,000	13.95
Lievre River	30	10,000	9.13

Lievre River	30	20,000	6.99
Lievre River	30	30,000	6.06
Chats Falls	30	5,000	13.20
Chats Falls	30	10,000	9.20
Chats Falls	30	20,000	7.80

Another section offering a splendid opening for enterprising capitalists to develop and exploit its water powers and industrial resources is the Sault Ste. Marie district. The Canadian share of the great falls on the "Soo" is yet undeveloped, while with the several falls on the Michipocoten River and the Steep Hill Falls on the Magpie River, there is easily 100,000 horsepower in the immediate vicinity. In the district to the north, millions of dollars worth of iron and other natural resources, the great spruce forests of the clay belt and an unlimited pulpwood area are awaiting development.

Committee on Classification of Technical Literature

Delegates from about twenty national technical and scientific societies met at the Engineering Societies Building, New York, on May 21 to perfect a permanent organization, the purpose being to prepare a classification of the literature of applied science which might be generally accepted and adopted by these and other organizations. It was the feeling of the meeting that such a classification, if properly prepared, might serve as a basis for the filing of clippings, for cards in a card index, and for printed indexes; and that the publishers of technical periodicals might be induced to print against each important article the symbol of the appropriate class, so that a file might be easily made which would combine clippings, trade catalogs, maps, drawings, blueprints, photographs, pamphlets, and letters, classified by the same system.

By request, W. P. Cutter, librarian of the Engineering Society's Library, read a paper on "The Classification of Applied Science," and after describing the existing classifications, stated that in his opinion no one of these was worthy of general adoption. He outlined a plan whereby a central office could collect all the existing classifications and with the help of the various national societies interested might compile a general system which, although not absolutely perfect, might be generally accepted.

The following societies were represented by delegates: United Engineering Society, American Foundrymen's Association, Society for Electrical Development, American Ceramic Society, American Institute of Architects, American Society of Agricultural Engineers, American Society of Refrigerating Engineers, American Gas Institute, American Water-Works Association, American Society of Mechanical Engineers, National Fire-Protection Association, American Society of Heating and Ventilating Engineers, Society of Automobile Engineers, Society for the Promotion of Engineering Education, United States Bureau of Standards, American Physical Society, Franklin Institute, American Institute of Mining Engineers, American Society for Testing Materials, National Electric Light Association, American Electro-Chemical Society, Illuminating Engineering Society, and American Railway Engineering Association.

The name adopted for this organization is "Joint Committee on Classification of Technical Literature." A permanent organization was effected by the election of the following executive committee: Fred R. Low, chairman; W. P. Cutter, 29 West 39th St., New York, secretary; Edgar Marburg, H. W. Peck and Samuel Sheldon.

Meeting of Engineering Foundation

The Engineering Foundation held its first regular meeting May 25, and selected a board to administer the trust founded by Ambrose Swasey, as described in our Feb. 2 issue. The board consists of Charles Warren Hunt and J. Waldo Smith, representing the American Society of Civil Engineers; Dr. Alexander C. Humphreys and Jesse M. Smith, American Society of Mechanical Engineers; Dr. A. R. Ledoux and Benjamin D. Thayer, American Institute of Mining Engineers; Charles E. Scribner and Dr. M. I. Pupin, American Institute of Electrical Engineers; Edward D. Adams and Howard Elliott, representing the general public. The officers elected were: Gano Dunn, chairman, by virtue of his office as president of the United Engineering Society; Edward D. Adams, vice-chairman; F. R. Hutton, secretary, and Joseph Struthers, treasurer.

A large number of applications have already been received from those who want to use the funds for research work. Because of the number of applications and the incomplete form in which many of them were received, a schedule of requirements for applicants is being prepared by the following committee, which was chosen by the board: Dr. A. R. Ledoux, chairman; J. Waldo Smith, Dr. M. I. Pupin and Dr. Alexander C. Humphreys.

Recent Court Decisions

Digested by A. L. H. STREET

Spread of Fire by Portable Engines—The law enacted by the Wisconsin Legislature in 1913, requiring traction and portable engines to be equipped with a "screen or wire netting on top of the smoke-stack and so constructed as to give the most practicable protection against the escape of sparks and cinders" and "with the most practicable devices to prevent the escape of fire from ashpans or fireboxes," has just been considered by the Supreme Court of the state in the case of Legro vs. Carley, 150 "Northwestern Reporter," 985. The court holds that the statute is sufficiently specific in its requirements to be valid, and that a spark arrester in a threshing machine, consisting of an inverted cone of screen wire, is not a sufficient spark arrester, if it has been permitted to remain unrepaired after the point of the apex has burned or rusted off.

Effect of Temporary Use of Gasoline Engine on Fire Risk—A clause in a fire policy reading, "This policy shall be void . . . if camphene, benzine, naptha or other chemical oils or burning fluids shall be kept or used by the insured, on the premises insured," does not invalidate the policy on account of the temporary use of a gasoline engine, especially where the insurance company must have contemplated such use of the engine. This is the holding of the Maine Supreme Judicial Court in the case of Bouchard vs. Dirigo Mutual Fire Insurance Co., 92 "Atlantic Reporter," 899. It appears that the defendant company issued to the plaintiff a policy containing the clause quoted, covering a farm house and barn, and denied liability for a loss because it resulted from using a gasoline engine in driving threshing machinery. But the court held that such use must have been contemplated when the policy was issued, and that the clause mentioned must be construed as applying to some permanent condition increasing the fire risk, and not to mere temporary use of a gasoline engine.

Responsibility for Employee's Negligence—The owner of a power plant is not liable for injury to a boiler company's inspector, resulting from negligence of an engineer employed by the owner, if, in undertaking to assist in the inspection, the engineer exceeded his authority. This, in effect, is the decision of the Illinois Supreme Court lately announced in the case of Johanson vs. Wm. Johnston Printing Co., 104 "Northeastern Reporter," 1046. The evidence showed that the boiler company was employed to inspect the boiler, which had been leaking, and sent the plaintiff to do the work. He went into the combustion chamber of the boiler, the fire having been drawn, and was scalded through leaking of hot water upon him. In his suit to recover for the injury, he relied upon the engineer's negligent failure to remain near the boiler as he had promised to do. The Supreme Court disposed of the case in the defendant's favor on the ground that the engineer was not authorized to assist in the inspection, and acted beyond the scope of his duties in so doing. The court said: "Outside of the scope of his employment, the servant is as much a stranger to the master as any third person, and an act of the servant not done in the execution of services for which he was engaged cannot be regarded as the act of the master."

Make Dinkel Steam Trap—We are informed by the Schütte & Koerting Co., Twelfth and Thompson Streets, Philadelphia, Penn., that they also manufacture the Dinkel steam trap, a description of which was published on page 644 of the May 11 issue.

At a Meeting of the American Physical Society, Prof. C. W. Chamberlain, of Denison University, Granville, Ohio, presented and demonstrated his compound interferometer, by which it is possible to measure 0.00000005 of an inch. It is next to impossible for the human mind to conceive the minuteness of a measurement of this kind. It is equal to the apparent size of the head of an ordinary pin viewed at a distance of 227 mi. or the size of a silver dollar viewed at a distance of 9000 miles. —"American Machinist."

ENGINEERING AFFAIRS

The Association of Iron & Steel Electrical Engineers will hold its annual convention at the Hotel Statler, Detroit, Mich., Sept. 8-11. Suggestions regarding arrangements and inquiries regarding accommodations should be addressed to A. H. Swartz, Chairman Convention Committee, Churchill Ave., Cleveland, Ohio.

The American Society of Civil Engineers has adopted resolutions providing that its representatives shall confer with the Federal authorities on the plan by which a reserve corps of army engineers shall be developed from its membership. The resolutions state that these men are not only seasoned in all lines of organization and constructive work, but are also closely in touch with the best workers from whom the rank and file of all branches of military service can be drawn. A committee has been appointed to take up with the War Department the plan of organizing this corps.

International Engineering Congress—The materials of engineering construction will receive special attention in the proceedings and discussions of the International Engineering Congress to be held in San Francisco, Sept. 20-25. The field will be treated under 18 or more topics, covering: Timber resources; preservative methods; brick and clay products in general; life of concrete structures; aggregates for concrete; waterproofing; volume changes in concrete; world's supply of iron; life of iron and steel structures; special steels; status of copper and world's supply; alloys; aluminum; testing of metals, of full-sized members, and of structures. These papers, with discussions, will be published as Volume 5 of the "Transactions," and will be illustrated. For full particulars apply to W. A. Cattell, secretary, 417 Foxcroft Building, San Francisco, Calif.

NEW PUBLICATIONS

MATERIALS OF MACHINES—By Albert W. Smith, Director of Sibley College, Cornell University. Published by John Wiley & Sons, Inc., New York. Size, 5x7 in.; 215 pages; 36 diagrams. Price, $1.25.

In the second edition, which has been entirely rewritten and considerably enlarged, Professor Smith's little book gives an elementary view of the manufacture and properties of iron, steel, copper, lead, tin, zinc, aluminum and the brass and bronze alloys. The first part of the book gives a brief outline of the metallurgy of the materials. It also takes up fuel combustion, the types of electric furnaces and the refractory materials used in lining metallurgical furnaces. The second part relates to chemical and mechanical properties, and includes chapters on testing materials, on the heat treatment of steel, and on brass and bronze alloys. The book is self-contained and the reader need not consult chemistries, metallurgies and works on strength of materials in order to use the information.

VOCATIONAL MATHEMATICS—By William H. Dooley, Principal of Technical High School, Fall River, Mass. Published by D. C. Heath & Co., New York. Size, 5x7 in.; 341 pages; illustrated. Price, $1.

The author has prepared this book for use in vocational schools, in which it is necessary to impress students with the direct application of their mathematical knowledge to trade and industry. After a review of the essentials of arithmetic and mensuration, problems peculiar to the carpenter, plumber, steam engineer, electrician, machinist and to the sheet-metal and textile worker are presented. To illustrate the method followed, the chapter devoted to engines contains an illustrated description of simple vertical and horizontal engines, of the indicator, methods of calculating horsepower, mean effective pressure from indicator cards, flywheel weight, steam lap and size of supply pipes. Of course, the derivation of the formulas is not given, but their application and problems relating to them are given. Much of the technical information has no bearing on mathematics, and in addition is not always correct. Such errors as the expression of latent heat in degrees and the labeling of a series as a parallel circuit should have been avoided.

PUBLICATIONS OF THE BUREAU OF MINES

Bulletin 88: The Condensation of Gasoline from Natural Gas. By G. A. Burrell, F. M. Seibert, and G. G. Oberfell; 1915; 106 pp., 6 pls., 18 Figs.

Technical Paper 101: Permissible Explosion-Proof Electric Motors for Mines; Conditions of Tests and Requirements for Test and Approval. By H. H. Clark; 1915; 17 pp., 2 pls., 1 Fig.

A limited supply of these papers is available for distribution to those interested. They should be ordered by number and title from the Director of the Bureau of Mines, Washington, D. C.

TRADE CATALOGS

Dodge Sales and Engineering Co., Mishawaka, Ind. Catalog. Gearing. Illustrated, 126 pp., 6x9 in.

B. F. Sturtevant Co., Hyde Park, Boston, Mass. Bulletin No. 218. Vertical engines. Illustrated, 16 pp., 6½x9 in.

Yarnall-Waring Co., Chestnut Hill, Philadelphia, Penn. Bulletin C. A. Simplex-Caskey valves for hydraulic service. Illustrated, 4 pp., 6x9 in.

Link-Belt Co., Philadelphia, Penn. Book No. 210. Wagon and truck loaders for handling coal, coke, stone, sand, etc. Illustrated, 48 pp., 6x9 in.

SKF Ball Bearing Co., 50 Church St., New York. Bulletin No. 25. SKF Ball bearings in machine tools and shop equipments. Illustrated, 68 pp., 6x9 in.

Smooth-On Mfg. Co., 572-74 Communipaw Ave., Jersey City, N. J. Pamphlet No. 4. Smooth-On Iron Cement No. 7 for water-proofing brick ad concrete construction. Illustrated, 4 pp., 6x9 in.

The Jeffrey Mfg. Co., Columbus, Ohio. Bulletin No. 165. Wagon and truck loaders for sand, gravel, etc. Illustrated, 16 pp., 6x9 in. Bulletin No. 166. Wagon and truck loaders for bituminous and anthracite coal. Illustrated, 24 pp., 6x9 in.

BUSINESS ITEMS

The American Pin Co., of Waterbury, Conn., has recently ordered from the Builders Iron Foundry, Providence, R. I., one large meter tube for boiler feed service. The Imperial Tobacco Co., of Montreal, Canada., has also ordered a 2-in. meter tube for the same service.

The Cooling Tower Co., with headquarters at No. 50 Broad St., New York, has been incorporated to handle the growing demand for the well-known "Mitchell-Tappen" cooling towers, the patents on which are now controlled by the new company, which also has additional patents pending. The operations of the company will not be confined to cooling towers alone but where the purchasers' manufacturing conditions warrant it the new company is prepared to design and install spray-nozzle systems and other cooling devices for the economical re-cooling of liquids from all forms of condensing, refrigerating, smelting or gas engine plants.

POSITIONS OPEN

MAN to sell heavily advertised power-plant specialties in New York; must have knowledge of power-plant equipment; an engineer will be considered; position permanent to right man with old-established house. Write full particulars, giving salary desired and past connections. P. 518, Power.

POSITIONS WANTED

ENGINEER, experienced in alternating and direct motors and generators, engines, turbines and ice machines; A-1 references. P. W. 521, Power.

CHIEF ENGINEER, employed in central station; seven years' experience with engines, turbines, dynamos, boilers; married; age 30. P. W. 511, Power, Chicago.

TECHNICAL GRADUATE, Middle West university, mechanical engineering, two years' practical experience, desires position with progressive firm. P. W. 524, Power.

MASTER MECHANIC, 28, twelve years' experience with steam engines (all types), boilers and general machinery; knowledge of theory and practice in mechanical and electrical engineering; excellent references. P. W. 514, Power.

A CAPABLE ENGINEER at present employed as chief engineer in a modern plant desires change where opportunity for further advancement is greater; can furnish references as to character, ability, etc. P. W. 512, Power.

CHIEF ENGINEER, technical education, broad experience, energetic, successful in handling plants and men, open for engagement July 1; desires responsible position; best of references as to ability and character; age 42. P. W. 522, Power.

The Prism That Refracts Our Vision

Boiler Plant of the Bessemer Coal and Coke Company

By Warren O. Rogers

SYNOPSIS—Six 72-in. return-tubular boilers are installed in pairs, with but one combustion chamber and one stoker for each pair. The fuel used is unsalable bone containing from 30 to 40 per cent. of noncombustible and averaging from 8000 to 11,000 B.t.u. per pound as fired.

A practice that will attract the attention of engineers is the burning of high-grade coal in the furnaces of coal-mining boiler plants. An instance where this is not done is at the power plant of the Bessemer Coal & Coke Co., Russellton, Penn., where a grade of fuel for which there is no market is burned with the aid of mechanical stokers, each feeding a common furnace for two return-tubular boilers.

The mines are about eighteen miles northeast of Pittsburgh, on the Bessemer & Lake Erie R.R. The main boiler plant consists of eight return-tubular boilers, 72 in. in diameter and 18 ft. long, each rated at 150 hp. Six are in one boiler house and two in another. The six were originally hand fired, the furnaces being supplied with steam jets to assist in the combustion. The other two were equipped with mechanical stokers supplemented by steam jets, with the idea of burning the bone which came from the mine. The arrangement did not prove satisfactory in operation, because of the high percentage of noncombustible in the fuel, so the furnaces were all burning the best slack and $\frac{3}{4}$-in. nut coal, worth $1 a ton at the mine.

Superintendent of Mines J. G. Bart believed that low-grade fuel could be burned if a properly designed stoker were installed. An unusual condition exists in this mine.

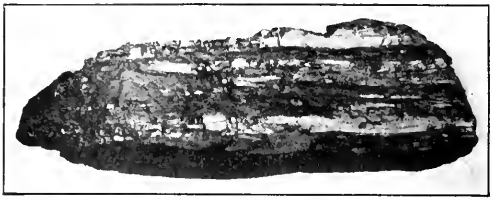

Fig. 2. Piece of Bone, the Bright Streaks Being Coal

There are two seams of coal about 3½ ft. thick and between them is a binder of bone composed of layers of slate and thin strata of coal. This is shown in Fig. 1. A piece of bone that was taken from a car of fuel is shown in Fig. 2 about one-half size. The bright streaks are the layers of coal, the dark portion being bone. Before the machine was put to work removing the bone, the latter was placed to one side by the miners and at convenient periods was hoisted to the surface and hauled away. The production was about 60 carloads a month,

Fig. 1. Cutting Machine Removing the Bone Binder from Between the Two Seams of Coal

and the cost of its removal, with an average haulage charge of about $6 a car, was not far from $360 a month, or $4320 a year. This bone has a heat value of between 8000 to 11,000 B.t.u. as delivered to the furnaces and an ash content of between 30 and 40 per cent.

To save the 100 tons of marketable coal that was burned each 24 hours under the eight boilers, to cut the cost of hauling away the bone and at the same time to reduce the boiler-room labor charges kept Superintendent Bart on the trail of a stoker that would fill the requirements.

About two years ago the work of installing a Taylor three-retort, underfeed stoker under each pair of boilers, or three stokers for the six boilers in the larger room, was

Fig. 3. A Three-Retort Underfeed Stoker Serving Two 72-In. Return-Tubular Boilers

begun. A single boiler would require a two-retort stoker and by placing two boilers over one three-retort stoker the initial cost was lessened and the efficiency was not reduced. Since the installing of the stokers, the boilers have been operated at 175 to 200 per cent. rating.

Fig. 3 is a view of the boiler room, showing the stokers placed with their center lines midway between the two boiler units. Fig. 4 shows the stokers from the rear end of the boiler setting.

The boilers are hung in pairs from steel railroad rails weighing 100 lb. per yard. The shells are separated 6 in., and the space between is filled with plastic cement. Fig. 5 gives a general idea of the method of placing the boilers. Each setting is 18 ft. 6 in. wide, with the boilers 6 ft. 6 in. center to center. The stokers are each 6 ft. $2\frac{1}{2}$ in. wide and extend under the boilers 9 ft. $9\frac{1}{2}$ in. They are operated by the fan blower, Fig. 6. From the top tuyeres to the boiler shells the distance is 3 ft. 6 in., and the top of the bridge-wall is 4 ft. from the bottom of the shells. The combustion chamber back of the bridge-wall is 11 ft. 9 in. wide and 12 ft. 9 in. long, with a height of 5 ft. 6 in.

Forced draft is obtained from an 8x10-in. engine-driven 9-ft. fan blower running at 320 r.p.m., which delivers air to a main duct 5 sq.ft. in area, running along the rear end of the boilers, and from which two branches, each 18 in. square, are taken to each stoker. These branches join to a wind box below the stoker. An air pressure of from $\frac{1}{2}$ to $\frac{5}{8}$ in. of water is maintained

Fig. 4. Furnace and Stoker Serving Two Return-Tubular Boilers

in the box under the stokers. Fig. 6 shows the general arrangement of the boiler, fan and air ducts and ash-disposal trench.

The bone fuel now used with the stokers is removed from the mine after being cut out from between the two seams of coal, and is hoisted to the surface, dumped into a single-roll crusher and then discharged to a double-roll crusher, which delivers it to a belt conveyor in

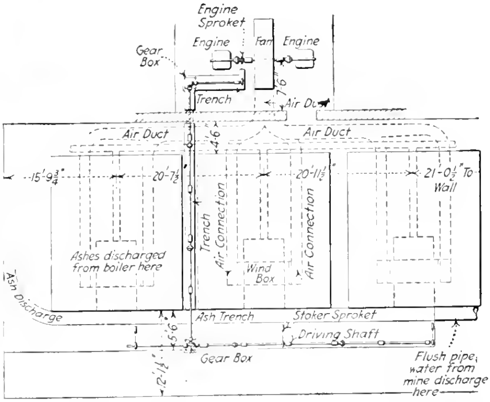

Fig. 5. Plan of Boilers, Ash Trench and Air Ducts

sizes not larger than $1\frac{1}{2}$-in. It is then carried to an overhead bunker having a capacity of 250 tons, or about two days' supply.

It is interesting to note that under former operating conditions eight boilers were required to carry the load, and about 100 tons of marketable coal was burned each 24 hours; the boiler-room force consisted of 10 men, five to each 12-hour shift, and it was difficult to keep

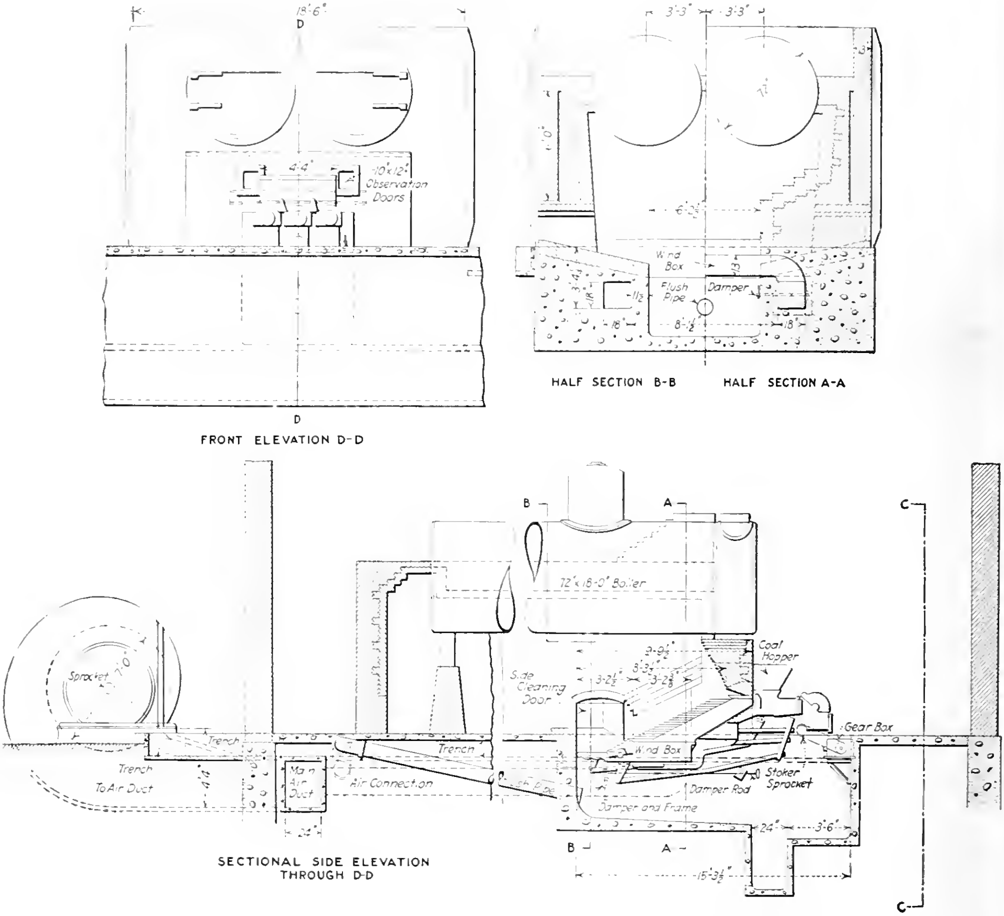

FIG. 6. DETAILS OF THE BOILER SETTING, AIR DUCTS AND ASH TRENCH

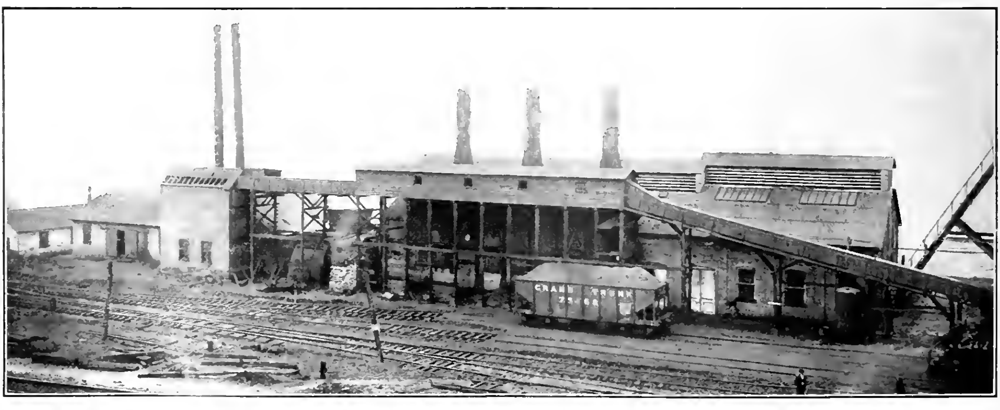

FIG. 7. GENERAL VIEW OF THE POWER PLANT OF THE BESSEMER COAL & COKE CO.

them owing to the hard firing conditions. The six boilers with their stokers now carry a heavier load than before the change, owing to the increased output of the mine and the substituting of an electric haulage system in place of mules. The boilers total 900-hp. normal rating, but have frequently delivered from 1600 to 1800 hp. with but three men on a shift, or six men for the 24 hours.

One hundred dollars' worth of marketable fuel is saved a day, and refuse that formerly cost about $6 a car to

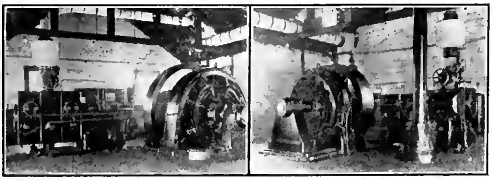

Fig. 8. The Two Generating Units

remove for filling-in purposes is for the most part burned in the boiler furnaces, and the removal cost of between $300 and $400 per month is saved.

An interesting method of disposing of the ashes has been worked out. They are flushed from the ashpit by a 10-in. stream of drainage water pumped from the mine. In front of the boiler a trench has been constructed, as shown in Figs. 5 and 6, 24 in. wide at the bottom, but with a shelf 3 ft. 6 in. wide at the top, making a total width of 5 ft. 6 in. The extreme depth of the trench is 3 ft. 6 in. The purpose of the shelf is to give an additional water head for flushing out the ashes.

The ashes are shoveled into the trench, which is below the level of the ashpit. A gate is provided at each boiler and when ashes are to be removed the last gate is closed until a head of water is obtained, when it is opened and the velocity of the escaping water carries the ashes with it. The plant is located at a considerable elevation and the trench discharges at the edge of the hill where there is sufficient ground to take care of the ashes for years to come.

The boilers are fed under normal conditions through a top connection, but in case of an emergency they may be fed through the blowoff. Each boiler connection to the header is provided with a nonreturn valve and the 12-in. header is likewise protected. A steam pressure of 100 lb. is maintained by the automatic speed control on the blower engine.

A general view of the plant from the railroad side is shown in Fig. 7. The three 45-ft. stacks serve the six boilers, and the two taller stacks the other two. At the extreme left is the engine room, which contains two units: One a 500-hp., four-valve engine directly connected to a 300-kw., 550-volt, direct-current generator at 150 r.p.m.; the other a 300-hp. engine directly connected to a 200-kw., 550-volt, direct-current generator at 180 r.p.m. The hoisting engine is in another engine room; it has a 26x36-in. cylinder and operates a hoist 260 ft. deep at a rate of 170 cars per hour, with an average of two tons per car.

A 10x10-in. engine directly connected to a 40-kw., 220-volt, direct-current generator is used for town lighting, and as it is in the hoist-engine room, requires no special attention.

The plant has attracted considerable attention because of several novel features, but chiefly because of the burning of a fuel that it had previously been impossible to use in a boiler furnace.

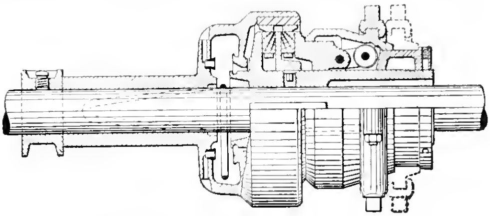
Dodge Safety Self-Oiling Clutch

An improved solid multiple-disk friction clutch that retains all the good points of the present clutch, with the addition of the important features of safety, efficiency and durability, has been developed by the Dodge Manufacturing Co., Mishawaka, Ind.

All moving parts of the mechanism of this new clutch, illustrated herewith, are concealed, making a smooth contour, so that there are no projecting moving parts. The design of the multiple friction disks, combined with the new roller toggle-operating mechanism, makes it a powerful clutch for its size.

The rolls on the toggle levers travel on conical surfaces arranged to give high pressure on the friction disks with a minimum amount of mechanism friction. The use of rollers in place of sliding parts makes the device easy to operate. The action of centrifugal force tends to keep the clutch disengaged when thrown out.

The apparatus is self-lubricating. An oil ring, revolving in a large chamber, or oil reservoir, carries a continuous supply of lubricant, which is circulated



Semisectional View of the Dodge Safety Self-Oiling Clutch

through suitable grooves to all parts of the sleeve carrying the pulley. This chamber is sealed to prevent oil working out into the mechanism. The shifter ring for engaging the clutch is made with a channel section that retains oil and assures lubrication at this point.

The clutch can be easily adjusted with a single nut adjustment that is simple and positive. Backing off this nut permits of the removal of the operating cone; this exposes the toggle mechanism and allows the removal of the inside mechanism for repairs. The best materials are used throughout.

The device may be easily applied to stationary or portable tools or countershafts, as well as pulleys, gears, sprockets, etc., and is especially suitable for high speeds.

Pasadena Electric Rates—Electric consumers in Pasadena, Calif., had to pay 15c. maximum per kw.-hr. up to 1908, when the city erected its own plant. The private company began its fight against the city by a reduction to 12½c. The city began operations with an 8c. rate; the private company met it. In 1910 the city made its lighting price 5c. maximum with a wholesale rate of 3c. and a power schedule of from 4c. to less than 1c. It is estimated that the saving to the city has been $100,000 per year since the plant was established. In 1913 the private company tried to put the Pasadena plant out of business by making its maximum rate 4c. in Pasadena, while it charged surrounding towns with no public plants at 6½c. to 10c. The State Legislature prohibited the company from making the other towns bear the losses of the company in Pasadena.—New York "American."

Getting Capacity in the Refrigerating Plant

By A. G. Solomon

SYNOPSIS—Is the plant that you have spent so much time on this spring giving its rated capacity? Is the condenser handling the gas as it should? Is the gas going to the compressor at the proper density and pressure, or is it superheated far more than is unavoidable? Can you add more load? These questions are well considered in this article.

During the next six months there are several questions which the engineer will ask himself: Is the full tonnage being got out of the plant? Are the ammonia compressors handling the amount of gas they should? Is the gas going to the compressors at the proper density and temperature? Are the direct-expansion coils handled properly? Are the brine and ice tanks handled right? Are the ammonia condensers doing their share of the work? Is the ice machine big enough to do the work demanded? Can a little more load be added?

The main question is to get the full capacity when it is needed. One part of the system may be holding all the other parts back.

Usually, the compressor is the first part considered and blamed when the temperature of the coolers and freezers begins to increase. In most cases putting the blame on the compressor is not justified. There is not much that can go wrong with the compressor. Leaky valves and pistons may happen, but are not likely except from long service. If the valves are ground in once a year and the cylinders and pistons examined and put in good condition at the same time, they will remain tight during a season's run.

Scale and dirt from the pipework may cut cylinders and valves, but there is little excuse for this. There are scale traps (or should be) on the suction lines to the compressors, and if they are cleaned at regular intervals the scale will be caught. All new pipe intended for ammonia systems should first be hammered and scraped to remove the scale. With reasonable care the compressor should give little trouble.

Condition of the Ammonia

So this really puts the success or failure of the plant on the manner in which the ammonia is handled. First, we will have to be sure that it is really anhydrous ammonia that we have in the system. There are two things that may be circulating in the system and taking up room and not giving good results. They are noncondensible gases and moisture. The so-called air is the most common and manifests itself as follows: Increased condenser pressure and consequently increased back pressure; frost melting from the machine and from the suction line; whistling sounds at the expansion valves; high discharge temperature and warm liquid lines and receiver. Sometimes, an insufficient charge of ammonia is taken as a sign of air in the system. The symptoms are somewhat the same. There should be a glass gage on the liquid receiver, and this should show at least half full when the machine is running on its proper load. If the liquid gets low in the receiver, the gas is allowed to enter the liquid line and then passes on to the evaporating coils, the compressor and condenser.

It goes through the evaporating coils, and instead of taking up heat by being vaporized it simply becomes superheated. The heat taken up by this gas is as nothing in comparison to that absorbed by the liquid, but the power required to pump it is about the same. So, before purging the system of air, put in enough ammonia to fill the receiver at least half full. Then, if there are indications of air, purge the condensers. Do not expect to get all the air out at one purging, but keep at it once a day till it is gone.

Moisture is sometimes allowed to remain in the system from careless handling during the steaming out of the evaporating coils. This does not often happen and seldom is the cause of serious trouble. Moisture in the system will in time show up in the oil traps and in the discharge-gas receiver. It will look like dirty water and is often called dead ammonia. No matter how full of ammonia this water is, it has no place in the system if it lies in the bottom of the gas receiver or oil trap. If there is an ammonia regenerator or purifier in the plant, the good ammonia can be boiled out and the moisture drawn off. But if there is no purifier, throw the dead stuff into the sewer. Noncondensible gases and moisture should not be troublesome in the plant, for they are easily got rid of.

Handling the Expansion Valves

Every engineer who operates a refrigerating plant is sure that he knows just how to handle the expansion valves to get the best results. It is a simple matter to open an expansion valve when a coil in a warm room is to be frosted.

We will assume that the cooler temperature has increased to 55 deg. The direct-expansion coils are either in a pipe deck above or else in the cooler itself. These coils are all free of frost. The proper way to begin to refrigerate this room will be to put on one coil and let it take up the steam and moisture from the atmosphere. This coil will frost quickly and will clear the room of steam. When frosted all the way to the return it should be shut off and another one put on. Do not open the expansion valves on all the coils at the beginning. This method of handling is to be recommended for two reasons. First, it will keep the coils more free from heavy frost and will give at least one clean coil to finish with. The coils that are used at first will be clean again, as the frost on them will be light, although thick, and will melt quickly.

The other reason is not so often considered, as its effect is not so plainly seen. We know that the ammonia that is in the coils when the room is hot is in a superheated state. The temperature of this gas will be the same as the temperature of the room. This gas will have to go through the ammonia compressor on its way to the condenser. The capacity of the compressor is rated by the weight of ammonia which it handles. The gas is light and occupies more space than a saturated vapor of the same weight. If this superheated gas is all sent to the compressor at once it will (for a time varying from fifteen minutes to one hour) greatly reduce the capacities of the compressor and the condenser.

To get an idea of how much difference there is in the space taken up by saturated vapor and superheated gas we have only to look at the ammonia tables. At 15.67 in. pressure one pound of saturated vapor will occupy about 9 cu.ft., while a pound of gas at a temperature of 55 deg. under the same pressure will occupy about 11 cu.ft. This superheated gas coming from the coils in the warm rooms will meet the saturated vapor from the coils in the cold rooms and cause superheating of the ammonia passing through the suction line on its way to the compressor.

If a wet or humid gas machine is used, a greater amount of liquid injection will have to be admitted during this time to keep the cylinder cool. If the compressor depends on a water jacket for the removal of the heat of compression, the gas will become more superheated on its admission to the cylinder. The temperature of this gas often reaches 150 deg. at the end of the suction stroke. No matter which way it is looked at, there is a distinct loss in refrigerating capacity when the warm cooler is first put on. By frosting one coil at a time and, by so doing, sending the hot gas to the machine in small quantities, the loss will not be so great. Another good plan to follow is to shut the expansion valves on all the coils in the rooms having a temperature below 32 deg., while getting the coils in the hot room frosted. These coils will then pump down and give up whatever ammonia is in them. This will give a greater amount of liquid to be circulated through the hot coils, and when they are first put on they will be able to evaporate more than when they become frosted. We know that the expansion valves can be opened much wider on a hot coil than on a cold one, as the greater temperature and amount of heat will evaporate much more ammonia. But do not forget that as the temperature of the room is lowered, the amount of ammonia fed to the coils must be decreased. If the expansion valves are left as first set, the ammonia will soon go to the compressor in a liquid state. This liquid will, by re-expansion, cut down on the capacity of the compressor. The condition of the ammonia reaching the compressor should be regulated by means of observation of a thermometer in the suction line. The closer this temperature is to the temperature of the saturated vapor at the pressure shown on the back-pressure gage, the greater will be the weight of ammonia handled by the compressor at a given speed.

Pipe Insulation

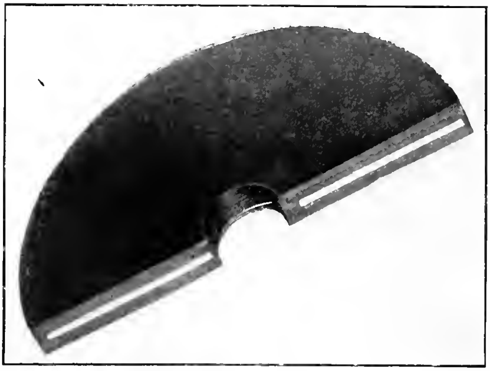
Superheating the ammonia by allowing heat to be absorbed through uncovered suction lines is a direct loss. A good rule to follow in a refrigerating plant is: Any pipe or apparatus which contains ammonia and is not used in the absorption of heat or the giving up of heat should be well insulated. This means to cover everything except the evaporating coils and the condensers. But the discharge line from the compressor to the condenser need not be covered, as the surrounding air will help to take away the heat caused by compression. The ammonia liquid line need not be covered in such places where the temperature of the rooms through which it passes is lower than the ammonia in the pipe. Do not allow an uncovered liquid line or a liquid receiver in a place where the temperature is higher than the condensing water used on the ammonia condenser.

The ammonia goes to the condenser to give up the heat it collected while evaporation was taking place. Here, we see the loss in condenser capacity caused by superheat. The gas must first be reduced in temperature to that of the saturated vapor at the condenser pressure before liquefaction takes place. So some of the condensing surface is used in taking away this superheat instead of liquefying and cooling the ammonia. After the ammonia is liquefied it should be cooled to the temperature of the coldest water available. Most plants use a cooling tower and reservoir and have a well or city-water line for making up what water is used or lost by wind and evaporation. This makeup water is, as a rule, much colder than the reservoir water and should be used for cooling the liquid before it is allowed to mix with the reservoir water.

The even distribution of water on the condenser is also necessary. Do not have some coils flooded while others are nearly dry. Have every foot of pipe doing its share of the work. Small leaks must be attended to just as soon as they are found, as they are generally the sources of loss of the ammonia. The big leaks are fixed at once, and the small ones should receive the same strict attention.

"Rub-Steel" Pump Valve

This pump-valve disk is a combination of rubber and steel. It consists of a steel plate placed in the center of the valve with a rubber composition on each side and edge; the rubber is attached to the metal by a chemical process. The plate embedded in the rubber is shown in the illustration. Its object is to give such strength to the valve that the pressures against which it works cannot



Reinforced Rubber Pump Valve

warp, twist or in any way get it out of shape. The rubber surfaces afford the proper seating qualities.

On account of the rigid reinforcement, the valve is kept in its true shape, high pressure is prevented from forcing the valve through the web of the valve seat and dishing of the valve is avoided.

The "Rub-Steel" valve disk is manufactured by the Voorhees Rubber Manufacturing Co., 18-50 Bostwick Ave., Jersey City, N. J.

Operation and Design of Auto-Transformers

By Norman G. Meade

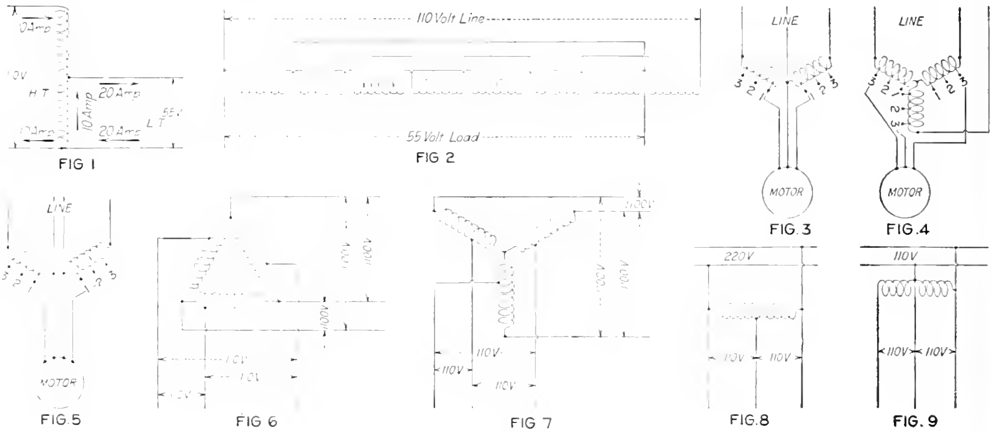
SYNOPSIS—The uses of auto-transformers and some of the corresponding connections; also the calculations and directions for constructing one of 10-kw. capacity.

The most common use for auto-transformers is the starting of induction motors, to supply a gradually increasing voltage as the motor accelerates. Other applications are balancing coils for three-wire distribution systems and three-wire direct-current generators, single-phase railway systems, and for general service where the ratio of transformation is not large.

There is only one winding per phase, serving as both primary and secondary, as is shown by the circuits of a single-phase auto-transformer in Fig. 1. Here the same two auto-transformers, one connected to each phase of a two-phase, four-wire circuit for starting a two-phase motor. Ordinarily, there are several taps in each auto-transformer connected to a controller to provide a gradually increasing voltage for starting.

Delta connections of a three-phase auto-transformer are shown in Fig. 6 and the Y-connections of a similar auto-transformer in Fig. 7. Both of these arrangements may be used for stepping up or stepping down the voltage.

Auto-transformers as applied to three-wire systems of distribution are shown diagrammatically in Figs. 8 and 9. In the former the auto-transformer is connected across a 220-volt line with the neutral tapped in at the center, giving 110 volts between each outside wire and the neutral and 220 volts between the outside wires. In Fig. 9 the



Connections for Auto-Transformers

number of turns is required as in the primary of a two-coil transformer of equivalent rating and where the ratio of transformation is approximately 2 to 1; also the same weight of copper as in the primary winding of such a transformer. The voltage per turn is uniform throughout the winding, and to secure a low-tension voltage of 55 when the high-tension voltage is 110, it is necessary only to make a tap midway between the ends of the coil, as shown.

To supply 1100 watts on the low-tension side requires a current of 20 amp., but as this is opposed in time phase relation to the high-tension current in this section, there will be only 10 amp. flowing in the coil. Owing to excessive magnetic leakage when the windings are continuous, as in Fig. 1, it is customary to make up the winding of several interspaced coils as shown in Fig. 2.

Figs. 3, 4 and 5 represent, respectively, two V-connected auto-transformers arranged for starting a three-phase induction motor, three single-phase auto-transformers, Y-connected, for starting a similar machine; and auto-transformer is also designed for 220 volts, but is connected to a 110-volt circuit from one end tap and the center tap, giving the same voltages as in Fig. 8.

Design of Auto-Transformers

Assume that it is desired to design an auto-transformer of 10-kw. capacity for a 25-cycle, 440-volt circuit with a 2 to 1 ratio of transformation, the low-tension voltage to be 220. Let it be of the core-type construction with two legs and let the winding be divided into eight coils, four per leg. Assume the efficiency to be 95 per cent.

$$Efficiency = \frac{watts\ output}{watts\ input}$$

Then for an output of 10,000 watts the input will be 10,000 ÷ 0.95 = 10,526 watts.

This limits the total full load loss to 526 watts, which should be about equally divided between the core losses and the copper loss, with perhaps a little greater copper loss. Therefore, let the copper loss be 300 watts and the core loss 226 watts. Assume a magnetic density of 30,000 lines per square inch of cross-sectional area of the core, which is a fair value for 25-cycle circuits. Then from curves showing hysteresis loss it will be found that for a density of 30,000 lines at 25 cycles, the loss is 0.1 watt per cubic inch of core for a good quality of soft iron in sheets.

The eddy-current loss will be small in a properly constructed core; hence it may be taken as 26 watts and the hysteresis loss 200 watts. Then the volume of the iron in the core will be 200 ÷ 0.1 = 2000 cu.in. The plates should be from 16 to 20 mils in thickness for 25-cycle circuits, and the oxide on the plates with a sheet of paper placed about every half-inch should be sufficient insulation. The volume of the iron core has now been determined, and it remains to proportion the core itself. Fig. 10 shows the type of core selected, and in proportioning it due regard must be given to the winding.

The core will be made square in cross-section, with the corners chamfered slightly. If the cross-section is made very small, the cores will be long and thin, the magnetic flux N will be small, and the coils will have to be provided with a large number of turns to generate the required electromotive force. Long cores also give rise to a long magnetic circuit, thus increasing the magnetizing current. On the other hand, if the cores are made very short the wire will have to be piled up deep in order to get it into the winding space, and the yoke across the ends will have to be made longer. Deep windings also mean a greater length of wire for a given number of turns. The best proportions are largely a matter of experience. For preliminary dimensions let the proportions shown in Fig. 10 be used, all of the dimensions being expressed in terms of the thickness of the core. Make the height $7\,a$; the volume of the core will then be

$$V = (2 \times 3.5\,a + 2 \times 5\,a)a^2$$

a^2 being the area of cross-section and $5\,a$ the distance between the yokes. This gives

$$V = 17\,a^3 = 2000 \text{ cu.in.}$$

whence

$$a = \sqrt[3]{\frac{2000}{17}} = 4.89 \text{ sq.in.}$$

This would represent the thickness of the core if it were solid iron. Part of the cross-section, however, is taken up by insulation between the plates, and the corners are cut off slightly, so it will be well to make the core 5 in. square. The other dimensions shown in Fig. 11 follow from this.

The impressed electromotive force is equal and opposite to the resultant of the counter electromotive force generated by the winding and that necessary to overcome the resistance of the winding. The drop in the winding is small compared with the impressed electromotive force and for present purposes may be neglected, hence the counter electromotive force generated in the winding may be taken as equal numerically to the impressed electromotive force. The number of turns required to produce this will depend upon the magnetic flux N which threads through the windings. The maximum magnetic flux through the winding will be $N = B_{max} \times a$, where B_{max} is the maximum value which the magnetic density reaches during a cycle, and a is the cross-sectional area of the core. In this case B_{max} is 30,000 lines per square inch, and a is 25 sq.in. Therefore,

$$N = 30{,}000 \times 25 = 750{,}000.$$

Taking the electromotive force generated in the winding as the equal and opposite to the line voltage,

$$E = \frac{4.44 \times N \times T \times f}{10^8}$$

where

N = Maximum value of the magnetic flux through the core;
T = Number of turns on primary coil;
f = Frequency in cycles per second;
E = Impressed electromotive force.

Applying this to the present example,

$$440 = \frac{4.44 \times 750{,}000 \times T \times 25}{10^8}$$

$$T = \frac{440 \times 10^8}{4.44 \times 750{,}000 \times 25} = 528$$

To make ample allowance let the number of turns be 600, or 300 to each leg. The current equals 10,000 ÷

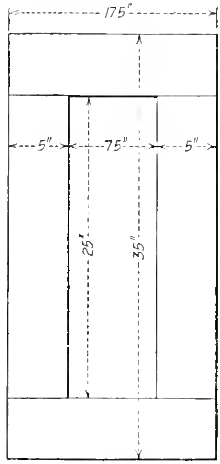

Fig. 11.

Core Dimensions

440 = 22.3 amp. Allowing 2000 circ.mils per ampere, the size of the wire will be 44,600 circ.mils, which corresponds nearest to No. 4 B. & S. gage. For this size of wire there are 4.5 turns to the inch. Allowing for insulation and space between coils, there will be approximately two layers on each leg. The approximate mean diameter of the coil is 7.5 in. and the mean length of one turn 23.5 in., say 25 in. The total length of the winding will then be 600 × 25 ÷ 12 = 1250 ft.

The resistance of No. 4 wire is approximately 0.25 ohm per thousand feet, which gives a resistance for the winding of approximately 0.32 ohm. The I^2R loss equals $22.3^2 \times 0.32 = 159$ watts. As the allowance for copper loss was 300 watts, this is well within the safe limits, and the efficiency will be greater than that assumed tentatively in the beginning.

Construction of Auto-Transformers

Having decided upon the core type of construction and determined the size of the core, the next step is to assemble the sheets. A wooden form should be provided, conforming to the internal dimensions of the core, and this should be laid on a level surface. Half of the iron sheets for the sides will be cut as long as the height of this form and half will be cut the overall height of the core. Similarly the ends will be made with half of the sheets as long as the width of the form and the other half as long as the overall width of the core.

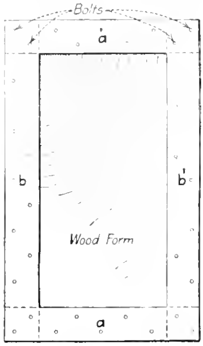

FIG 12

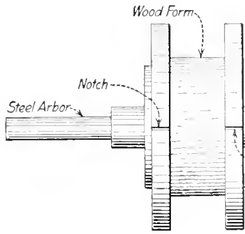

FIG. 13

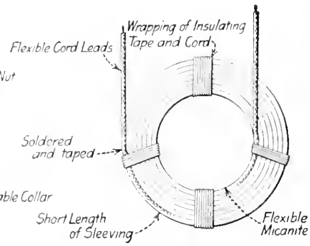

FIG. 14

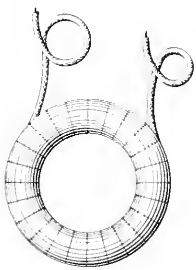

FIG 15

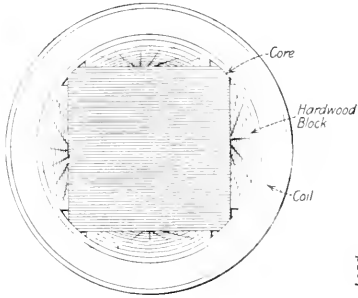

FIG. 16

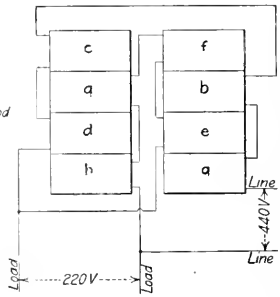

FIG. 17

WINDING DETAILS AND COIL CONNECTIONS

Place two long strips, b and b' (Fig. 12), against the form and select two of the shorter end strips, a and a', and place them at the ends of the form. Next lay on two short strips b and b' and two long strips a and a'. This construction will give lapped joints. When the desired thickness of iron has been built up in this manner, the iron should be clamped, drilled and riveted, as indicated. The bolts can be removed and the top yoke withdrawn, leaving dovetailed connections for the top of the core. The core is then ready for the assembling of the coils.

The next step is to provide a form for the coils similar to that shown in Fig. 13. The distance between the collars should conform with the height of the coil, with the center slightly tapered to facilitate the removal of the finished coil. There should be about four slots on the circumference of each collar on the spool, in which pieces of cord are laid before winding is started. These cords are for binding the coil before removing it from the form.

Figs. 14 and 15 show, respectively, a partially completed and a completed coil. Flexible leads are soldered to the coil ends and insulated as shown. When the coil is wound, place a strip of flexible micanite around the inner surface and wrap with tape and cord at four places as shown, after which the temporary tie cord can be removed and the coil securely wrapped with webbing. It should then be heated to about 200 deg. F. and immersed in some good insulating compound and baked.

Provide some rounded hardwood blocks that have been thoroughly soaked in insulating compound and place them around the cores as shown in Fig. 16. Slip the coils in position with mica washers between them and between the top and bottom coils and the core. The coils should then be connected as indicated in Fig. 20, a, b, c and d being connected together as are e, f, g and h, and the leads joined as shown.

Deboalt made no appearance and was unrepresented by counsel.

Trapped in Boiler Amid Hissing Steam

Andrew Monsen, a boiler cleaner, employed by the Equitable Light and Power Company, who lives at 61 California street, narrowly escaped being scalded to death in the basement of the Phelan Building this afternoon. While Monsen was working inside the boiler, the engineer, not knowing that he was inside, turned on the steam. Monsen was taken unconscious to the Central Emegency Hospita.

Improvements in V-Notch Meter

In the Mar. 31, 1914, issue, page 115, was illustrated the Hoppes V-notch meter in the original form. Since then several improvements have been made. There are many places in which the recorder had to be located where there was considerable vibration, and this not only made a wide mark on the chart, but in some instances the integrator was so interrupted as to make it unreliable. To overcome these difficulties a much longer and heavier guide has been designed which has overcome the previous defects.

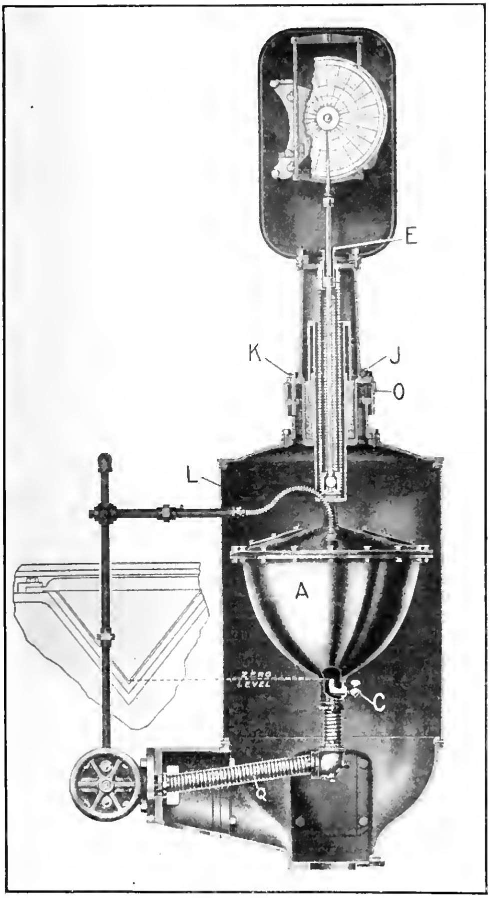

Fig. 1. Improved Weigher Recorder and Recorder Head

Figs. 1 and 2 show the changes made. In addition to improving the guide, the adjusting band O, Fig. 1, has been changed to the bottom of the column for adjusting the instrument to the zero level, which obviates the necessity for changing the brass sleeve E. All that is necessary now to adjust the zero level is to loosen the screws K and turn the band O up or down until the water drops slightly from the pet-cock C. All of the other adjustments have been made at the factory before shipment.

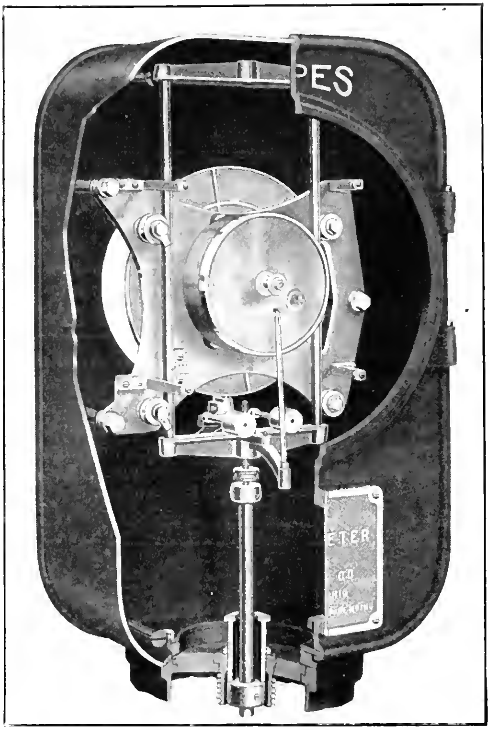

Fig. 2. Improved Recorder Head, Showing Chart Side of the Instrument

The improved recorder head, Fig. 2, is also made, when desired, to be placed below the cabinet L, as shown in Fig. 3. This is a desirable feature where the meter tank has to be placed at a considerable elevation above the floor or on the floor above the room where it is desired to have the recorder head. This illustration also shows clearly the connection of the water behind the weir with the weighing vessel, A, Fig. 1. These improvements add to the adaptability of the meter.

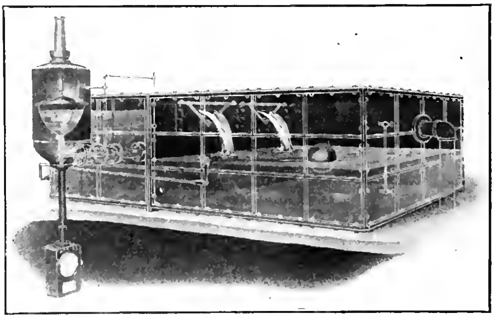

Fig. 3. Recorder Head Placed Below the Tank and Cabinet

Oxyacetylene Welding in Pipe Work

By W. Lee Roueche*

SYNOPSIS—Welded pipe is being more and more used each year, and the progress of its application is therefore of interest to watch. The relative cost of welded and flanged steam header favors the former. The article illustrates some interesting examples of pipe welding and gives valuable results from destruction tests on welded pipe.

It is only in the past decade that the design and construction of piping systems for power plants have received the careful thought and study of designing engineers which their importance warrants. Joints and massive fittings have been a potential source of trouble and expense, and a minimizing of their number is desired. The perfecting of the oxyacetylene torch has made this possible and also has enabled better engineering.

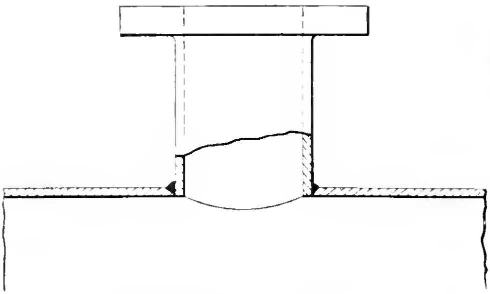

Fig. 1. Section Showing Construction of Welded Joint

The old-style header, built up with cumbersome flanged fittings, is fast becoming obsolete. It is now practical to build headers of the same relative strength as the pipe itself and in lengths limited only by shipping and erecting facilities. The relative cost is in favor of the welded header, more particularly in the larger sizes and where there are a number of outlets. A welded job is also much lighter, therefore easier to erect and support. It is built of the same material throughout and avoids the uncertainties due to defective castings and unequal expansion strains. The number of intermediate joints is reduced to a minimum, and in many instances they are cut out altogether. It has been found practical to close the ends of headers with convex heads, dished to the proper radius and welded on, thereby doing away with all joints except those at the nozzle connections.

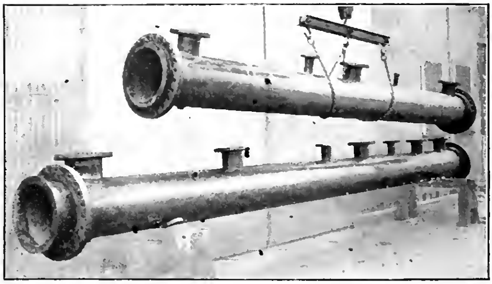

Fig. 2. Welded Header, 18 In. Diameter; Total Length 48 Ft. Note Outlets of Various Sizes

The usual method of construction is to take lap-welded merchant steel pipe of the proper diameter and thickness and where necessary weld together to get the desired length. The holes for the outlets are cut either in the usual manner or with the cutting torch. The nozzles are then welded on after being shaped to fit the curvature of the pipe. Different manufacturers have various methods of attaching the nozzles. The method used by the writer, which has proved to equal the strength of the pipe itself, is shown in Fig. 1. The pipe is beveled so as to form an angular groove of about 45 deg. with the nozzle. The fillet is then built up to the proper thickness. Nozzles of any size up to the diameter of the header itself have been successfully used. All welds are annealed after the header is completed, to relieve strains that may have been produced during the welding process. The

[illegible] hydraulic pressure 2½ times the working pressure.

Fig. 2 shows an 18-in. header 48 ft. over all, built in two sections, with six 7-in. boiler connections and five distributing outlets ranging from 2 in. to 10 in. This header was tested to 600 lb. hydraulic pressure and has been in successful operation for more than two years.

Fig. 8. Pipe Coil for Ammonia Plant; Has 180 Ft. of Pipe

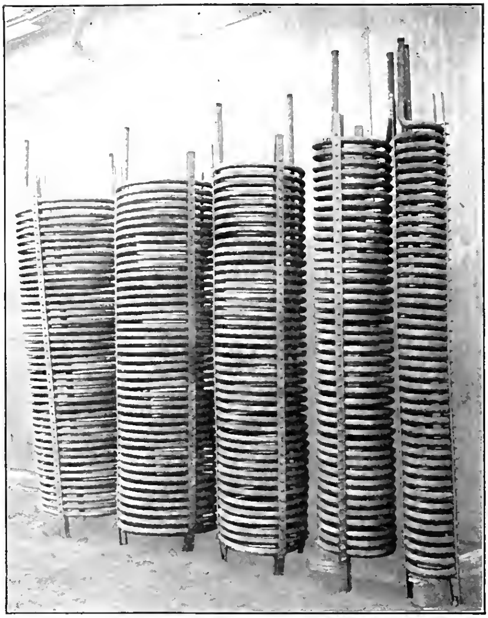

Fig. 9. Five Coils Having Total of 1400 Ft. of 1½-In. Pipe

Fig. 3 shows a 14-in. header 31 ft. 2 in. over all, with four 8-in. and one 4-in. seamless steel nozzles.

Fig. 4 is a good example of work that would have been practically impossible without the welding torch. All the headers are of 14-in. o.d. pipe ⅜ in. thick. The gooseneck was originally made in four sections and then made into two by welding. The location of the welds can be clearly seen in the photograph. The whole was installed in the same relative position as shown. The 14-in. outlet on the middle header connected to the upper end of the gooseneck. These headers were built to meet a peculiar condition in a Southern plant and have been in service about two years.

Fig. 5 is a further example of the advantages of the oxyacetylene weld. This is a special 8-in. expansion U-bend made to suit special conditions. The weld can be plainly seen at the top, just over the crane hook. The finished bend contains 37 ft. of pipe.

In long runs of pipe it is possible to eliminate from 40 to 50 per cent. of the joints. Fig. 6 shows ten lengths of 8-in. pipe for a high-pressure steam line averaging over 40 ft. each.

Another good example of a welded header is shown in Fig. 7. This is an 8-in. header 30 ft. over all, with two 8-in., two 6-in. and two 5-in. seamless steel nozzles. The 8-in. and 5-in. nozzles are in the same plane set at 90 deg. to each other.

The possibilities of oyxacetylene welding in all classes of pipe have only just begun to be realized. It is being successfully used in ammonia work, where there is a wide field for it. Figs. 8 and 9 are good specimens of this class of work. The former is for a reboiler in an absorption plant. The coil is 19 in. outside diameter and contains 180 ft. of 1½-in. extra heavy pipe. Fig. 9

shows a set of the same kind of coils which nest together, the five coils containing about 1100 ft. of 1½-in. extra heavy pipe. These coils were tested to 800 lb. hydraulic pressure.

Destruction Tests of Welds

The writer has made several destruction tests in order to compare the strength of the weld with that of the pipe. These have proved conclusively the efficiency of the weld when properly made. In the first test, a piece of 12-in. full-weight pipe, 5 ft. long and equipped with lap-joints and rolled-steel high hub flanges, was used. A 4-in. seamless steel nozzle was welded on midway between the flanges, and the ends closed with extra heavy cast-iron blind flanges bolted on. At 2000 lb. hydraulic pressure one of the blind flanges gave way, while the weld showed no signs of stress. The second test was made with a piece of 6-in. full-weight pipe 5 ft. long. The pipe was cut in the middle and butt-welded with the torch. The ends were fitted with lap-joints and rolled-steel flanges and blanked with extra heavy cast-iron blind flanges. Three blind flanges were broken in succession at hydraulic pressures of from 2100 to 2300 lb. The bolts showed stress at 2300 lb. One end of the pipe was then cut off and a ⅜-in. thick convex head butt-welded on. A special flange was made for the other end and the bolts increased from twelve ⅞-in. to twelve 1-in. Hydraulic pressure was again applied. At 3300 lb. the flanged joint failed owing to the dishing of the rolled-steel flange. Neither weld on examination showed any indication of failure. The theoretical bursting pressure of 6-in. full-weight pipe, as given by the manufacturer, is 1200 lb., and this test was made without annealing the welds. It was found that the outside diameter of the pipe was increased almost ¼ in. The third test was made with a piece of 5-in. full-weight lap-weld merchant pipe about 6 ft. long, butt-welded in the middle as in the second test, and both ends closed with a ⅜-in. thick convex head butt-welded on. At 2700 lb. the seam of the pipe opened up. This was welded with the torch and hydraulic pressure again applied. At 3950 lb. the pipe burst, rupturing the metal longitudinally to one side of the seam where it had been rewelded with the torch.

Automatic Electric Control of Pumps

By George J. Kirchgasser

SYNOPSIS—An interesting description of the applications of automatic electric control devices for pumps in various kinds of service.

Probably the commonest type of motor-driven machine to which the automatic starter has been applied is the pump. From the small house and sump pump to the largest types used on water systems, automatic or remote control has proved of distinct advantage.

Sump pumps are used to keep basements clear of water. The basement floors of buildings of today are frequently below the level of the sewers and considerable water drains in after rains or thaws. A pit is usually provided so that this water is collected in one place. A small pump called a sump or bilge pump, usually driven by a vertical motor, is used to prevent overflowing into the basement. To automatically start and stop this pump so that there will be insurance against flooding the basement and against useless waste of electric power, is one of the common applications of the motor starter, or controller.

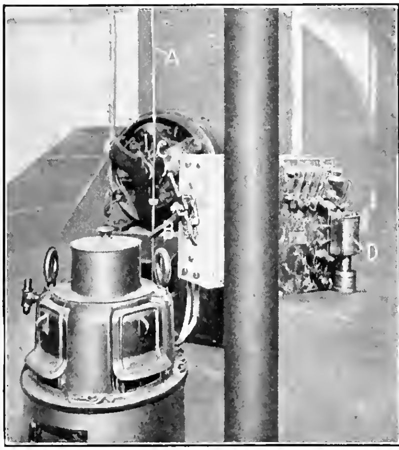

Fig. 1

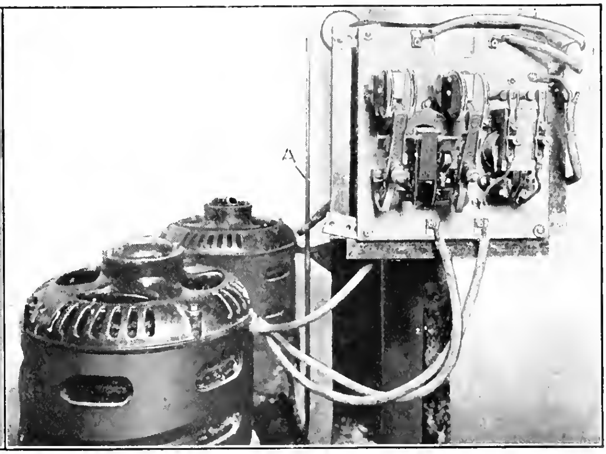

Fig. 2

Control Devices for Direct- and Alternating-Current Motor-Driven Sump Pumps

The illustrations, Figs. 1 and 2, show automatic controllers for direct-current and alternating-current motors.

In the first the float switch is mounted so that its operation is easily explained. As the water in the pit rises, the rod A, mounted on a float, rises also. This rod has two stops, one of which is shown. As the float and rod rise, the lower stop engages the movable arm B of the float switch. When this moves through a certain distance the weighted tumbler arm C of the switch causes the latter to close, and this in turn causes the solenoid D of the starter to become energized. The motor is thus started and accelerated to normal running speed. The pump will be driven until the water level has been lowered to a predetermined point. When this is reached the upper stop on the rod will have tripped the float switch open, which causes the automatic starter to cut the motor from the line and thus bring it to a stop. The pump may be put in operation for long or short periods, it may be started and stopped many times a day or only a few times a year, but no attention is required, and current will be used only when necessary and for as short a period as required to lower the water to the desired level.

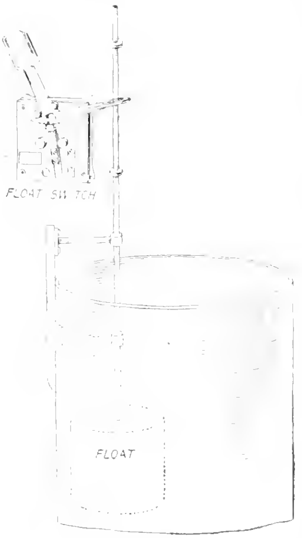

FIG. 3. THE FLOAT SWITCH

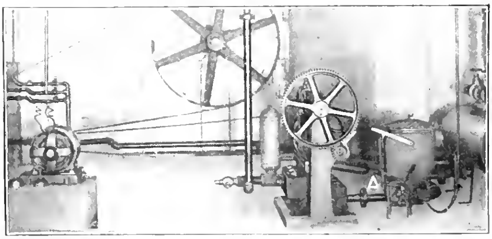

FIG. 4. THE FLOAT SWITCH OF THIS MOTOR-DRIVEN RETURN SWITCH IS ACTUATED BY THE WATER LEVEL IN THE PUMP GOVERNOR

For small sump-pump equipments operated by alternating-current motors the magnetic switch shown in Fig. 2 is used to throw the motor across the line or to cut it off, as the water level demands. In this installation the float switch, operated by the vertical rod A, is mounted on the post in back of the automatic starting-switch panel, one end of the lever alone being visible. Fig. 3 shows how the sump float is arranged.

Fig. 4 shows a simple but interesting application in a school building, of the same type of automatic switch and float switch. The latter is mounted near the floor (see A), while a magnetic switch is mounted on the wall and not shown in this view. A $7\frac{1}{2}$-hp., three-phase, 60-cycle, 220-volt motor of the squirrel-cage induction type is used. Back of the float switch is shown the automatic pump regulator and condensation receiver used in connection with the steam pump to automatically return the condensation from the heating system or other apparatus to the boiler. Fig. 5 shows such a receiving apparatus for returning condensation to the boiler, in which an automatic pump regulator and condensation receiver are employed. As the water rises, the float is raised and at a certain level causes the tumbler arm of the float switch to close the magnetic switch and set the motor and pump in motion. The float switch does not carry the motor current, but simply the energizing current which causes a magnetic switch (as in Fig. 6) to close and connect the motor to the line. After the level

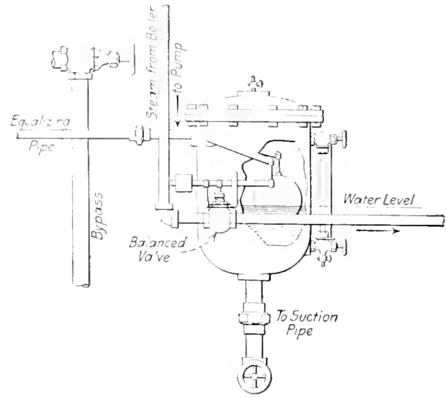

FIG. 5. SHOWING THE PUMP GOVERNOR

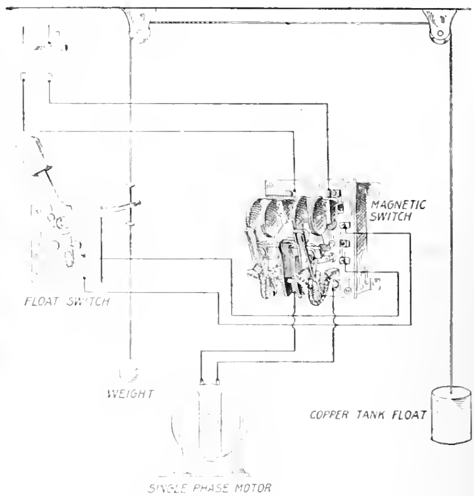

FIG. 6. AUTOMATIC STARTER FOR SINGLE-PHASE MOTOR

drops, the float switch is tripped open and the motor disconnected from the line.

In the keeping of any sort of open tank filled to a desired level the same methods of control may be used, except that the float and float-switch operations are opposite from those used in connection with the sump pump. In the ordinary tank system the motor is started and put in operation when the level is low and stopped when it reaches a desired high point. The same kind of float switch or an inclosed type may be employed. Figs. 6 and 7 show the wiring for automatic control of single- and three-phase motors respectively.

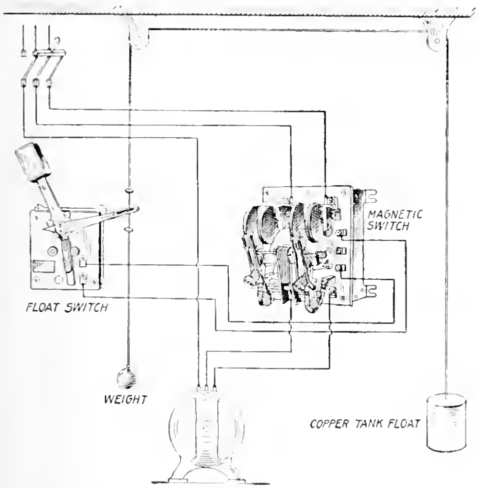

Fig. 7. Wiring of Automatic Starter for Three-Phase Motor

Pumps or compressors operating on closed systems are controlled in a similar way, the automatic starter being actuated by a pressure-regulated switch instead of a float switch, as shown in Fig. 8.

House pumps are required in all buildings where the city water pressure is not sufficient to supply the upper floors. These pumps are not required at all times, but only when the demand made on the system lowers the pressure maintained. To do this in the most economical and best way, automatic control of the starting and stopping of the pumps is necessary. The pressure requirements are thus always maintained. Fig. 9 shows two of three triplex house pumps in the Continental and Commercial National Bank Building, Chicago. These pumps are driven by 20-hp., 220-volt, direct-current motors automatically started and stopped by the three automatic

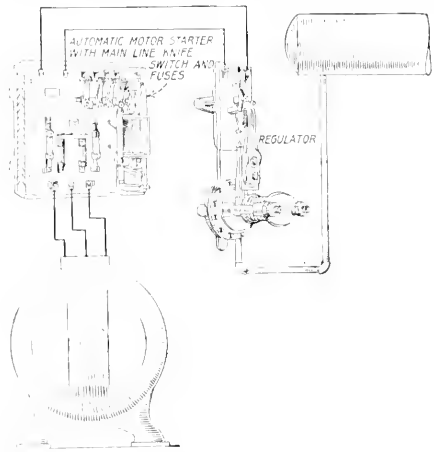

Fig. 8. Wiring and Controls for Starter for Direct-Current Motor

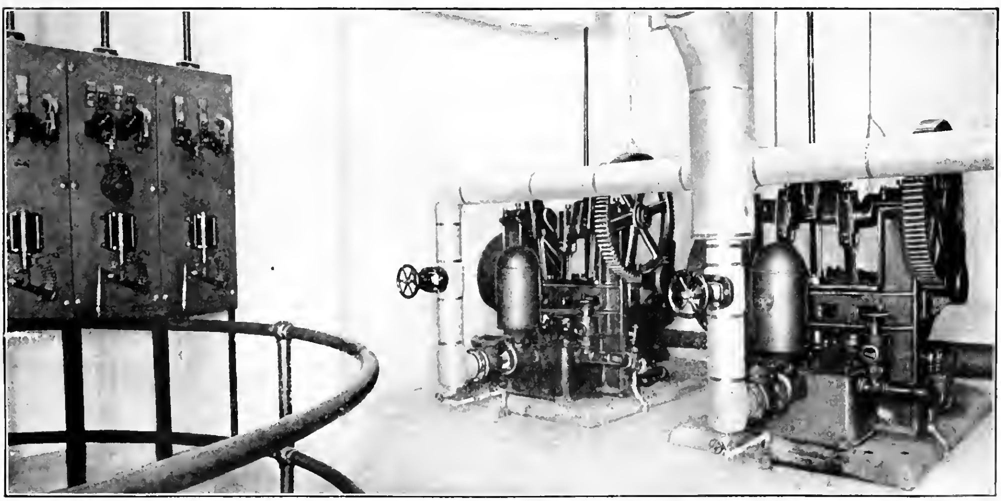

Fig. 9. Two of Three Electrically Controlled House Pumps in Office Building

First, one is cut in, then if the demand increases, another is started, and so on until the demand is met

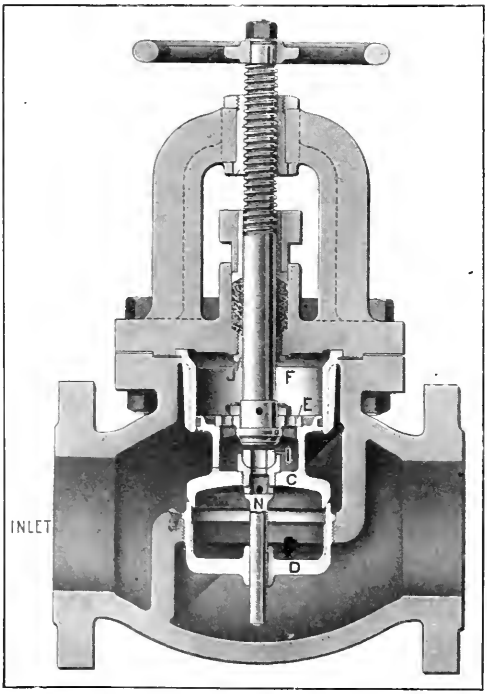
controllers shown on the panel. This equipment is arranged so that when the first demands are made, one motor is set in operation. If the demands of the service are greater than can be cared for by one pump, the second one is put in service and the third also, should it be needed. A pilot arrangement on the controller panels makes it possible to have any one of the three put in service first, followed by the others, thus dividing the work equally for a given period.

In the case of the automatic fire-pump controller any decrease in the pressure on the sprinkler system due to opening of a sprinkler head or to valve leakage causes the pump to be set in motion until the pressure supposed to be maintained in the system is again reached.

Similar machines, as vacuum cleaners, compressors and blowers, are also controlled automatically or by a push-button switch closing the automatic starter solenoid or magnetic circuit in the same way that a float switch or pressure regulator does. In buildings tenanted by dentists and physicians compressed air is usually furnished by compressors located in the basement and automatically controlled by pressure regulators and automatic motor starters, to keep a suitable pressure on the system regardless of the demand.

Lunkenheimer Balanced Throttle Valve

The balanced throttle valve illustrated herewith has been designed to operate with ease and with efficiency, combined with durability. When the valve is in place the steam enters above the disk, otherwise the value of



Lunkenheimer Balanced Throttle Valve

the bypass is lost. With the valve closed pressure enters the balancing cylinder past the piston ring and through the drain hole in the bottom of the disk cylinder. As a result, the pressure above the disk is equal to that in the inlet of the valve. This pressure aids in keeping the disk tightly sealed, and it is relieved by the bypass *I*, the opening through which is covered by the bottom of the stem when the valve is closed. When the handwheel is turned slightly, this opening is uncovered and the steam above the piston passes through the holes in the retaining ring *E*, thence through the hole in the bypass disk and through the drill holes in the bottom of the main-disk guide stem *N*; this relieves the pressure above the piston while the valve is being opened and the arrangement prevents pressure above the disk during the opening of the valve.

The drain hole in the bottom of the disk cylinder is to relieve the condensed steam that may accumulate in the cylinder when the valve is connected in a vertical position. When the valve is in a horizontal position the water in the disk and in the balancing cylinders will drain past the piston ring. Both the main and the bypass valves are operated simultaneously. Provision is made for regrinding the seating surfaces of the main seat and disk seating surface.

This valve is manufactured by the Lunkenheimer Co., Cincinnati, Ohio.

Long Chances with the Portable Engine

By Loe Addy

The operation of a portable engine is not a very angelic occupation, and at times it would seem that there must be a destiny to guard the operators from misfortune.

Upon one occasion, while overhauling a second-hand sawmill outfit, a wooden connecting-rod was used as a template for a new rod and was left on the engine when the workmen left the mill on Saturday evening. The next morning the owner, anxious to try his new engine, got up steam, turned it on and gave the flywheel a whirl. The wooden connecting-rod broke and the crosshead drove the stuffing-box gland through the cylinder head.

The engineer of a threshing outfit fed vinegar into the boiler at the rate of about six gallons a day for several days. It was supposed to prevent the foaming of the bad water taken from ponds and muddy copperas streams. The engineer said that the boiler needed blowing down, but he had twisted off the stem of the blowoff valve. The boiler had not been washed out in weeks. Its internal condition can better be imagined than described.

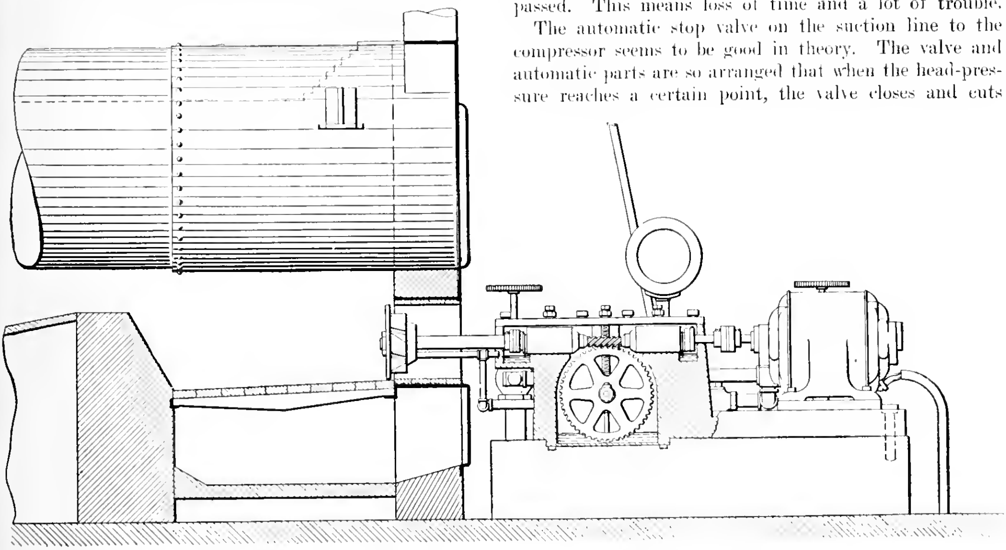
The speed of the sawmill engine was controlled by a lever bolted to one of the arms of the governor, from which the belt was removed. A wire attached to the end of this lever extended to a wooden lever within reach of the sawyer, thus furnishing means for shutting off the steam. When the wire was released the balls dropped by gravity, giving a full head of steam. The lever was secured by being hooked behind a nail in a post, to be released when the power was needed. It can readily be imagined about how sensitive the control was. They certainly placed great confidence in that wire and nail; for if the lever became unhooked or the wire broken, or even if the engine moved forward a trifle on its foundation, it would run wild under a full head of steam.

There certainly is no machine called upon to operate under as many trying conditions as the traction engine of a threshing outfit. A stationary engineer would hardly care to operate a unit under such conditions.

While descending a hill the furnace door is usually opened and perhaps the fire damped in order to protect the crown-sheet, which now has no water over it. At times on a short hill this precaution is not taken, and when level ground is reached the water comes surging back over the heated plate; yet, it is comparatively seldom that an explosion occurs. There are occupations more monotonous than that of the engineer of a traction engine.

Rotary Crude-Oil Burner

The rotary crude-oil burner illustrated herewith is manufactured by G. E. Witt Co., 862-864 Howard St., San Francisco, Calif. The principal feature is the placing of the burner on a horizontal shaft in front of the furnace, away from the heat, the air passing through it carrying the heat toward the back of the boiler, which overcomes trouble from overheating. The burner is driven by a motor, and the device is self-contained. With the exception of the burner, all of the apparatus is outside the furnace.



ROTARY CRUDE-OIL BURNER APPLIED TO A RETURN-TUBULAR BOILER

This burner is suitable for boilers of small capacity, and is noiseless in operation. It has also been applied to boilers up to 140-hp. capacity, which demonstrates its wide range of application for both high- and low-pressure work.

Peripheral Speeds—As compared with the 38 ft. per sec., which is considered the limit in safe speed for a cast-iron flywheel, some of the peripheral speeds attained by the disks of steam turbines are striking. In a paper presented to the Manchester Association of Engineers, R. F. Halliwell says: "The highest peripheral speed which it is possible to employ is probably found in the 300-hp. DeLaval turbine, in which, with a 30-in. wheel running at 10,000 r.p.m., a velocity of over 1300 ft. per sec. is reached."

Ammonia Compressor Alarm

By G. A. Robertson

There has been considerable comment recently among refrigerating engineers as to the proper manner of installing relief valves or other similar devices to guard against serious accidents from excessive head-pressure in the refrigerating system.

Some have located a relief valve in a bypass line between the suction and discharge lines of the compressor, and there have been a few installations of automatic suction stop valves. Both of these methods have features that are undesirable. The relief valve installed in the bypass between suction and discharge lines, is set so as to let ammonia gas in the high-pressure side pass to the low-pressure side of the system, when the head pressure for some reason has increased to an undesirable point. When this valve has been lifted off its seat once or a few times, it is almost sure to leak. In order to inspect it, guard valves would have to be installed, which are undesirable, or the engineer would have to shut down and pump out the pipe lines that were bypassed. This means loss of time and a lot of trouble.

The automatic stop valve on the suction line to the compressor seems to be good in theory. The valve and automatic parts are so arranged that when the head-pressure reaches a certain point, the valve closes and cuts off the supply of ammonia gas to the compressor. There is some doubt as to whether the valve would respond when needed, since it is likely to stand for a long time without operating.

The writer desires to call attention to an alarm installation for the compressor. An ordinary ammonia relief valve (about 1-in.) is placed between the cylinder and the guard valve of the compressor, and the outlet connected to a ½-in. whistle fifteen or twenty feet from the machine. The valve is set to blow at 25 or 30 lb. above the usual head-pressure. Just as soon as the pressure reaches this point the whistle blows and gives warning. Should the machine be started with the guard valve closed, the whistle gives warning immediately. The operator could then stop the compressor in time to prevent an accident.

Some Notes on Fans*

By A. A. Potter and S. L. Simmering

SYNOPSIS—Rules and approximate equations for the capacity and cost of fans and blowers.

For the production of artificial draft use is made of chimneys, fans, blowers and steam jets. Under ordinary conditions a chimney 125 ft. high will give a draft of about 0.75 in. of water, or about 0.43 oz. pressure, and a chimney 250 ft. high will give a draft of about 1.5 in. of water, or 0.87 oz. pressure.

A chimney, once built, is limited in its capacity, whereas a fan may ordinarily have a range of pressure from 0.25 oz. to 4 oz., depending on the speed at which it is operated. This range of draft pressure makes it readily possible to meet any overload which may be suddenly demanded of the plant. A combination of the natural or chimney draft and forced draft is frequently used. The chimney draft in this case is made sufficient to overcome the resistance to the flow of the gases due to the flues, passages and chimney walls, while the draft produced by the fan is sufficient to overcome the resistance to the air in passing through the fuel bed and also to supply the necessary air for the combustion of the fuel.

Air Required for Combustion

If the coal burned consisted of pure carbon and perfect mixing were possible, about 12 lb. of air would be needed for every pound of fuel burned. As a general rule, however, under actual operating conditions about 18 lb. of air is required per pound of coal. The volume of one pound of air at 32 deg. F. and atmospheric pressure is approximately 12.5 cu.ft.; hence, the total volume necessary at this temperature to burn one pound of coal is about 225 cu.ft. For any other temperature t the volume becomes,

$$\frac{(460 + t)\,225}{492}$$

If

w = Weight of coal burned per hour;
t = Temperature at which the air or gases enter the draft-producing apparatus;
A = Volume of air in cubic feet per minute;

then

$$A = \frac{225\,w\,(460 + t)}{60 \times 492} \text{ or, } A = wk$$

The values for k for different temperatures are as follows:

t	k	t	k
60 deg. F.	3.96	300 deg. F.	5.79
80 deg. F.	4.11	400 deg. F.	6.55
100 deg. F.	4.27	500 deg. F.	7.32
200 deg. F.	5.03	600 deg. F.	8.09

The forced-draft apparatus would handle the air at a temperature of about 80 deg. F., and an induced-draft apparatus at about 550 deg. F., if no economizer were used. Hence, from the above the following approximate rules are deduced:

Rule 1—The cubic feet of air to be supplied per minute by a forced-draft apparatus is equal to four times the number of pounds of coal burned per hour.

Rule 2—The cubic feet of gases handled per minute by the induced-draft apparatus when no economizer is used, is equal to eight times the number of pounds of coal burned per hour.

Capacity and Cost of Fans

Table 1 gives the capacity of fans in cubic feet per minute corresponding to pressure in ounces per square inch for three different speeds. The approximate cost of the

15	175	150
18	300	175

fan is also given in each case, and the size is expressed as the diameter of the fan in inches. For sizes of 18 to 48 in. the relation between cost and size is very indefinite, but the approximate cost in dollars, C, may be represented by the equation,

$$C = 0.5\,D + 1 \text{ (lower limit)}$$

in which D is the diameter of the wheel in inches. For sizes of 25 to 60 in. the approximate cost is

$$1.66\,D + 21 \text{ (upper limit)}$$

and for 60 to 132 in.,

$$6.94\,D - 266$$

Effect of Flue-Gas Temperature

Calculations based on a temperature of 60 deg. F. would not be correct for temperatures of 400 or 600 deg., which are common in induced-draft systems. The principles upon which the necessary corrections are made are as follows:

When air is heated it expands, and the weight of a given volume varies as the absolute temperature. The necessary fan speed to produce a given pressure is proportional to the square root of the absolute temperature. The power required to drive a fan varies as the velocity of the flow when the pressure and the outlet area remain constant.

The effects of flue-gas temperature on the speed and capacity of fans are shown in Table 2.

TABLE 2. EFFECT OF FLUE-GAS TEMPERATURE

Editorials

Burning Low-Grade Fuel

The leading article of this issue should be read with more than passing interest. It tells of a moderate-sized plant in which, by simply changing the boiler-furnace equipment, there resulted a saving amounting, in round numbers, to thirty-five thousand dollars per year.

Under the former conditions coal fresh from the mine was burned in the boiler furnaces of the Bessemer Coal & Coke Co. This fuel had a marketable value of about one dollar per ton and one hundred tons was burned every twenty-four hours.

A five to six-in. layer of bone exists between the coal deposits, and it cost from three to four hundred dollars a month to remove this bone from the mine. It had no value as a fuel. When attempts were made to burn it the result was most unsatisfactory.

Six of the power-plant boiler furnaces were recently equipped with mechanical stokers, and now this fuel, that cost something like forty-two hundred dollars a year to remove, is burned under the boilers, with a saving of the run-of-mine coal formerly consumed and a saving in the bone-removal charge. Furthermore, the boiler-room force has been reduced from ten to six men for the twenty-four hours.

This bone contains between thirty and forty per cent. ash content and averages about eighty-five hundred British thermal units per pound as fired. With this fuel and the stoker equipment, the boilers have been operated at one hundred and seventy-five to two hundred per cent. of rating.

There is a lesson in this for the plant that might burn low-grade fuel and does not, and it shows that intelligent investigation into furnace conditions can result in a surprising saving in operating expense as well as, in this instance, the burning of a fuel that was considered worthless. Instances are rare where such great savings can be effected, but it always pays to be vigilant. These people were doing their best under the old conditions, but some one thought of improving the conditions.

Stokers for Locomotives

The summary of a report by D. C. Buell before the annual meeting of the International Railway Fuel Association appearing elsewhere in this issue is interesting as indicating the latent possibilities of the locomotive stoker. What will perhaps come as a surprise to many is the fact that the fundamental reason for the application of stokers to locomotives is that maximum capacity of the engines can be obtained with more certainty under trying conditions than under hand-fired conditions, even with two firemen to a cab. Formerly, the argument for locomotive stokers emphasized the greater economy over hand-firing and the elimination of smoke, just as did the early statements enumerating the advantages of stokers for stationary boilers. Experience seems to be proving that it is the greatly increased capacity possible with a minimum of labor that is the sum and substance of the superiority of stokers for locomotives, just as it is for stationary boilers.

Another quite natural characteristic to be expected is that locomotive-stoker manufacturers have in most, if not all, cases had to adapt their product to the locomotives, but were never frequently favored by designers considering how the locomotive could be made to more favorably receive the stoker. The stoker builders' experience parallels that of the early steam-turbine manufacturers. The turbine, of course, ran too fast, and it was for a long time known that its speed could not be reduced without commercially impossible sacrifices in economy, before builders of "the other end," meaning the driven machine, made serious efforts to adapt their products to turbine speeds.

Engineers may be progressive and radical as they wish, but the fruits of their labors find commercial application only as fast as conservative business permits.

By the way, what is the state of the art regarding stokers in marine practice? Indications are that marine men are going to be true to tradition and not adopt the stoker until its success has been absolutely assured everywhere else.

Welded Pipe Work

The first notable change in steam mains for power plants was the doing away with the double header—the elimination of that emergency steam container considered so indispensable when the header in service developed a serious leak. Plant designers omitted the second header only after experience demonstrated that if the pipe material was sound and the fitting properly done, leaks or steam-main troubles serious enough to warrant cutting out the entire header would not occur. The next advance comes in the reduction of the number of flanges on headers and in mains. A steam leak is not only an eyesore, but makes a sound that disturbs your conscience, drops water down the back of your neck and, unfortunately, costs money. As the leaks invariably occur at the flanges, why have more flanges than necessary?

Autogenous welding has been a great help to various industries, and there are few places in the power plant where it does more lasting good than it does when applied to the heavy piping. As the writer of the article on this subject, appearing elsewhere in this issue, remarks, header and pipe may be made up in lengths limited only by shipping and erecting facilities. In the case of headers the welded header is not only lighter, being more easily supported than a flanged one, but it costs less.

Welding is also proving well suited to pipe-coil construction. Coils are usually inclosed in a shell or vessel, and if a leak occurs, it must be quite serious to be quickly discovered. Welding makes it possible to make up exceedingly long coils with no joints except at the inlet and outlet ends, which are outside the shell containing the coil. Where special bends are needed, the welding process sometimes offers an easy solution to what might be a troublesome problem both in construction and erection.

Quite naturally, considerable apprehension was felt in the early days of the application of welding to high-pressure piping. Many will not permit its application to boilers, and it may be expected that extensive experience with welded steam pipe or the wide dissemination of the results of many destruction tests on welded boilers, will be necessary before the torch will find a field of usefulness on boilers other than cutting old ones into junk and facilitating their removal and transportation to the pile. In this respect the destruction tests described in the article referred to are interesting and encouraging.

Recent License Legislation in Massachusetts

As the smoke of the recent heated discussion of license legislation rises above the good old Commonwealth of Massachusetts, an amended license law is seen to have resulted. Supervision of boilers, inspections and licensing remains in the hands of the boiler-inspection department of the District Police.

Before considering this last amendment a little history of the license-legislation tendency in the Commonwealth during the last few years will assist in more clearly comprehending the causes back of the recent change.

Section eighty-two of the original law stated that "Licenses shall be granted according to the competence of the applicant . . ." Again, Section eighty-one rules that ". . . he shall receive, within six days after examination, a license graded according to the merits of his examination, irrespective of the grade of license for which he applies."

In this law nothing was said about a man holding one grade of license being compelled to serve a specified time before he could apply for one of a higher grade. It was in 1911 that the desires of many for a time-service clause found a place in the law which, as then amended, made it necessary for applicants to have served specified times under lower-grade licenses before they could lawfully apply for licenses of a higher grade.

That part of Section eighty-two relating to special licenses seems to have been objectionable to many manufacturers, particularly those whose plants were run most of the time by water power, but which had steam power for low-water periods or for emergency purposes. The law allowed an engineer a special license for a particular plant, "provided, however, that no special license shall be granted to give any person charge of, or permission to operate, an engine of over one hundred and fifty horsepower." This same section also allows a man holding a second-class license ". . . to have charge of and operate a boiler or boilers, and to have charge of and operate engines, no one of which shall exceed one hundred and fifty horsepower, . . ."

It is seen that a plant having an engine or engines of more than one hundred and fifty horsepower and operated most of the time by water power was compelled to have a first-class engineer in attendance. This, it seems, was the thorn in the manufacturer's side. So this year the much-talked-of House Bill No. 1111, widely circulated with a form letter urging those approving to request their representatives to support the bill, was presented. This bill aimed to overcome the special-license objection by providing that a person desiring to have charge of a particular plant might, on examination, receive a third-class license, which, according to Section twenty-one of the bill, allowed "the holder to have charge of and operate any particular steam engine or engines." The firemen's license would have covered the boiler or boilers.

So much was asked for in Bill 1111 that the proponents suffered the experience of the dog that stopped to look at himself while crossing the brook with a bone in his mouth. A compromise was effected in which the manufacturers are allowed to have engineers holding special licenses to operate plants with engines of any capacity, so long as the plants are run by water power exclusively during the major part of the year.

We see no objection to this amendment, as it does not make these plants more dangerous to public safety than before, provided, of course, that the examiners do their duty. It should ease the strained relations between employers and engineers.

The Plumber and Us

Can it be that the plumber intends encroaching upon the domain of the power engineer?

From a recent issue of the *Plumbers' Trade Journal* it is gathered that there is a growing belief among master plumbers that their future "resembles a broad path of progress leading to the top of contract hill, the apex of which will be reached when the master plumber handles not only the plumbing, but the heating, ventilating, power plant, lighting, elevators, sprinkler equipment and refrigeration work as well."

These are high-sounding words, my masters, and would seem to indicate that the "apex" alluded to is, just at this minute, impossible of discernment. It is reasonable to say, however, that the plumber of today—once a worker in lead and popular mainly as a medium for threadbare witticism—has in many directions so broadened his one-time field of endeavor as to include much inter-related work. He has, for example, become "familiar with the radiant warmth of the heating system"; he is already attracted "toward the power handled by the little copper wire"; his association with boilers has privileged him to talk intelligently on pounds pressure and B.t.u., and his anxious inquiries in his trade papers show his interest to be greatly beyond the use of the soldering iron and the pipe cutter. Furthermore, he informs us that, as "consolidation is the modern trend in every line," he feels that in the future he will "handle" a large, thick slice of the mechanic arts—or cease to exist!

A most confident and ambitious person is the plumber man, as no one will deny. He insists that the sanitary wholesomeness now enjoyed by the public is mainly owing to his efforts, and that in due time his trade will be a profession.

As to his desire to annex the territory, to occupy the terrain, of the powers now controlling the power-plant, the heating and ventilating, refrigeration and elevator domains, one is inclined to the opinion that the plumber in his present state is vainly striving to separate from its main body a huger portion than he can successfully masticate.

Correspondence

Putting Crank Disk on Shaft

On page 654 of the May 11 issue is a letter requesting information on tightening a loose crank without removing it. I believe that it is almost impossible to do this and make a safe job, because after the engine has been run for some time with a loose disk it will not only hammer the hole out of true. but will also deface the surface of the shaft, so that the disk, if made tight, would be out of line. Consequently, the crank would not be true.

There are several methods of tightening a disk, all depending on the conditions, material available and tools at hand. I know of one case where the disk was riveted onto the shaft, and another where the shaft and the disk were drilled, reamed and tapped to receive tapered bolts at several points on the shaft. In the latter case the disk was out of line, although it was run for some time by leaving the crankpin brasses keyed slightly loose. This caused a slight pound, which increased until the tapered bolts became loose and hammered, so that they could not be removed. Eventually, a new shaft and crank disk had to be purchased. So it is cheaper in the long run to put on the new disk first and see that the shaft end is in proper condition before the disk is put on, or it may be necessary to rig a turning tool and means for revolving the shaft to true up the battered end before the disk is fitted.

The cause of many a loose crank disk is in the heating before it is placed on the shaft. In most cases where the job is to be done a long way from the shop, the disk is blocked up on brick supports with a fire beneath it. In many instances the fire is too hot and the flame will concentrate through the hole in the center of the disk, causing the edge around the hole to become very hot, perhaps a bright-red heat before the rest of the disk shows signs of turning red at all. This is where the mistake is made in judging the temperature which the metal should stand at the edge of the hole without ruining its contracting quality, causing it to crush together or stretch when the shaft is expanding from the heat of the disk. This is owing to the fact that the outside edge of the disk is usually much cooler and does not expand as the shaft does, and the metal around the hole, being hotter, is compressed, thus causing a misfit when cold. The fire should be a slow one and very even, and a cover should be placed over the hole to prevent the heat concentrating on the inner surface and edges. The disk should then heat gradually and evenly to a very dull or cherry red and no hotter. Even though it may be a little harder to draw on the shaft, it will contract to a good tight fit when cold.

The space in which the metal is compressed while hot extends back to a circle about one inch larger than the bore for the shaft and the pin cannot be made tight without removal and refitting, often by refitting and reshrinking over a shim or bushing. When the keys are not the proper size to fill the keyways in the shaft and hub, small steel strips should be made to fit on top of them to prevent the key from working up or down and wearing out the sides of the slots, which will happen with a loose disk or wheel, though it may not be noticed at the front or face of the hub.

I had an experience with a crank disk that had been overheated at the bore. This was to be put on a 650-hp. cross-compound engine just being erected. The job was a time contract, and the engine had to be ready or penalties would be exacted. The time was short and it was urgent that the disk be put on before dark, as there was no light to work by. It was heated over a roaring hot fire, and overheated at the center, but it went on nicely. The engine was assembled, tightened up and adjusted and ran smoothly with normal load. When the overload was put on, however, the trouble was discovered—the low-pressure disk had loosened, the bore had battered about $^1/_{64}$ in. out of true, and one would have thought there was 4 ft. play judging from the hammering before the engine could be stopped. A new disk was sent from the shop, but in the meantime, to avoid loss of time and penalty, it was decided to try calking the boss of the hub around the shaft. This held the disk tight enough for normal load, but only contracted the metal in the hub to a depth of ½ in. or less in the 6 in. of the disk's thickness and would have given way again as soon as load enough was put on the engine to bring extra strain on the disk. Greater precaution was taken in heating the next disk and it went on the shaft nicely and gave no trouble.

R. A. CULTRA.

Cambridge, Mass.

Replying to Mr. Jensen's letter, it was a mistake to have the keys fit tight sideways. If he will pull these and substitute keys made with side clearance, which are tight top and bottom, driving home with a 20-lb. sledge, he will have no further trouble. In preparing the new keys have them made with heads to facilitate pulling during the process of fitting, which will require some care. After driving home, the heads can be cut off. The keys, being tight at the top and bottom, pull the crank to practically a forced fit on the opposite side of the shaft.

JOHN F. HURST.

Louisville, Ky.

I would suggest that Mr. Jensen take out the old keys and replace them with new ones properly fitted. Do not try to use up the old keys by placing liners in with them, as this is only a makeshift.

Making keys grip on the sides of a keyway is a method much used by machinists in this country. Why, I do not know. The proper way to fit a key is to have it large enough so that when first driven in it will go only about three-eighths of the way. It is then driven out and the high spots filed off. The bottom of the key does not require to be filed, and the sides should merely touch.

Repeat the operation, driving in and out until the key reaches within 3/4 in. of being home, then use a heavy sledge for the final drive. The key is driven flush. Should any part project, chip off and file. If it has been properly fitted there will be no more trouble.

This is the method I have used on the wheels of locomotives after they had been shrunk on, and were not beaded over. The sketch did not show whether the keyway is extended beyond the crank disk to allow the driving out of the keys, but if not and there is room, it will be necessary to do so, just enough to allow the key drift to enter.

C. Sword.

Cohoes, N. Y.

In regard to Mr. Jensen's loose crank disk, I would advise drilling and tapping five tapered holes, half in the disk and half in the shaft, then screwing in tapered bolts very tightly. Cut these off flush and peen the shaft evenly all around so as not to throw it out of line. Take time and pains with this job.

B. C. White.

Yonkers, N. Y.

[Letters covering many of the points mentioned were received from William Braunbeck, of New Brighton, Penn., and James E. Noble, of Toronto, Can.—Editor.]

Cost of Handling Ashes With Steam Vacuum System

In the article describing the boiler plant of the Union Brewing Co. in St. Louis, which appeared in the May 18, 1915, issue of Power, the paragraph on page 665 referring to the cost of handling ashes is rather ambiguous. We are in a position to know that the 10 to 12c. was intended as the total cost per ton, including the charge for steam. A casual reading might give the impression that the 10 to 12c. included only the fixed charges, such as depreciation, interest, etc. Since the article was written we have had an opportunity to inspect one of our systems that has been handling ashes at the rate of 60 tons per day, and from the results of this inspection we are confident that the main pipe will handle at least 100,000 tons before it is ready for the scrap heap. Taking a small plant producing 10 tons of ashes per day, or 3000 tons per year of 300 days, as a typical example, we have found that the cost for repairs has amounted to $8.50, or $0.00285 per ton. Figuring the initial investment at $1000, interest at 6 per cent. would amount to $60 per year, or 2c. per ton. At the rate of 3000 tons per year, the equipment would last for 33⅓ years, or in round numbers, say 30 years. The depreciation then could be figured at 3⅓ per cent. and this proportion of $1000 amounts to $33.33 per annum, or $0.01111 per ton. Summing up, the charges for upkeep, interest and depreciation amount to $0.03396, or approximately $0.034. To this must be added a charge of about 6c. per ton of ash for steam, making a total of $0.094 per ton, which figure may be compared to the 10 to 12c. given in the article.

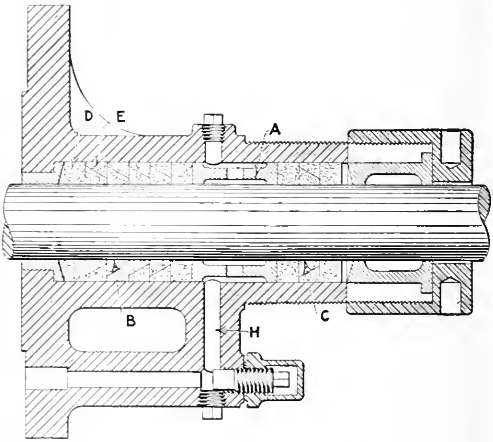
Ordinarily, in a plant handling 10 tons of ashes per day, no additional labor would be required to operate the vacuum system, but to meet all contingencies the following comparison may be of interest: Where 10 tons of ashes per day are handled by hand over a distance of 100 ft., the cost is rarely below 20c. per ton, or a total cost of $2 per day. Assuming this charge per ton for wheelbarrow conveyance and also as a labor charge for the vacuum ash-handling system, which would handle the total amount of ashes in 2 hours, the charge against the latter would be only 40c. as compared to the $2 given above. Adding the $0.94 for the other items entering into the cost of the vacuum system gives a total of $1.34 for the 10 tons. Without allowing anything for the equipment that would be needed in hand conveyance, the saving is 66c. per day, or $198 per year of 300 days. On this basis the earning is nearly 20 per cent. on the investment, so that in a little over five years the equipment would pay for itself. At the end of this time the saving would be much larger, as the interest and depreciation items would have been eliminated.

R. H. Miller,
Girtanner-Daviess Engr. & Contr. Co.

St. Louis, Mo.

Ammonia Stuffing-Boxes

The ammonia-pump piston rod is usually made of hard hammered steel and frequently separates from the steam piston rod. The reason for this construction is apparent. The pump piston rod wears rapidly, and if the machine



Stuffing-Box of Ammonia Compressor

is fitted with a two-piece piston rod the pump rod may be replaced when worn without disturbing the steam rod.

A long stuffing-box, as shown, is divided into two compartments by the gland *A*. In packing an ammonia stuffing-box care must be taken that this gland is over the port *H*, leading to the suction of the pump. With a box constructed in this way the first set of packing *B* is subjected to cylinder pressure. Any leakage past this packing is reduced to suction pressure at once, thus the second set of packing *C* is only subject to this pressure. The port *H* should always be kept clear. This port can be closed by means of the plug and the space about the gland filled with oil to act as a seal, if desired.

When the stuffing-box is properly packed with alternate plain (*D*) and sectional (*E*) rings, as shown in the sketch, there is no necessity for subjecting the packing to great pressure to keep the box tight. If the rod is worn it should be removed at once and turned true, or if this is impracticable a new pump piston rod should be installed.

It is impossible to properly pack the stuffing-box when the rod is badly worn.

THOMAS J. ROGERS.

Brooklyn, N. Y.

Gasoline Engine Run on Natural Gas

In answer to the inquiry of Mr. Gawthrop as to the feasibility of using an automobile engine on natural gas, I believe the results would not be satisfactory.

Last year in Texas, I ran upon a similar proposition. In this case the engine was taken from an old Buick car and was belted to a 15-kw. alternating-current generator. The engine was provided with a Pickering governor, bolted to the crank case and belt driven from the crankshaft. The governor stem, through levers, handled the gas and air butterfly valves. We found that it was necessary to arrange the valve levers so that, for a given movement of the governor stem, the air valve moved through a greater angle than did the gas valve. This was owing to the fact that on light loads the mixture became too lean to explode if the two valves regulated to the same degree.

The outfit ran fairly well, although it was necessary to watch it constantly and it required far more attention than did the 100-hp. gas engine in the plant. The amount of lubricating oil used was excessive, as the engine, although in excellent condition, tended to heat up after a three- or four-hour run. While it was impossible to check the consumption with any degree of accuracy, it was the belief of the operators that the gas per horsepower was at least 50 per cent. greater than in the regular gas engine.

As regards the speed regulation, on a fairly steady load the lights did not flicker and the voltage fluctuation was small. However, when the load dropped off suddenly the engine would speed up considerably, in which case the engineer would run to change the gas-valve link rod, thereby bringing the speed back to normal.

No gasoline engine will burn natural gas economically unless means be provided to increase the compression, such as fitting new cylinder heads. If this is not done, the amount of gas used is excessive. For any given cylinder dimensions an engine will develop approximately five-eighths as much power on gas as on gasoline, in ordinary operation. Consequently, the 60-hp. automobile engine should develop about 50 hp. at 1000 r.p.m. or 37.5 hp. at 750 r.p.m.

Mr. Gawthrop, in using a 17½-kw. generator, would require not more than 27 hp. Therefore, his engine need never deliver more than 65 per cent. of its rated capacity. At this load he will do well to obtain a horsepower-hour on less than 25,000 B.t.u., or 50 per cent. more than a regular gas engine would use at this percentage of full load (17,000 B.t.u. at 60 per cent. load.) A standard-make gas engine at full load will ordinarily develop a brake horsepower-hour on 11,000 to 12,000 B.t.u. If the outfit develops 27 b.hp., the additional heat required would be 351,000 B.t.u. per hour, which, based on a six-hour run, would be 2,106,000 B.t.u. daily. Not knowing the gas used, one can merely estimate its heat content. Assuming 800 B.t.u. per cubic foot, the autombile engine will demand 2630 cu.ft. per day more than the gas engine. If gas costs 25c. per thousand cubic feet, the extra fuel consumption of the automobile engine would be about $240 yearly. Of course, the lighting load will vary, so that the 27 hp. will probably be the maximum rather than the normal load. Nevertheless, the gas consumption will be at least as much as given above, since on any smaller load it will be still more per horsepower-hour. Therefore, it would probably be cheaper to purchase a gas engine, thus also avoiding the worry, trouble and extra fuel expense that he will undoubtedly experience with his automobile engine.

L. H. MORRISON.

Fremont, Neb.

With reference to Mr. Gawthrop's inquiry, page 654, May 11 issue, as to the use of a gasoline engine on natural gas, I would advise him to increase the compression about 25 per cent. either by putting plates on the piston or cylinder head or by employing a new piston to fill up the extra clearance. Plates on the piston head are not satisfactory owing to the weight. He will need a heavier flywheel also. If operated without the above, and, as on gasoline, the engine will develop from 40 to 60 per cent. of its former power.

B. C. WHITE.

Yonkers, N. Y.

Uniform Size for Catalogs

I should like to call the attention of manufacturers and dealers to the desirability of uniform-sized catalogs. The writer, like many others, likes to file by subject, and catalogs are very awkward to handle as they are now issued. One large heating concern issues a number of publications, and no two of them that I have seen are of the same size.

This looks like a small matter, but filing catalogs for reference would be much more conveniently done if the advertisers saw the matter as it appears to the user of the catalogs.

LEWIS F. BROWN.

Winston-Salem, N. C.

The Storage Battery and Its Limitations

The storage battery as a power-plant auxiliary is looked upon by some engineers as objectionable, because of the constant and skillful care required. The writer believes, however, that there is no electric apparatus that responds so readily to good care as the storage battery, and it can be watched easily by means of a hydrometer and voltmeter, as well as by the gassing during overcharge. Where a battery set is properly installed in a clean and well-ventilated place, heated in the winter to approximately 70 deg. F., and is properly cared for and worked in accordance with its capacity, it will repay the owners in more ways than one.

The present lead sulphuric-acid battery appears to reach its all-around maximum usefulness on the 220-volt system, or less. Most batteries in power stations are installed for emergency or standby service and depend mostly on ampere-hour capacity for maximum usefulness. To increase the voltage above 220 means increasing the number of cells, and proportionately increasing the cost to keep the ampere-hour capacity the same. Consider a 220-volt and a 550-volt railway system and a proposed 2000-ampere-hour battery. The initial cost of the former will be less than half that of the latter, which also holds true as to maintenance. In order to keep down the initial cost of the 550-volt railway battery, the ampere-hour capacity is often sacrificed, leaving a train of troubles behind that are not easily remedied, especially with increasing load. In cases where it is possible to shut down a few hours each night, a storage battery for lighting purposes and light loads can be made to pay for the investment by keeping the load factor higher on the generating set, with a saving in coal and oil and a chance for small repairs during shut-down periods.

BEN DAWSON.

Cedar Rapids, Iowa.

Broken Corliss Exhaust Valve

On our 42x60-in. Allis blowing engine, from some unknown cause the bottom exhaust valve broke at the eye where the stem fits in. We had no spare valves, and to avoid a loss of several hundred dollars a day, a rapid repair was necessary. The broken piece was clamped back

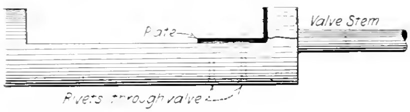


FIG. 1. EXHAUST VALVE REPAIRED

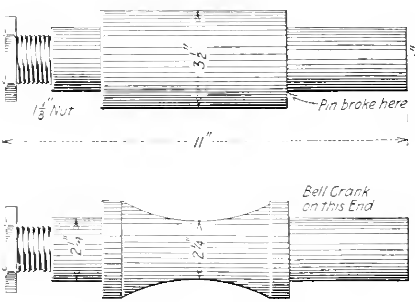

FIG. 2. DASHPOT PIN, SIZE REDUCED

in place temporarily, a plate was bent into the shape shown, and drilled and riveted to the valve. The stem was then put in and holes were drilled through stem and valve and countersunk. The parts were then riveted together and smoothed off to make a running fit, Fig. 1, and the engine was started five hours after the accident.

On a 96-in. low-pressure blowing engine with a Corliss valve gear a lot of trouble was caused by the breaking of the dashpot pins. Different kinds of material were used without success, the pins lasting from six weeks to three months only. A change was finally made, as shown in the illustration, Fig. 2. Instead of making the pin straight across, some of the metal was turned out, which made it much lighter and gave it a chance to spring a little. After this change, the pins lasted from six to twelve months.

Facing up Rubber Pump Valves

When pump valves become worn they have to be faced up or replaced with new ones. The usual way of facing by hand, using sandpaper on a block of wood having a true face, requires considerable work, time and sandpaper.

The pump I have in mind has 24 valves costing $1 each, so they cannot be thrown away when they begin to leak. The rig I use for facing the valves is made from a square block of wood held in the lathe chuck and turned down to the size of the disk, and the extreme end to the size of the hole in the center of the valve to act as a guide. Four brads, driven in and pointed so as to sink into the back of the valve, hold it from turning while facing. In this way old valves are made serviceable for a long time.

A Pipe Stopper

An arrangement used by plumbers for the same purpose as that described in the issue of May 25, on page 724, is made in the following way. It consists of a ¾-in. pipe with a long thread on one end, over which is screwed an iron washer about one inch smaller than the inside diameter of the pipe to be plugged. Next to this washer a cup leather is placed, then a smaller washer, and a ¾ locknut.

The outer end of the pipe is connected to the water service. When the stopper is inserted into the pipe beyond the riser and the water is turned on, the pressure will open out the cup leather and prevent any water passing it. A set of leather and iron washers for each size of waste pipe will make it possible to clear almost any line about the place.

Removing Dents from Tanks, etc.

Frequently, tanks, pipes and floats of metal become dented, which is objectionable in one way or another, and the dent cannot be got at from the inside. There are two ways of getting rid of the dents; one is by heating and the other is by hammering externally. The former method is preferable for very thick tanks. The heat should be applied around the depression so that the metal on the borders will be heated and expanded, and then at suitable intervals the dented portion should be cooled. This will keep contracting and drawing the dented part back into place. An easier method for thinner articles consists of tapping around the edges of the dent with a light hammer, which will bring the dent out. Neither process is quick, but both are effective.

Inquiries of General Interest

Butt Joint with Single Cover Plate—For a boiler shell, what advantage over a lap joint has a butt joint with a cover plate on only one side?

T. H. R.

With a single cover plate, the cover behaves simply as an intermediate plate attached to the two main pieces by an ordinary lap joint, and unless the cover plate is of sufficient thickness to prevent its bending, a butt joint has no advantage over a lap joint.

Air-Supply for Ventilation of Assembly Rooms—What quantity of air-supply is regarded as adequate for good ventilation of assembly rooms?

R. G.

The requisite air-supply by ventilating apparatus will depend largely upon the character of building construction and the period for which the rooms are occupied. For ordinary conditions the average quantities recommended by authorities as a minimum quantity of outdoor air which should be supplied per room occupant per hour may be stated as follows:

For theaters, 1200 cu.ft.

For factories, workrooms, courtrooms and auditoriums, 1500 cu.ft.

For school and college rooms, 1800 cu.ft.

Reversing Eccentric with Same Angle of Advance—If the eccentric of an engine with direct-connected valve gear is set so that it has an angular advance of 28 deg. and it is desired to change the direction of rotation of the engine, how far and in what direction should the eccentric be moved to obtain the same angle of advance with the engine reversed?

J. B.

Angular advance of 28 deg. signifies that the eccentric is $90 + 28 = 118$ deg. ahead of the crank, and for opposite direction of rotation with the same angle of advance, the eccentric should be turned back 118 deg. on the other side of the crank; or, what would be the same thing, the eccentric might be turned $360 - (2 \times 118) = 124$ deg. forward in the first direction of rotation of the shaft.

Chimney Crack From Expansion of Lining—What causes a crack to form all around a brick chimney at about three-fourths of its height? The crack developed after the chimney had been in use only a short time and reappeared after it had been repointed.

A. H. W.

In construction, the core or lining has undoubtedly been incorporated with the outer walls at a point above the crack, and from expansion of the lining from heat the upper portion of the shell has been raised from the lower portion. By driving steel wedges in the crack at a time when the lining is at highest temperature the core, upon cooling, may separate itself from the shell and cause no further trouble after repointing the outside. The surest remedy would be to remove the upper portion of the stack down to a point where the lining can be stopped off and rebuild the exterior in such a manner that it will not be affected by the expansion of the lining.

Properties of Nickel Steel—How is nickel steel made, and how does its strength compare with that of simple steel?

C. S.

Nickel steel is made by adding metallic nickel, nickel ore or ferro-nickel to the bath of the openhearth process. The finished product usually contains 3 to 4 per cent. nickel, about 0.3 per cent. carbon, 0.7 per cent. manganese and 0.02 per cent. phosphorus. The presence of nickel decreases the corrosiveness and increases the density and strength of the steel. On account of its high elastic limit and toughness, nickel steel is well adapted to resistance of sudden stresses and shocks. As compared with simple steels of the same tensile strength, a 3-per cent. nickel steel has about 15 per cent. higher elastic limit and about 25 per cent. greater elongation, and as compared with simple steels of the same carbon, the nickel steel up to 5 per cent. nickel has about 40 per cent. greater tensile strength with practically the same elongation and reduction of area.

Quality of Steam by Separating Calorimeter—In using a separating calorimeter the graduated glass gage on the instrument showed that the calorimeter in a given time had collected 0.15 lb. of water, and during the same time there was 2 lb. 14 oz. of condensate of the dry steam added to the condensing water. What was the quality of the steam?

W. C. H.

Where W represents the weight of water that the calorimeter separated from the steam, and W_1 represents the weight of dry steam condensed after separation, then the total weight would be $W + W_1$ and the quality q, or dryness, would be represented by the formula,

$$q = \frac{W_1}{W + W_1}$$

As $W_1 = 2$ lb. 14 oz. $= 2\,^{14}/_{16}$, or 2.875 lb., and W = 0.15 lb., then by substitution,

$$q = \frac{2.875}{0.15 + 2.875} = 0.954, \text{ or about 95 per cent.}$$

Size of Pump—With 50 ft. of piston speed per minute, what diameter would be required for the piston of a pump to supply 140 gal. of water per min., allowing 7 per cent. reduction of displacement by slippage and piston rod?

C. W. O.

Allowing 231 cu.in. per gal. and for the reduction of capacity by slippage and piston rod, the required gross displacement would be

$$\frac{140 \times 100}{100 - 7} \times 231 = 34{,}774+ \text{ cu.in. per minute,}$$

which for a piston speed of 50 ft. per min. would require a piston having

$$\frac{34{,}774}{50 \times 12} = 57.95 \text{ sq.in. of area}$$

which corresponds to

$$\sqrt{\frac{57.95}{0.7854}} = 8.59,$$

or about 8½ in. diameter.

Starting Torques of Motors—How do the starting torques of series- and shunt-wound direct-current motors compare with those of squirrel-cage and wound-rotor types of alternating-current motors?

C. H. R.

The starting torque of a series motor may be several times the full-load torque, the torque increasing much more rapidly than the current or nearly as the square of the current, until magnetization approaches saturation, when it varies more nearly as the current, the maximum torque being at the minimum speed. In a shunt-wound motor the starting torque varies directly as the current and may be 2 to 2¼ times the full-load torque. In a squirrel-cage motor full-load torque requires several times the full-load current, hence this type of motor is not adapted for use where a heavy starting torque is required. A wound-rotor type induction motor will start under full-load torque with little more than full-load current, and with a high-resistance rotor the starting torque can be increased beyond the full-load torque.

Air Required for Combustion of Gas—What number of cubic feet of air is theoretically required for the combustion of a cubic foot of gas consisting of 75 per cent. CH_4, 20 per cent. C_2H_6 and 5 per cent. C_3H_8?

N. C. I.

In formation of the products CO_2 and H_2O the volumes of O_2 from the atmosphere will be required in the proportions of

$$CH_4 + 2\,(O_2) = CO_2 + 2\,H_2O,$$

0.75 of a cubic foot requiring $2 \times 0.75 = 1.5$ cu.ft. of O_2;

$$2\,C_2H_6 + 7\,(O_2) = 4\,CO_2 + 6\,H_2O,$$

0.20 of a cu.ft. requiring $^7/_2 \times 0.20 = 0.7$ cu.ft. of O_2; and

$$C_3H_8 + 5\,(O_2) = 3\,CO_2 + 4\,H_2O,$$

0.05 of a cu.ft. requiring $5 \times 0.05 = 0.25$ cu.ft. of O_2. That is, combustion of 1 cu.ft. of the mixture requires

$$1.5 + 0.7 + 0.25 = 2.45 \text{ cu.ft. of } O_2.$$

As oxygen contained in air constitutes 20.92 per cent. of its volume, then as 4.78 cu.ft. of air will be required to furnish 1 cu.ft. of oxygen, the 2.45 cu.ft. of oxygen needed for combustion of 1 cu.ft. of gas will require $4.78 \times 2.45 = 11.71$ cu.ft. of air.

Distribution of Heat in Gas-Engine Cylinder*

By A. H. Gibson and W. J. Walker

An experimental gas engine recently installed in the engineering laboratories at University College, Dundee, appeared to afford exceptional facilities for an investigation into the cylinder losses. This engine, built by the National Gas Engine Co., Ltd., has a cylinder diameter of 11 in. and a stroke of 19 in., and the connecting-rod may be lengthened so as to vary the compression ratio between the limits 5.17 and 6.62. Governing is on the hit-and-miss principle. A special feature is the arrangement of the cylinder jacket in two parts—one surrounding the exhaust valve and that portion of the exhaust passage included within the cylinder casting, and the other covering the breech end and barrel of the cylinder. The jacket water is led in series through the two sections, its temperature being measured before and after passing through each. The heat attributed to jacket losses in a gas engine having the usual arrangement of jackets includes a certain amount which, correctively, should be attributed to exhaust losses. In the engine under consideration the magnitude of these two sources of loss can be ascertained with much greater accuracy.

In order to measure the heat contained in the exhaust gases after leaving the cylinder, an exhaust cooler was fitted to the exhaust branch. In this cooler the temperature of the gases was reduced by their passage over a series of 33 tubes, each ⅝ in. outside diameter and 4 in. long. The jacket water passed through these tubes on its way to the cylinder jackets, and its temperature was measured before and after passing through the cooler.

The trials were carried out with a view to determine how the distribution of heat through the engine varies with the speed of the engine, the brake horsepower, the compression ratio and the richness of the mixture.

The normal speed of the engine is 200 r.p.m., but in the trials a range of speeds from 140 to 260 r.p.m. was examined. The maximum brake horsepower depends on the speed and mixture, its values being approximately as follows:

Air Ratio—(Vols.) Gas	Speed, R.p.m.		
	150	200	250
7	25.0	31.5	36.0
9	20.0	25.0	28.5
11	16.5	20.5	23.5

In the trials the brake horsepower was varied from zero up to this full-load capacity. Three different compression ratios were adopted—5.17, 5.70 and 6.62—and three different air-gas mixtures were used—7 : 1, 9 : 1 and 11 : 1. In individual trials of the same series the richness of the mixture varied by not more than 5 per cent. on each side of the mean, and in the majority of cases the variation did not exceed 2 per cent. either side.

Town gas was used, having an average analysis of: CO_2, 3.8 per cent.; O_2, 1.1 per cent.; CO, 13.0 per cent.; CH_4, 26.3 per cent.; C_2H_4, 4.7 per cent.; H, 38.0 per cent.; N, 13.1 per cent. The gas supply was measured by a dry meter, and its mean lower calorific value, which was used in all calculations, was 520 B.t.u. per cu.ft The air-supply was also metered.

Systematic analyses of the exhaust gases were carried out, mainly with a view to insuring that combustion was complete before the end of expansion. In no case was more than a trace of combustible found in the gas, and in the majority of cases no trace was found.

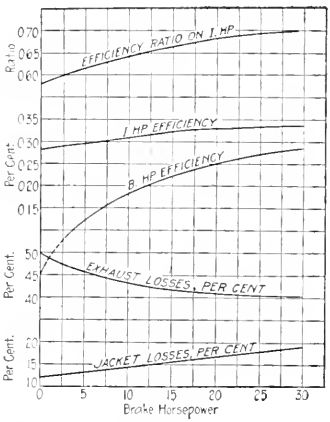

Fig. 1. Performance with a 5:17 Compression Ratio; Air: Gas = 9:1, and 200 R.p.m.

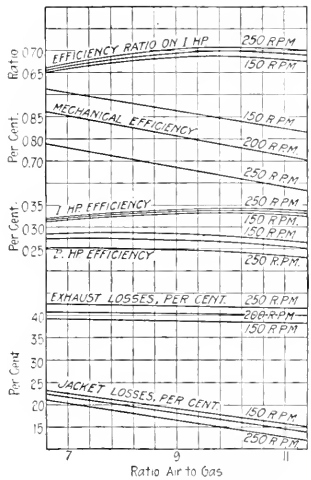

Fig. 2. Full Load with a Compression Ratio of 5:17

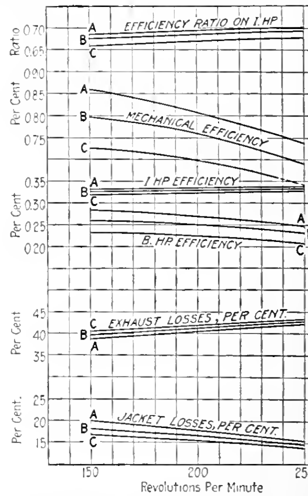

Fig. 3. Compression Ratio = 5:17; Air: Gas = 9:1. Curve A at Full Load Curve, B at .8 Load, Curve C at .6 Load

Of the total heat in the exhaust gases leaving the cylinder, part was absorbed by the water in the exhaust-valve jacket and part in the exhaust-gas cooler. The latter was not sufficiently large to cool down the gases to atmospheric temperature, and their temperature on leaving the cooler was between 200 and 300 deg. F. The heat carried away by these gases was estimated from a knowledge of their weight, specific heat and temperature.

From the data obtained, a series of curves was plotted, and by interpolation from these curves the more important data corresponding to speeds of 150, 200 and 250 r.p.m. and to brake horsepowers of 10, 15, 20, 25 and 30 were deduced for each gas mixture and for each compression. The main results of the investigation may be summarized as follows:

The mechanical efficiency increases with increasing load, diminishes as the ratio of air to gas increases (Fig. 2), diminishes as the speed increases (Fig. 3) and is sensibly independent of the compression ratio (Fig. 4). The maximum efficiency attained in these trials, namely, at full load with the richest (7 : 1) mixture and at the lowest speed (150 r.p.m.), was 88 per cent. At the normal speed of 200 r.p.m. and with the same mixture, the efficiency was 85 per cent., while with this same speed and the weakest (11:1) mixture, it fell to 76.7 per cent.

*From a paper read before the Institution of Mechanical Engineers, May 14, 1915.

The thermal efficiency, as measured on the indicated horsepower, increases with the load (Fig. 1), attains a maximum with an air-gas mixture of approximately 10 : 1 (Fig. 2), increases slightly as the speed increases (Fig. 3), and increases as the compression ratio increases (Fig. 4). The maximum thermal efficiencies attained were as follows:

Compression ratio		5.17	5.70	6.62
		Efficiencies		
Speed	150	33.1	34.4	36.5
	200	33.9	35.3	37.4
	250	34.4	35.8	37.9

As measured on the brake horsepower, the thermal efficiency increases with the load (Fig. 1); attains a maximum with an air-gas ratio of 8 : 1, that is, with a richer mixture than gives maximum indicated efficiency (Fig. 2); diminishes as the speed increases (Fig. 3), and increases with the compression ratio (Fig. 4). The maximum efficiencies based on the brake horsepower were:

Compression ratio		5.17	5.70	6.62
		Efficiencies		
Speed	150	27.9	29.1	31.0
	200	27.5	28.6	30.2
	250	25.7	26.7	28.3

Adopting the air cycle as the standard of comparison, the ideal efficiencies corresponding to the various compression ratios were:

Compression ratio	5.17	5.70	6.62
Air cycle efficiency	0.482	0.501	0.532

The ratio of the actual thermal efficiency, measured on the indicated horsepower to the corresponding air-cycle efficiency, increases with the load (Fig. 1), has a maximum value when the ratio of air to gas is approximately 10 : 1 (Fig. 2), increases slightly with the speed (Fig. 3), and is sensibly independent of the compression ratio (Fig. 4). At full load and with the most efficient air-gas mixture, the relative efficiencies were, for all compressions:

Revolutions	150	200	250
Efficiency ratio	0.687	0.700	0.709

The exhaust losses, in per cent., diminish as the load increases (Fig. 1), diminish very slightly as the ratio of air to gas increases (Fig. 2), increase as the speed increases (Fig. 3), and diminish as the compression ratio increases (Fig. 4). At full load the exhaust losses in these trials were between 33.6 and 42.5 per cent. The former value corresponds to a weak mixture, high compression and low speed, and the latter to a rich mixture, low compression ratio and high speed.

The percentage of heat carried away by the water flowing through the cylinder jackets, not including the exhaust-valve jacket, increases with the load (Fig. 1), diminishes as the ratio of air to gas increases (Fig. 2), diminishes as the speed increases (Fig. 3), and is sensibly independent of the compression ratio (Fig. 4).

Since at 150 r.p.m. the period of contact per cycle, of hot gases and cylinder walls, is 1.66 times as great as at 250 r.p.m., the rate of heat transmission through the cooling surfaces is evidently much greater at the highest speed. An examination of the indicator diagrams, moreover, shows that the maximum pressure and temperature attained in the cylinder are approximately 6 per cent. greater at 150 than at 250 r.p.m., so that this increased rate of transmission is obtained in spite of a lower gas temperature. The reason is apparently to be found in the fact that the greater turbulence of the working fluid at the higher rates of speed increases its effective conductivity to an extent which more than counterbalances the effects of a smaller temperature difference and a shortened time of contact. Other things being equal, a 6-per cent. increase in the temperature of the gases would probably increase the heat transmitted by conduction and radiation by some 15 per cent., so that it may be taken approximately that the effective conductivity is increased in the same ratio as the speed of the engine.

The radiation loss diminishes as the load increases, increases as the ratio of air to gas increases, diminishes as the speed increases, and increases slightly as the compression ratio increases. At full load, radiation accounts for between 5 and 14 per cent. of the heat given to the engine, the former value obtaining with a rich mixture, high speed and low compression ratio and the latter with a weak mixture, low speed and high compression ratio.

DISTRIBUTION OF HEAT UP TO END OF EXPANSION STROKE

Since part of the heat carried away by the jacket water passes into the cylinder walls after release, this should, in a true heat balance, be credited to the exhaust. The item attributed to radiation represents heat lost by radiation from the hot exposed surfaces of the piston and of the unjacketed portion of the breech, and from the outer surface of the jackets. Although this loss is wholly due to heat flow through the walls, only part of this flow takes place during the expansion stroke. The remainder, occurring after the end of this stroke, is also to be attributed to the exhaust.

Thus in a heat balance drawn for the working fluid up to the end of expansion, the apparent heat flow into the walls is to be increased by the greater part of this radiation loss and to be diminished by that part of the heat transmitted to the jacket water during exhaust. Similarly, the apparent exhaust losses are to be increased by some small part of the radiation loss and by that part of the heat given to the jacket water during exhaust. The net result is that both the wall losses and the exhaust losses, as given by direct measurement, are to be increased by some unknown proportion of the radiation loss.

The results indicate, in general, that of the total radiation loss obtained by difference from the heat measurements a proportion ranging from about 0.33 to 0.40 is to be added to the apparent exhaust losses, the remainder going to increase the

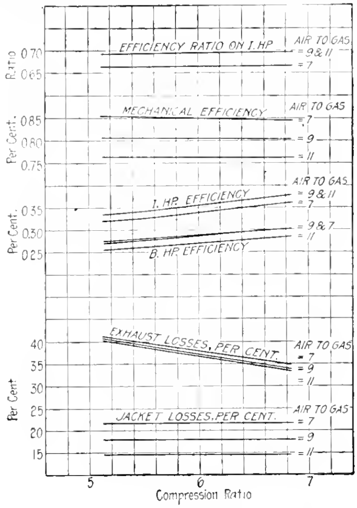

FIG. 4. FULL LOAD AT 200 R.P.M.

apparent jacket or wall losses. This proportion reaches its highest value with the highest compression ratios and with the richest mixtures.

A comparison of these with results obtained in a similar manner by Hopkinson on a slightly larger engine, shows a fairly close agreement. In round numbers the figures are as follows:

	Air/Gas = 10.8		Air/Gas = 8.1	
	Hopkinson	Authors	Hopkinson	Authors
Heat as i.hp.	37	36	33	35
Heat in exhaust	42	41	39	39
Heat flow to walls	21	23	28	26

The heat entering the exhaust-valve jacket ranges from 8 to 12.5 per cent., being the greatest at low loads, low speeds and with low compression ratios and rich mixtures. If this be added to the cylinder-jacket loss, it gives the loss as determined from trials of an engine fitted with the usual arrangement of jackets.

Under favorable circumstances it appears that a heat balance sheet obtained by measuring the indicated work and jacket heat of a commercial type of engine, and by estimating exhaust losses by difference, is in extremely close agreement with the balance sheet based on the internal energy of the gas at the end of expansion. For fairly rich mixtures and lower compression ratios the measured jacket losses are, however, always in excess of those more correctly computed from the internal energy of the gas.

Hydrogen Was Discovered or isolated in 1766 by Cavendish, an eccentric English chemist, who called it "inflammable air," but the French chemist, Lavoisier, named it hydrogen, meaning "water former." Nitrogen was also identified as a constituent of air at about the same date as oxygen and hydrogen (1766 to 1774) and named nitrogen by Chaptal, because of its existence in niter.

Illinois N. A. S. E. State Convention

The eleventh annual meeting of the Illinois State Association, N. A. S. E., held in Decatur, May 26-28, proved to be one of the best in the history of the organization. Business was attended to promptly by the engineers, exhibits were good, and the entertainment was lively from beginning to end. Good fellowship prevailed and the close coöperation between the engineers and the exhibitors contributed largely to the success of the convention. The first session opened promptly Wednesday morning at the St. Nicholas Hotel, with W. H. Jennings chairman of the local committee, presiding. After the opening prayer by Rev. C. E. Jenney, Mayor Dan Dinneen made an address of welcome, to which Fred W. Raven, national secretary, responded.

Dr. G. E. Fellows, president of Millikin University, of Decatur, in an interesting address on education, referred briefly to the educational work of the organization, and then turned to the broader aspect of his subject and showed how education was correlated with the advancement made by the human race. Up to 150 years ago the people thought that they needed a king to do their thinking for them and tell them what they must do. France was the first country to give the people the opportunity to rule themselves and to allow them freedom of thought and action. Most of the advancement made has been since that time. The greatest thing that ever happened to this country was the act signed by Abraham Lincoln setting aside grants of lands in the various states, which made possible the state universities and provided higher education for the people at large. For the past thirty years serious attention has been given to industrial education, and during this time more progress has been made than in all the previous years. It is evident, then, that progress and advancement are largely dependent on education.

In his response, John Lane, editor of the "National Engineer," contended that it was a general mistake to confound education with teaching. Schools teach men, but they must educate themselves. If they cannot retain or apply what they have learned, then the teaching is useless. The man who can apply what he does know to the best advantage, whether learned in college or in practice, will make the most progress and be of the most use to the community.

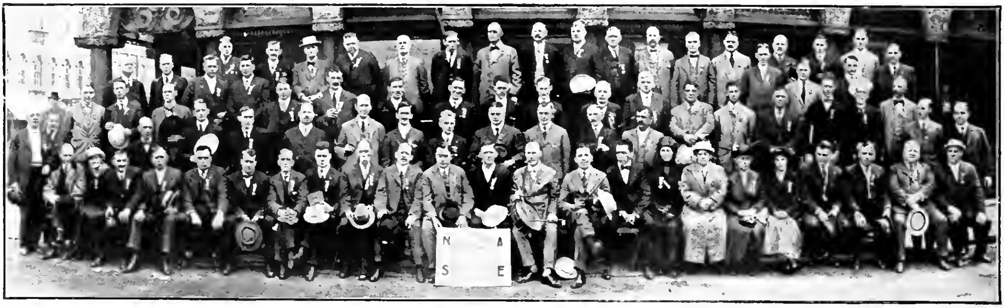
After a brief talk by Charles Cullen, president of the Central States Exhibitor's Association, W. E. Hill, state president, was formally introduced and the meeting was officially opened. The usual committees were appointed and the session adjourned.

The afternoon was spent in a trip to the Wabash locomotive shops. A large number of engines were being overhauled, and the work proved to be of exceptional interest. For the benefit of the visitors a locomotive weighing 78 tons was raised from the floor, moved a distance of 50 ft. and lowered upon the wheels placed for it, in five minutes. The placing of the engine was so accurate that it was not necessary to move it to the right or the left as it was lowered in position.

In the evening State Deputy Henry Misostow delivered an address at a special meeting of exhibitors and engineers. His topic was "Efficiency," of which there were two kinds, one sensible and the other commercial. The former created more for the same expenditure of energy. Employees were treated as men and encouraged to use their brains in performing their duties. In the other system men were made into machines and their efficiency based on the amount of their work. There should be no distinct demarcation between engineers. Any engineer can be as good as any other provided he puts as much energy into his work and puts forth the same amount of effort to become efficient. Many men look at the man above them admiringly and think, "He is better than I." This admission should never be made until the same effort has been exerted to become efficient. At the close of the address Messrs. Hickey, Tilley, Thompson, Fiske, and the famous quartet gave an excellent and thoroughly enjoyable performance.

At the business session Thursday morning there were 32 accredited delegates from 13 associations out of 17 belonging to the state organization. In his report President Hill stated that two new locals had been added in the past year and one of these had joined the state association. The president spoke highly of the work of the educational committee. Secretary Anderson reported a net gain of 43 members, which was a little over 3 per cent. of the total number affiliated with the state body. John S. Alt, chairman of the legislative committee, reported that license and inspection laws similar to those in force in Massachusetts and Ohio had been presented to the state legislature, and by compromising on the boiler pressure and the square feet of radiation requiring a licensed engineer, it was thought that the chances were excellent for the bill to pass at the present sitting of the legislature. The compromises thought necessary were to raise the boiler pressure from 10 to 20 lb. and to increase the radiation from 5000 to 20,000 sq.ft.

In the afternoon the engineers were taken through the Decatur High School and shown the annual exhibit of the pupils. In the auditorium of the school they listened to an interesting lecture by Prof. G. E. Goodenough, of the University of Illinois, on the development of the steam tables and on the properties of saturated and superheated steam. The professor gave briefly the leading events in the development of the steam tables, reviewing the work of Regnault, Callendar, Knoblauch and Linde, Davis, Peake and Grindley and other authorities who had contributed to the work. By means of charts he compared the results obtained by these various experimenters and calculators. He commented on the accuracy of their work and in curve form presented the results obtained from a formula he had developed after a careful consideration of all the data that had been previously given on the subject.



DELEGATES AT ILLINOIS N. A. S. E. STATE CONVENTION

In the evening delegates and visitors were entertained at the exhibitors' hall, with a theater party sandwiched in between. The ball game scheduled between the engineers and supplymen for Friday morning was called off on account of rain. At the last session on Friday afternoon, Henry Mistele, of Milwaukee, one of the national trustees, talked on the good of the order, referring particularly to education and the most effective medium for education the association possessed—"The National Engineer." He asked the engineers to support their paper and spoke of the value of the advertising section. Peoria was chosen as the next convention city, and the following officers were elected: Henry Misostow, state president; Charles Scott, vice-president; G. R. Anderson, secretary-treasurer; W. E. Hill, state deputy. "Dad" Beckerleg installed the officers, and the convention adjourned for another year.

The exhibits were up to the usual standard, the following firms being represented: The V. D. Anderson Co., Crandall Packing Co., Dearborn Chemical Co., Edward Valve & Manufacturing Co., Greene, Tweed & Co., Hawk-Eye Compound Co., Garlock Packing Co., Home Rubber Co., Jenkins Bros., H. W. Johns-Manville Co., Keystone Lubricating Co., Lunkenheimer Co., "National Engineer," Peerless Rubber & Manufacturing Co., Wm. Powell Co., "Power," Madison-Kipp Lubricator Co., H. Mueller Manufacturing Co., National Boiler Specialties Co., Perolin Co. of America, The Screiber Perfect Boiler Skimmer & Cleaner Manufacturing Co., Standard Oil Co.

Mechanical Stokers for Locomotives

Before the seventh annual convention of the International Railway Fuel Association, held in Chicago, May 17-20, the committee on firing practice, D. C. Buell, chairman, presented an interesting report on mechanical stokers as applied to locomotives. A brief summary follows:

The original conception of a mechanical stoker for locomotives contemplated the adoption of the stoker on a fuel-economy basis. The claims were based on the fact that the stoker supplied coal to the fire uniformly and according to the single-scoop method; that it overcame the necessity of opening the fire-door and the consequent cooling effect in the firebox and that it avoided the production of black smoke. The introduction of larger and heavier power, together with the desire to work this power to maximum capacity on low-grade lines where continuous firing is necessary, has brought about a new problem. The amount of coal necessary to burn per hour to keep these locomotives working at full capacity is such that there has been a demand for two firemen on all locomotives weighing over 185,000 lb. on the drivers.

The real economy of the stoker is in the increased tonnage that can be handled by stoker-fired locomotives—not in the saving of fuel, as seems to be the general impression. The large, mechanically fired locomotives are able to handle more tonnage than the same locomotives would be given if hand-fired, and they handle this tonnage at a higher speed and with greater certainty than under hand-firing conditions. The development of the stoker has made possible the development of locomotives designed to burn coal continuously at a rate in excess of the capacity of the ordinary fireman to supply it, so that the real reason for the improvement and adoption of the mechanical stoker is found in the economic necessity of reduced operating costs. Other causes giving an incentive to stoker development are the possibility of increasing the capacity of locomotives already in service and the possibility of using cheaper fuel on such locomotives.

There are three companies now manufacturing locomotive stokers commercially; and in addition, the Pennsylvania Lines West of Pittsburgh have developed the Crawford stoker and applied it extensively to their own locomotives. According to the most reliable figures obtainable on Apr. 1, 1915, there are 935 locomotives equipped with stokers, which are distributed between twenty different lines of railroad.

There seems to be no fixed factor that can be used as a sure guide as to the size of the locomotive that would warrant the installation of a stoker. One report indicates that any locomotive of 200,000 lb. total engine weight, with cylinders of 22 in. or over should be equipped with a stoker. A second report states that engines having a tractive effort of 50,000 lb. or over, should be stoker-fired. It seems to be the consensus of opinion, however, that locomotives should be hand-fired when the coal consumption for an extended period does not exceed 4000 lb. per hr. It is the general belief that the stoker will give about 10 per cent. increased tonnage capacity as compared with hand-firing under the same conditions as to grade and time, although some reports indicate that the tonnage increase will be more. Stoker-fired engines will make better time with the same tonnage on the same grade than hand-fired engines, and there will be a saving on the basis of the amount of coal burned per thousand ton-miles. This is due to the fact that additional tonnage may be handled by stoker-fired engines with about the same gross amount of coal as with hand-fired engines.

The meat of the whole stoker problem is, that increased tonnage can be handled. If increased capacity of locomotives is desired, then stokers are economical. If maximum evaporation is what is required on large engines, its attainment may result in a sacrifice of tonnage capacity. A number of other advantages were given, such as reduction of smoke and spark loss. The first cost of the stoker installation is between $1500 and $1700. Maintenance cost including interest on the original investment, is anywhere from ½ to 1c. per mile. This item is more than counterbalanced if a cheap grade of fuel is used with the stoker.

Briefly summarized, the results of the use of locomotive stokers are as follows: The stoker is over 90 per cent. efficient. A six months' record of the use of stokers on the Norfolk & Western R.R. shows an efficiency of 97½ per cent. Roads having a considerable number of stokers in service show a performance of over 50,000 miles per engine failure on stoker-fired locomotives. It seems conservative to state that the stoker will show a satisfactory fuel economy based on ton-mile performance; that is, while it may not show a reduction in the gross amount of coal consumed per trip, it will show that it can haul more tonnage, using about the same gross quantity of the same or a cheaper grade of fuel, than a hand-fired engine. From the coal producer's standpoint, the increased demand for slack coal and screenings for stoker-fired engines will be of benefit. The stoker obviates the necessity for two firemen on large engines. No complications are introduced in the way of detention at terminals, engine failures on the road, or in connection with the smoke-elimination problem. To sum up, the stoker, even in its present state of development, pays in every case where real stoker jobs are indicated.

Looking into the future, the development of the stoker makes possible and practical the design of larger locomotives. In fact, engines have been purchased within the last two years and are being built today which would neither have been purchased nor built had it been necessary to have them hand-fired. Particular reference is made here to the large decapod, mallet and triplex engines. So far, manufacturers have been compelled to adapt their stokers to existing locomotives. It is safe to say that in the future the design of large locomotives will contemplate the application of a stoker, and the design will be modified as may appear necessary to insure convenient, economical and successful application of correspondingly modified and improved stokers.

Central-Station Conditions

The general conditions of the central-station industry are reviewed by T. C. Martin, in his annual report on progress to the National Electric Light Association. While the industry has suffered to some extent by the general business depression, and has not maintained the normal rate of increase, still the outlook is encouraging. Figures from 65 per cent. of the companies indicate that for the second half of 1914 there was an increase in earnings of at least 5 per cent. The combined operating revenue of the Brooklyn system, for example, showed a gain for 1914 of 10.5 per cent.; the gross earnings of the Providence system increased 9.25 per cent. over the preceding year, and new business showed a gain of 18.7 per cent. The Pacific Gas & Electric Co.'s gross earnings for 1914 were about a million dollars greater than in 1913, and the Detroit-Edison system showed a gain of 11.1 per cent. The gross earnings of the central-station industry as a whole in 1914 are estimated in excess of 375 million dollars. This is in addition to the lighting and power work done by street-railway systems.

The yearly peaks and load factors of the leading systems for 1914 were as follows:

System	Peak Load in Kw.	Date of Peak Load	Yearly Output in Kw.-Hr.	Yearly Load Factor Per Cent.
Niagara Falls Power Co.	131,520	Jan. 5	906,513,620	78.7
Ontario Power Co.	130,500	Sept. 23	781,664,400	68.4
New York Edison Co.	229,787	Dec. 23	719,193,535	35.7
Pacific Gas & Electric Co.	124,000	Oct. 29	658,298,000	60.6
Penn. Water & Power Co.	74,000	Dec. 17	277,200,000	42.5
Philadelphia Electric Co.	77,728	Dec. 1	250,697,952	36.8
Boston Edison Co.	65,342	Dec. 21	194,137,400	34
Brooklyn Edison Co.	49,300	Dec. 9	153,946,900	35.6
Commonwealth Edison Co.	306,200	Dec. 15	1,114,130,000	43.6

Apparently, the diversity of the loads along the Atlantic seaboard did not vary greatly, since the annual load factors of the Boston, New York, Brooklyn and Philadelphia companies are not far apart. The Pacific Gas & Electric Co., however, with its greater territory and greater diversity of load, shows a much higher load factor, as do also the Ontario Power Co. and the Niagara Falls Power Co.

OBITUARY

Samuel C. Midlam died on June 2 at the age of 83 in New York. He served in the navy during the Civil War, was chief engineer of the old United States Man-of-War "Otsego" when that vessel was sunk in Albermarle Sound, and also served on the old "Atlanta" and the gunboat "De Soto." After his retirement from the navy, nearly thirty years ago, he entered the service of the Hudson River Day Line. When he retired last year as chief engineer of the Day Line steamer "Albany," he was said to be the oldest engineer in the United States, in point of age as well as service.

Hydro-Electric Plants in New England are producing more than 2,000,000,000 kw.-hr. of energy, which, if produced by coal, would mean the annual consumption of 3,000,000 tons of that fuel, according to figures given by Henry I. Harriman, president of the Connecticut River Power Co., in an article in the "General Electric Review."

PERSONALS

E. A. Thompson has resigned as smoke inspector of the City of Baltimore and will take up consulting and efficiency engineering, with offices at the Hansa House, Charles and German Sts., Baltimore.

Myron J. Bigelow, formerly mechanical engineer with the Molyneux Mailing Machine Co., Buffalo, N. Y., has opened a consulting engineering office, with headquarters at 47 Hawthorne St., Akron, Ohio.

ENGINEERING AFFAIRS

The American Boiler Manufacturers' Association will hold its annual convention at the Lawrence Hotel, Erie, Penn., June 21-23. One of the most important matters to be considered is the means of securing the adoption of the A. S. M. E. Boiler Code by the several states. J. D. Farasey, East 37th St. and Erie R.R., Cleveland, Ohio, is secretary.

The National Association of Master Steam and Hot Water Fitters will hold its twenty-seventh annual convention June 21-24, at the Hotel Wisconsin, Milwaukee. An attractive program has been arranged, and the coöperation and active support of all members are requested to make this the most successful convention in the association's history.

The American Supply and Machinery Manufacturers' Association held its annual convention at the Bellevue-Stratford, in Philadelphia, June 3 and 4. A number of excellent addresses were made on topics vitally concerning the business of the members, notably an address on "The Power Problem," by C. M. Ripley, and an address on "Fundamental Business Conditions," by P. F. Bryant, of Wellesley Hills, Mass. The entertainment features included a vaudeville-smoker and a dinner-dance.

The New England Association of Commercial Engineers, 308 Equitable Building, Boston, Mass., has selected the new building now under construction at the corner of Oliver and Franklin St., and will use the basement and first two floors as an exhibit, while the upper floors will be used for a meeting room and lecture hall for the several engineering organizations and mechanical societies and for offices. It is thought that the whole building will be occupied by those interested in the machinery and power-equipment field. It is expected that the exhibit will be opened on Oct. 1 in the new building. Mr. Lewis L. Warren is manager of the exhibit.

The American Iron & Steel Institute held its eighth general meeting on May 28 at New York. The following papers were presented: "Blast Furnace Advancement," by Andrew E. Maccoun, superintendent, Edgar Thomson Blast Furnaces, Carnegie Steel Co., Braddock, Penn.; "Merchant Rolling Mills," by Jerome R. George, chief engineer, Morgan Construction Co., Worcester, Mass.: "The Commercial Production of Sound and Homogeneous Steel," by Edward F. Kenney, metallurgical engineer, Cambria Steel Co., Johnstown, Penn.; "Waste-Heat Boilers," by Charles J. Bacon, steam engineer, Illinois Steel Co., South Chicago, Ill.; and "Recent Progress in Corrosion Resistance," by Daniel M. Buck, metallurgical engineer, American Sheet & Tin Plate Co., Pittsburgh, Penn.

The National Association of Manufacturers held its annual meeting May 25 and 26 at New York. The sessions were devoted mainly to legal and economic questions. The convention adopted the report of the Committee on Fire Prevention, stating that full coöperation between state legislators, insurance companies and property owners, and the spending of more money by municipalities and legislatures for fire prevention were the best means for reducing the enormous waste of the nation's resources. The convention, through the Committee on Accident Prevention and Workmen's Compensation, held that mechanical safety devices can prevent but a small percentage of accidents, while the large majority must be prevented by education, organization and individual caution, with emphasis upon individual caution. The Industrial Betterment Committee rendered a preliminary report on the legislative minimum wage, concluding that such legislation was not wanted by employees or employers and had been unsatisfactory to both, and that undesirable industrial conditions could best be improved through practical education and by stricter legal supervision.

BUSINESS ITEMS

The Homestead Valve Manufacturing Co., Desk D, Pittsburgh, Penn., is conducting a prize name contest, offering $50 cash as a prize for a suitable name for a new gate valve.

E. W. Swartwout, formerly of the Chicago office of the Nordberg Manufacturing Co., Milwaukee, Wis., will hereafter be associated with Mr. McLaren, in the New York office of the company. Enlarged offices have recently been taken in the new Equitable Building, 120 Broadway, New York. The Chicago office will be in charge of John E. Lord.

James Beggs & Co., manufacturers of the Blackburn-Smith feed-water filter and grease extractor and the Beggs sewage ejector system, have opened offices in Saginaw, Mich., and Cleveland, Ohio. Their representatives at these points will give prompt attention to inquiries received from the State of Michigan and the northern part of the State of Ohio, respectively.

The "S-C" Regulator Co., Fostoria, Ohio, has established the following branch offices: Chicago, Ill., 1535 Lytton Building, in charge of L. K. Deckerson and E. H. Bolton; New Orleans, La., 315 Carondelet St., George Keller; Atlanta, Ga., 702 Candler Building, E. F. Scott; Charlotte, N. C., 1213 Realty Building, James E. Weinhold. In Birmingham, Ala., the company will be represented by the McClary-Jemison Machinery Co.

The Berwind-White Coal Mining Company, Windber, Penn., recently ordered twenty-six 2½-in. Simplex "Seatless" blow-off valves from the Yarnall Waring Co., Chestnut Hill, Philadelphia, Penn. The interesting feature of this order is that it makes the fifth repeat order as a result of a six-months' trial of two valves shipped Feb. 11, 1914. The Corrigan-McKinney Co., Cleveland, Ohio, has recently ordered 56 of these 2½-in. valves.

The Terry Steam Turbine Co., Hartford, Conn., has appointed Merton A. Pocock as district sales manager for the territory included in Minnesota, North Dakota and South Dakota. His office is 400 Endicott Building, St. Paul, and this arrangement supersedes the company's previous selling agreement with Robinson, Cary & Sands Co., of St. Paul. The company has also appointed the Hawkins-Hamilton Co., Peoples National Bank Building, Lynchburg, Va., as representatives for Virginia.

The Diesel-type engine manufactured by the McIntosh & Seymour Corporation, of Auburn, New York, will in future be sold in the Texas and Oklahoma territory through the agency of Arthur G. Wright, 209 Slaughter Building, Dallas, Texas. This appointment excludes that portion of Texas west of a line drawn north and south through Del Rio. Mr. Wright's extensive experience with the machinery business and particularly with all types of power plants, renders him a valuable consultant to those who are considering new installations, and his advice may be sought by all interested parties.

Among the orders recently received for Venturi meters by the Builders Iron Foundry, Providence, R. I., are the following: H. C. Frick Coke Co., Pittsburgh, Penn., three 4-in. meter tubes with Type M register-indicator-recorders; Union Bag & Paper Co., Woolworth Building, New York City, one 4-in. meter tube with Type M register-indicator-recorder; John B. Mallers, Chicago, Ill., one 3-in. meter tube with Type M register-indicator-recorder. All these meters are for boiler-feed service. The West India Management & Consultation Co., 129 Front St., New York City, has ordered for the Trinidad Sugar Co. two 2½-in. meter tubes and Type M register-indicator-recorders for the measurement of maceration water. The company has also received two orders for meter tubes for the measurement of air—one from the Combination Engine & Compressor Co., Bradford, Penn., for a 2-in. meter tube and manometer to be used in the testing of air compressors, and one from Purdue University, Lafayette, Ind., for a 4-in. meter tube.

Purposeful Anecdotes

A true plain story of the success of a plugger—to encourage those who think only the gifted or lucky win out.

° ° °

A Life Story

HERE is the condensed history of an engineer. With self-respect and a little determination, so he declares, anyone can do as well or better.

He was taken from school before he was 10 years old. For five years he worked at plumbing, but did not like it. Then he worked four years at steam and hot-water heating, attending night school during two of these years.

Next, he became an assistant engineer on a lake steamer. At this time he started to study engineering books and journals. At 21 years he secured a situation as an apprentice in a large factory.

Next, he was the engineer in a large modern hotel, after which he went with the Canadian General Electric Co. as trouble man in its Peterboro works. The Ontario Government offered him a situation as stationary engineer, and he accepted.

At present he holds a position with the Canadian Government as chief engineer in a large plant and has a staff of sixteen men. Incidentally, he has received altogether several hundred dollars in the past few years for contributions on engineering, etc., to technical papers. He describes himself as only an ordinary man, by no means smart or clever, but he is temperate and has never been afraid to do a little extra work with no extra pay.

He has been down-hearted more than once and even wrote to Power for advice some years ago and he received encouragement in reply. Power has this engineer's address.

Norfolk & Western Electrification

SYNOPSIS—Power for the electrified section of 30 miles is supplied by a 30,000-kw. steam plant at Bluestone Junction and five substations. Generation is at 11,000 volts three-phase, transmission at 44,000 volts single-phase and the trolley voltage 11,000 single-phase; step-down transformers and phase-converters on the locomotives transform the current for use in three-phase induction motors. Regenerative braking is employed.

The electrified section of the Norfolk & Western Ry., known as the Elkhorn grade, is located on the main line in the southern part of West Virginia and extends from Bluefield to Vivian, a distance of about 30 miles. This is a switching and short-haul division between the coal fields and Bluefield, operated to a large extent independently of the other traffic on the main division. In addition to the heavy-tonnage coal-train service, however, freight and passenger traffic over this section is also handled in part by electric locomotives, which are used as pushers on the steep grades. The purpose in electrifying this section was to increase the capacity by materially reducing the time required to handle traffic and to provide a more economical and efficient service over the heavy grades. The heavy freight trains are handled with electric locomotives at a running speed up the grades of 14 miles per hour, as compared with 7½ miles under steam operation. Further saving in time is effected by the elimination of the delays occasioned by the steam engines occupying the tracks while taking on coal and water at several places on the grades. Moreover, one electric engine takes the place of two Mallet steam locomotives over the division, or two electric engines take the place of three Mallets up the grades and at practically double the speed.

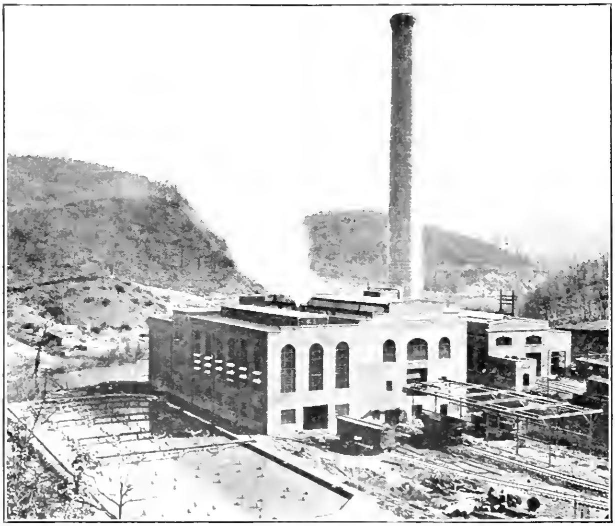

Fig. 1. Power-Plant Building and Spray Pond

The transmission and distribution system is single-phase at 25 cycles, and power is collected from the overhead catenary at 11,000 volts. The locomotives, however, are equipped with phase-converters which, in connection with step-down transformers, change the single-phase current of the trolley to three-phase for use in the three-phase induction-type traction motors. Thus, while retaining all the advantages of high-voltage, single-phase distribution and collection, the advantages of three-phase induction motors for the heavy traction service is also secured.

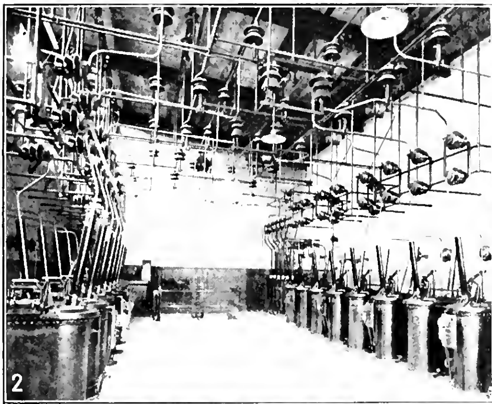
Another important feature of the employment of polyphase induction motors for traction is the electric braking of the trains at constant speed while descending grades. This not only utilizes the energy of the moving trains to drive the motors as generators and thus return energy to the line, but also permits the heaviest train to be handled down the mountain grades with a single engine at a uniform speed of about 15 miles per hour, while the air brakes are held in reserve for bringing the train to a stand-still when necessary.

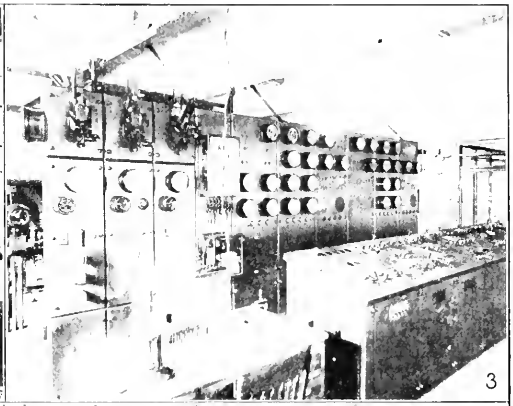
The Power Station

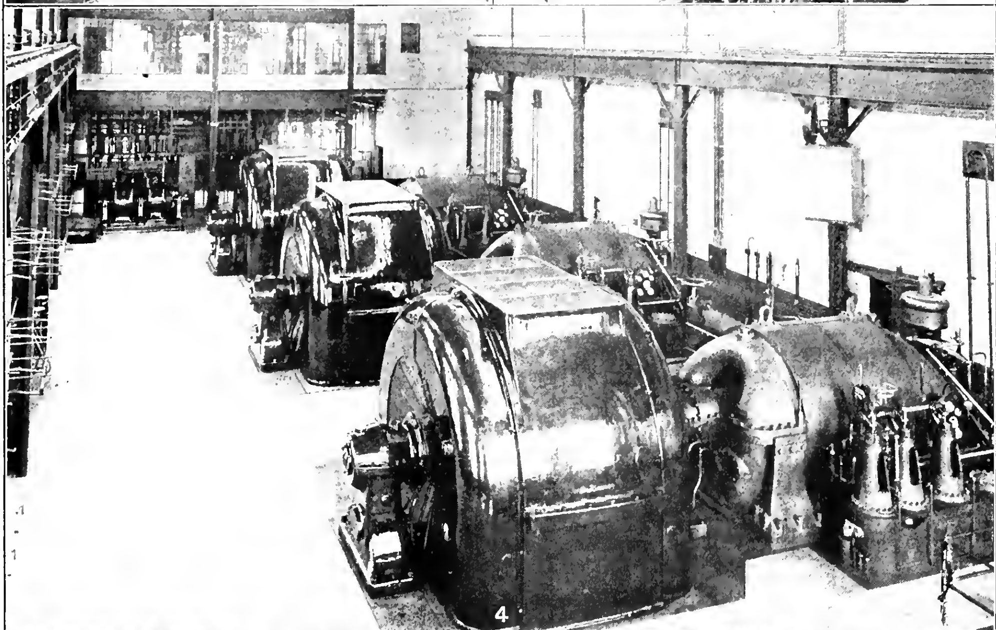
The power station was located at Bluestone, on the Bluestone River, mainly for the reason that this is practically the only available source of water for boiler feed and condensing purposes in the district, and the company had already constructed a dam and reservoir here for the water supply for the steam locomotives. The main building contains a boiler room 79x158½ ft., and a turbine room 56x158½ ft. Across the east end of the latter a section 26 ft. wide is assigned for the switching equipment, offices and other facilities and is fitted with intermediate floors and galleries. On the main floor is the low-tension switching room, separated from the turbine room by a heavy wire screen; the next floor is the operating gallery overlooking the turbine room. On the ground floor of the extension building are the step-up and step-down transformers, and on the second floor is located the high-tension switching apparatus.

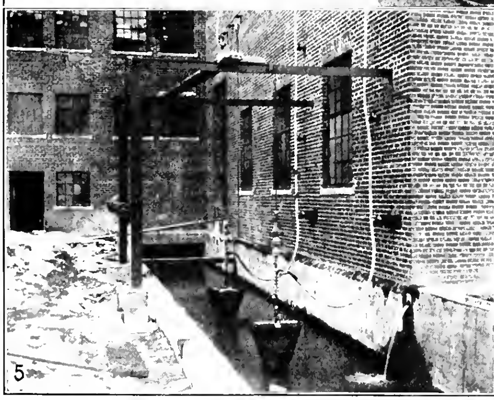
Coal and Ash Handling

Coal is received in hopper-bottom cars on a siding along the south side of the station, the cars discharging into a steel hopper under the track. Below the hopper is a single-roll crusher which empties into an inclined conveyor of the bucket type having a capacity of about 60 tons per hour, at a speed of 80 ft. per min. This elevates the coal to a hopper at the east end of the boiler-room monitor, and from this hopper the coal is fed to a horizontal distributing conveyor extending longitudinally









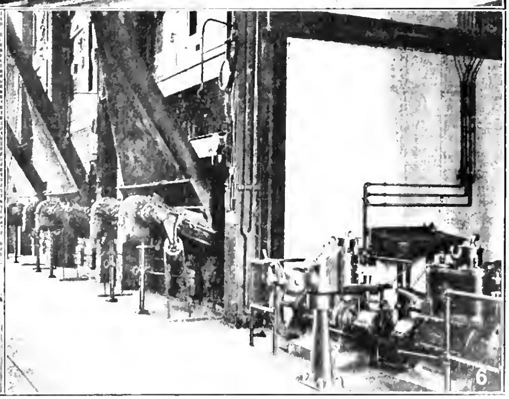


Fig. 2. High-Tension Switching Room. Fig. 3. Control Board. Fig. 4. Turbine Room. Fig. 5. Regenerated Power Loading Rheostats. Fig. 6. One Side of Boiler Room

over the boiler room. Coal is distributed by means of nine handwheel-operated gates to two storage bins having a capacity of about 350 tons. The coal-handling machinery is driven by alternating-current motors.

Ashes are discharged through the ashpit hoppers to steel platform cars each carrying two 1-cu.yd. buckets. These are run outside the boiler-room basement to a loading trolley, the buckets being lifted from the platform cars and emptied into gondolas by means of a traveling electric hoist. The hoist motors are 220-volt direct current.

Boilers and Stokers

The boiler plant comprises ten Stirling-type water-tube boilers arranged in two rows with an aisle between. Space is provided for four additional boilers. They are designed for a working pressure of 225 lb. gage and 150 deg. superheat. Each is fitted with an underfeed stoker of sufficient capacity to evaporate 61,000 lb. of water per hour into steam at 200 lb. gage and 150 deg. superheat when supplied with feed water at 200 deg. Each row of stokers is driven by two automatic steam engines, and the stokers are capable of developing 300 per cent. normal boiler rating when burning coal having a heat value of 12,250 B.t.u. Steam from the exhaust header is discharged into two horizontal Cochrane feed-water heaters, each capable of heating 225,000 lb. of water per hour from 40 to 225 deg. F.

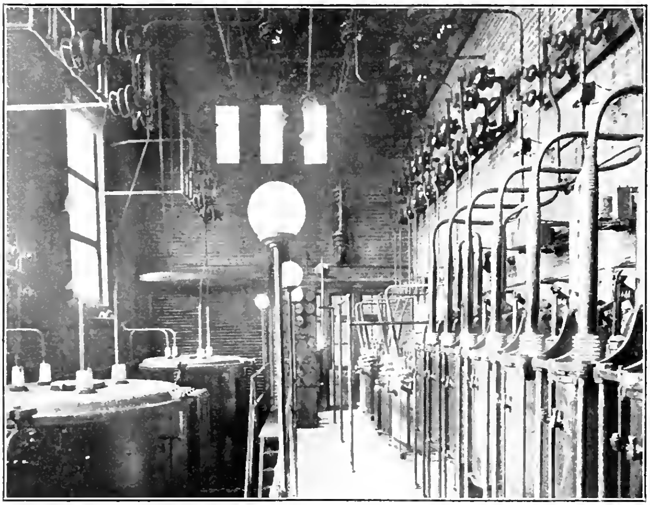

Fig. 7. Interior of Substation

The feed water is taken from the intake canal and pumped to the heaters by two low-head pumps of the horizontal volute single-stage double-suction type having a capacity of 650 gal. per min. against a head of 45 ft. These pumps are driven by 20-hp. steam turbines. From the heaters the water flows to the two boiler-feed pumps which are also of the horizontal volute three-stage double-suction type, designed to operate against a working head of 600 ft. These are driven by 175-hp. steam turbines.

The Stack Details

The stack is of the radial-brick type, 268 ft. in height, or 250 ft. above the grate, with a minimum inside diameter of 20 ft. A 4-in. brick lining extends 75 ft. from the bottom of the flue opening, with a 2-in. air space between the lining and the column.

The forced-draft installation in the boiler-room basement consists of three Sturtevant multivane fans, driven by steam turbines through 4 to 1 herringbone reduction gears. The rated capacity of each fan is 150,000 cu.ft. of free air per minute against a static pressure of 6 in. of water when running at 540 r.p.m.

Steam-Turbine Equipment

The initial equipment consists of three main generating units with space provided for a fourth. These are of the horizontal Westinghouse type rated at 10,000 kw., with steam at 190 lb. gage and 150 deg. superheat when operating at a 28½-in. vacuum and 1500 r.p.m.

Each turbine is equipped with a Le Blanc condenser, and injection water is taken from the tunnel that runs under the basement floor. The condenser injection water and air pumps are driven by a horizontal turbine. The air pump discharges into the intake canal and the injection pump into a pipe leading to the spray-cooling pond. Each condenser is capable of maintaining a vacuum of 28 in. when condensing 145,000 lb. of steam per hour, with cooling water at 70 deg. F. The exhaust steam from the turbines driving the condenser pump is automatically admitted to the main turbines when the supply of exhaust steam is more than is required for feed-water heating. The water from the circulating pumps of all the condensers is discharged into the cooling pond. If the supply of river water is low and not suitable for boiler use, the water is sprayed into the pond and then discharged into the intake canal. If there is sufficient cold river water of suitable quality, the water from the condensers is not sprayed, but is discharged into the pond, from which it is allowed to flow into the river reservoir several hundred feet below the intake and circulates up the stream to the intake, the complete circuit being about 1400 ft. At the west end of the pond is a sluice gate opening into two 36-in. pipes which discharge into the river some distance below the power station. As the normal level of the river is about 3 ft. below the bottom of the pond, the basin may be drained by the sluice gate if necessary.

The Steam Piping

The main steam header runs the entire length of the boiler room on the turbine-room side. It is of 12-in. flanged-steel pipe, and is fed by 8-in. lines from the boilers. Each boiler has an automatic nonreturn stop and check valve, and each turbine is fed by a 12-in. line from the header. Expansion is cared for by long radius bends. All straight lengths of main and auxiliary steam piping are of full-weight wrought steel with van stone extra heavy steel flanges, and all bends and offsets of the main and auxiliary steam lines are of extra heavy steel, the exhaust-steam piping up to 10 in. in diameter being of merchant pipe with standard-weight screwed cast-iron flanges, the bends and offsets of extra heavy pipe and standard-weight cast-iron flanges. All exhaust lines of 12-in. diameter or over are of cast iron with standard-weight fittings.

The piping is covered with 85 per cent. magnesia blocks 1½ in. thick, the smaller live-steam pipes having one layer and the larger ones two layers. The exhaust and low-pressure piping is covered with air-cell sectional blocks of asbestos paper finished with rosin-sized paper and canvas, as in the case of live-steam piping.

Generator Installation

The main generators have a rating of 10,000 kw. at 80 per cent. power factor, 11,000 volts, 25 cycles, single-phase. At this rating they are specified to operate 24 hours, with a rise in temperature not exceeding 60 deg. C. above the temperature of the cooling air. This temperature rating is used because the load factor and form of the load curve are such that a rating on this basis gives a truer conception of the size of plant required than would be obtained by adhering to the usual temperature basis of rating machines operating on a high load factor. The armatures are wound three-phase, the traction load being taken off one-phase only and the auxiliary motors around the power house running off the three-phase bus. This of course necessitates a much larger machine for the given output, but has certain advantages over the use of single-phase generators.

Each generator is ventilated by a blower with a capacity of 50,000 cu.ft. of air per minute against a static head of 5 in. of water, the fan being driven by a 100-hp., 440-volt, three-phase motor. The blowers are located in the basement.

There are two turbine-driven and one motor-driven exciters. They are compound-wound machines with commutating poles and each has a capacity of 600 amp. at 250 volts. Voltage regulation is effected by a Tirrell regulator.

Power for signal service is applied by two turbine-driven generators, supplying 60-cycle, single-phase, 4400-volt current.

Turbine Oiling System

Oil is pumped from a Bowser filter to storage tanks having a capacity of 3000 gal. and located 32 ft. above the turbine floor. From the tank it flows by gravity to the turbine oiling system, consisting of a water-cooled reservoir from which the oil is pumped from the governor and the bearings by a gear-driven pump operated from the turbine shaft. The oil is supplied to the governor at a pressure of 45 lb., which is reduced to about 10 lb. by a reducing valve before passing to the bearings. From the bearings it returns to the cooling reservoir.

Switching Apparatus

The generator leads connect through oil switches with a three-phase, 11,000-volt bus which is sectionalized, three-phase power for the auxiliary services being taken off the island section. Power for the railway service is taken off one phase only, as previously stated. This phase connects with three 5000-kv.-a., 11,000 to 44,000-volt transformers, the secondaries being connected to 11,000 single-phase feeders. The secondaries of these transformers have their middle points grounded through resistance.

No brick or concrete busbar compartments are used. Instead, the bus structure consists of copper tubing carried on insulators mounted on pipe framework. Copper tubing and bare wire are used wherever possible, insulated wire being employed only where the conductors are carried in conduits. All the oil circuit-breakers are electrically controlled from the operating gallery, the control being from the auxiliary direct-current busbars or a storage battery located in the turbine-room basement.

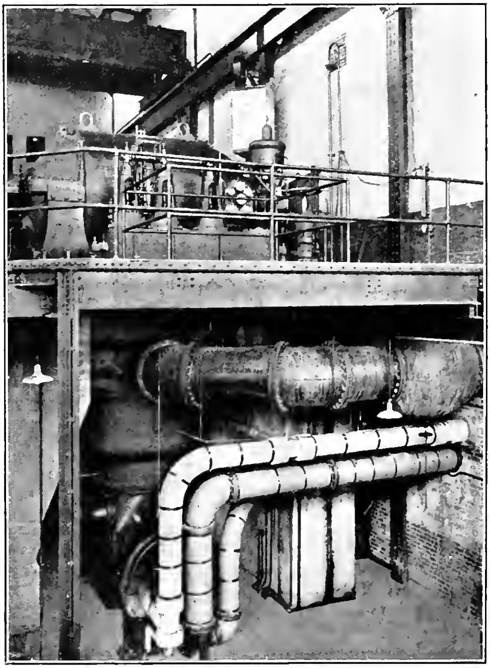

Fig. 8. Le Blanc Condenser under Turbine

Regeneration Loading Rheostats

Excess regenerated power returned at no load passes to the 11,000-volt bus and through the various transformers back to the generators if they are running under very light load or no load. If no other load were provided, the regenerated power would reverse the generators and operate them as motors. To prevent this, a loading device consisting of electrodes immersed in the intake canal and controlled by suitable switches, is provided. The operation is automatic by means of a group of relays and magnetic switches, current transformers, etc., so connected that when the amount of excess regenerated power reaches, say 300 kv.-a., the closing relays throw in one water rheostat on the 11,000-volt bus. As soon as the regenerated power exceeds the capacity of one water rheostat by 300 kv.-a., another closing relay throws the second water rheostat in on the 11,000-volt bus. The difference between the amount of excess regenerated power and the capacity of the water rheostat in service is made up by the generators. When the excess regenerated power has become reduced to zero, with one rheostat in service, all of the rheostatic load being sup-

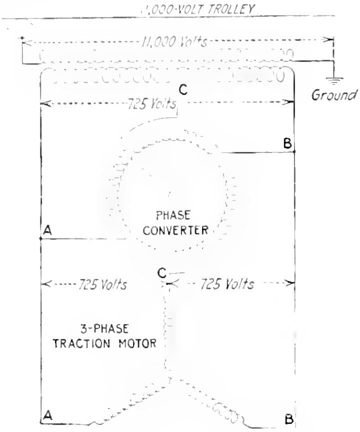

Fig. 9. Phase-Converter Circuit

plied by the generators, one of the tripping relays trips the circuit-breakers and this cuts the rheostat off the 11,000-volt bus. These water rheostats are located outside of the transformer house, as shown in Fig. 5.

Transmission and Substations

As previously mentioned, power is transmitted at 44,000 volts, 25 cycles, single-phase to five substations, where it is stepped down to 11,000 volts. The oil circuit-breakers in the substations are remote-controlled and will be operated from adjacent signal towers or passenger stations or the yardmaster's office, thus requiring no special attendance. The transformers are of the single-phase, oil-insulated, water-cooled type, with primaries wound for 44,000 and secondaries for 11,000 volts, and are equipped with thermostats which, at high temperatures, close a bell-alarm circuit to the nearest operator's office. Two transformer filter outfits have been provided, one for the power house and the other for the substation. Each equipment consists of a filter press, drying oven, and motor-driven centrifugal oil pump.

Locomotive Details

From the 11,000-volt trolley the operating current is taken by a pantagraph and led to the locomotive transformer through an oil circuit-breaker. A phase-converter is connected to the low-tension side of the transformer and operates constantly when the locomotive is in service. To its extended shaft are coupled a blower for cooling the motors, transformer and other parts, and through a clutch, the air compressor. The converter is an induction motor with a short-circuited or cage-wound secondary, having two windings on its stator, one to drive the rotor and the other to furnish current out of phase with the main supply current. The motor circuit of the primary winding of this converter is connected across the secondary of the locomotive transformer and receives current at 725 volts. The arrangement of winding is such that with the converter running, a current of 90-deg. phase displacement is induced in the second winding on the primary of the converter. By connecting this displacement circuit to the middle tap of the main transformer, a three-phase current is produced by the ordinary

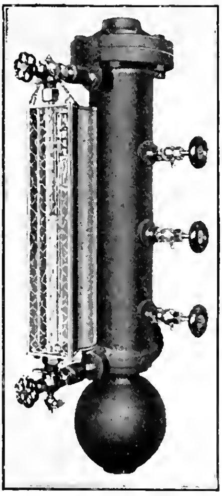
*Substation, line and locomotive equipment not listed two-phase and three-phase methods of connection (see Fig. 9). It is necessary only to convert a portion of the current used in the motors, as a large part comes directly from the main transformers. For starting the converter, a single-phase series commutator-type motor is mounted directly on its shaft.

Each locomotive is equipped with eight traction motors of the three-phase induction type with wound secondaries for four-pole and eight-pole operations. There are two running speeds, namely, 14 and 28 miles per hour. In starting, resistance is inserted in the secondary circuit of the motor by means of a liquid rheostat. For the 14-mile speed all the motors are connected in parallel having the eight-pole combination, and for the 28-mile speed they are also connected in parallel, but with the four-pole combination.

Safe Guard Gage Glass Reflector

In the safe operation of a boiler it is of the greatest importance to be able to see the exact water level, and the more clearly the water line can be seen, the better for all concerned. In this connection the Reordway Manufacturing & Sales Co., of Chicago, has recently perfected a gage-glass reflector and guard which makes the water show red and protects the operator against accident by breakage of the water glass. The device surrounds the gage-glass. It is made of aluminum with a wire-glass front. Within the casing an electric light so reflects on the water as to make it appear red, thus making a positive distinction between that part of the glass containing water and the part containing steam. The water level can be seen from any point in front of the guard and the possibility of a false level due to discoloration of the glass or condensation running down the sides is avoided.



Reflector and Safe Guard

At both the top and bottom of the reflector rubber gaskets prevent the metal from touching the water glass, and as the latter is inclosed, it is maintained at a temperature approaching that of the steam. The glass is not subjected to drafts in the boiler room, and the strains due to expansion or construction are obviated to such an extent that breakage is less frequent. Even if breakage should occur, the aluminum casing and the wire-glass cover protect the fireman from any serious injury. The reflector is made to fit any standard water-gage glass and is easily applied.

Railroad Expenditures—The average expenditure of one of the leading Eastern railroad systems every time the clock ticks off a minute, is $191.63 for supplies. In a year it buys $100,722,006 worth of material of such wide diversity as coal and soft soap, ink and feather dusters, steel and paint.

JUST FOR FUN

Getting a High Vacuum

The engineer was summoned to the office upstairs to see what was wrong with the radiator. Though it was a vacuum system, the radiators were full of water, which indicated stoppage in the return line. After examining all valves on the return line back to the boiler room, he went to the vacuum pump. Sure, there was 25 in. of vacuum, and the pump was running free and easy, but the valve on the suction pipe was closed. The fireman stated he could not keep a good vacuum on the gage with the suction valve open, so he closed it and used a little more city water on the spray jet and held up the vacuum beautifully.—*R. A. Cultra, Cambridge, Mass.*

Imported for a Purpose

The inclosed clipping is from a recent issue of an English magazine. The unknown professor mentioned in the advertisement has evidently copied his idea from his American brother faker, but he has put in a few new points which are about as funny as anything I have ever seen in an advertisement. He tells prospective customers that coal ore improves on nature by making the coal give out just as much heat as usual, but that the coal will burn just twice as long as usual.

SCIENCE VERSUS NATURE

Science has demonstrated how it can triumph over nature, for here is a product of mankind which actually improves nature and makes coal give out just as much heat as usual, but uses only half the energy.

COAL-ORE—THE HEART OF THE COAL

It is nothing more nor less than the scientific adaptation of the natural elements of heat storing as discovered by the eminent professor who conducted the experiments. The application of coal-ore has demonstrated infallibly that coal can be made to last twice as long and yet still give out the same heat. A single **shilling packet** will be ample to treat a **Ton of Coal.**

James E. Noble, Toronto, Ont.

Circuit Incomplete by a Foot

It was the custom of the repairmen in the car barn of a street railway to set various traps to shock any new comer. The drinking water was kept in a bucket on a small shelf. A carefully concealed live wire had been run down the back of the post with a free end of sufficient length to be brought around the post and hooked on to the handle of the bucket. One day a new man started to work, and the water-bucket trap was promptly set for him. Water was sprinkled on the floor around the drinking place to make sure that the ground connection would be good. After the new comer had taken several drinks without result (the connections being examined carefully after each drink and pronounced O. K.) and the rest had gone thirsty all the morning, someone inquired as to his "open-circuited condition." The explanation was quite a surprise to everyone, as he stated that he had helped to shock new men in his time and was perfectly well aware that the water bucket was loaded. He explained that the reason he was not affected was, that he was so unfortunate as to have a cork foot in place of one he had lost, and that it was only necessary for him to raise the good foot from the ground when getting a dipper of water. The limp was on the new comer, but the laugh was on the gang.—*J. E. Terman, Hartford, Conn.*

Factors Affecting Commutation

By Arthur H. Brame

SYNOPSIS—The influence upon commutation of armature reaction, induction in the commutated coils, local currents in the short-circuited coils, and the proper selection of brushes.

In the study of commutation it is necessary to consider separately the influence of the distortion of the main magnetic field by the field produced by the armature current, the induction in the commutated coils by the sudden stopping and starting of the currents in the opposite direction, the local currents flowing in them while they are short-circuited by the brushes, and the important part played by the brushes.

Consider first the armature carrying a current supplied from some external source, as in a motor, while the field magnets are left unexcited. Conductors on the same side of the neutral plane carry currents in the same direction, while the conductors on one side carry currents in the opposite direction from those on the other side. The armature as a whole is, therefore, producing a cross magnetization, or a magnetic field across that which is established by the field magnet (see Fig. 1). Since two magnetic fields cannot exist in the same place at the same time, the outcome is a field across the armature which is the resultant of the armature and the field-magnet fields. The armature field at both top and bottom strengthens at one side and weakens at the other the field due to the magnets, and this results in a distortion. When the machine is running fully loaded the coils do not reverse in electromotive force at points directly between the polepieces, but at points further around in the direction of rotation in the case of generators and backward in the case of motors, due to this distortion of the field by the armature currents (see Fig. 2). Therefore, the brushes must be given forward or backward lead, according to whether the machine is a generator or motor; otherwise there will be sparking.

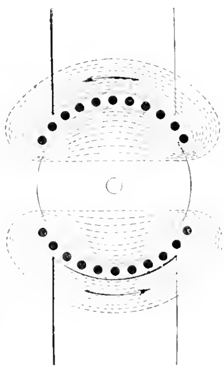


Fig. 1. Illustrating Magnetic Field Produced by Armature

Suppose the armature to be divided into 60 coils connected to a 60-bar commutator. The brushes will short-circuit at least one of these coils, and in some cases two, as they pass from one side to the other. The short-circuit on any coil lasts but a brief time, for if the armature be running at, say 10 revolutions per second, then one coil, forming only $^1/_{60}$ of the whole, will be short-circuited for $^1/_{600}$ of a second twice in each revolution.

Up to the moment of its being short-circuited by the brush, the coil (in a two-brush machine) has been carrying half the total current flowing in the external circuit, and in $^1/_{600}$ of a second this current has to be stopped, the electromotive force in the short-circuited coil reversed, and a current equal to half the external current, but in the reverse direction, started in it. If this be done before the short-circuit is broken the coil will break away from the brush without any sparking, but not otherwise. The only way to accomplish this is to give the brushes a further angle of lead, so that the coil, when on the point of being short-circuited by the brush, is cutting through the field in the reverse direction, so that this particular coil is developing an electromotive force contrary in direction to that which is urging the current through it. The reverse electromotive force on short-circuit rapidly stops the current flowing against it and starts another in the opposite direction. If the current in the short-circuited coil has not reversed on the short-circuit being broken, the current in it will be opposing the currents in the other coils on the side to which it has now been connected, and both will tend to arc across from the receding commutator bar to the brush, as indicated in Fig. 3.

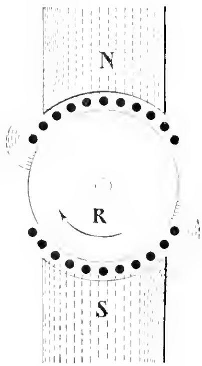

Fig. 2. Showing Field Distortion Due to Armature Reaction

It is evident that if the field magnet be magnetized to a high degree the pole tips will be highly saturated and the distorting effect of the armature current will be considerably less, owing to the high reluctance introduced into the circuit; hence the necessity for adjusting the position of the brushes for changes in the load will be decidedly less. In most modern dynamos this is done to a great extent, and in many machines there is no sparking at the brushes within ordinary variations of load, even on large overloads, though the brushes be fixed in position; this is especially true where carbon brushes are employed and the ampere-turns per commutator bar are small.

The current developed in the armature of a generator has to be collected by brushes pressing on the commutator segments. These are made either of copper or carbon, the brush-holders being designed to suit. Arrangements must be made for feeding the brushes forward as they wear, and to allow any brush to be raised and held off while the machine is running. Carbon brushes offer more resistance than copper, not only in the specific resistance of the substance, but also, and more particularly, in the contact resistance. This extra resistance, although it makes a great difference in the resistance of the circuit formed by the coil which is short-circuited by the brush, does not appreciably affect the resistance of the whole circuit, and it has a very beneficial effect on the commutating properties of the machine. Consider Fig. 4. The current is here flowing out by the carbon brush, and the coil *B*, which is becoming short-circuited by the brush, has a relatively high resistance put into its circuit, soon reducing its current to zero. The current from coil *A* now divides at the brush, the larger portion going directly through the brush and a small portion passing through coil *B* to the brush, for the brush and coil *B* are in parallel. As the coil moves further around, more of the brush comes into contact with segment 3 and less with segment 2, until finally it is only just in contact with segment 2 (Fig. 5).

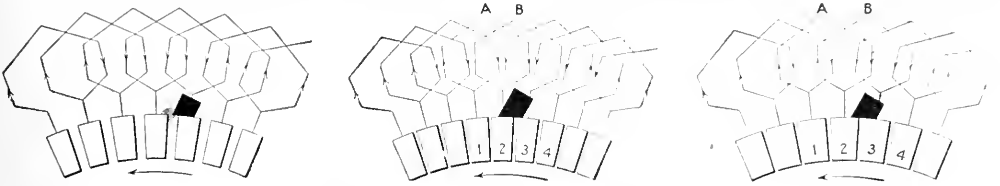

FIG. 3 FIG. 4 FIG. 5

ILLUSTRATING DIRECTIONS OF ARMATURE CURRENTS

As this proceeds the resistance from 2 to 3 across the brush is steadily increasing and, consequently, a larger and larger part of the current in *A* passes through *B* to the brush, until finally, as the brush breaks away from 2, there is little or no current flowing in that segment and, therefore, there is no sparking at the break. This enables the machine to be run with fixed brushes under large variations in the load, often from zero to full load; and the substitution of carbon for copper brushes has often prevented sparking in machines that before gave trouble in this respect.

There is one disadvantage, however, in using carbon brushes—one cannot allow as large a current density in the brush contact, otherwise they would get exceedingly hot. The maximum allowable current density found in practice is 70 amp. per sq.in. against 250 amp. with copper brushes. Since it takes a certain length of time to reverse the current, the brushes must be of sufficient thickness to short-circuit the coils for that length of time; on the other hand, they must not be so wide as to short-circuit a number of coils at the time, as this again would increase the tendency to sparking on account of increased self-induction.

Since the direction of a current causing a certain motion is opposite to the direction of the current caused by that motion, it follows that in a generator the current induced in the short-circuited coil has the opposite direction with relation to the current flowing in the armature from that induced in the short-circuited coil of a motor in the same position, when rotating in the same direction. That is, if in a generator the brushes are shifted so that the current induced in the short-circuited coil has the same direction as that flowing in the half of the armature it is about to join, in a motor revolving in the same direction and having its brushes set in exactly the same position, the current in the commuted coil (which absolutely has the same direction as in the case of the generator) would, relatively, have a direction opposite to that flowing in the half of the armature to which it is transferred by the act of commutation. While the brushes, in order to attain sparkless commutation, must be shifted with the direction of rotation, or must be given lead in a generator; in a motor they have to be shifted backward, or given lag.

In a generator the effect of commutation is a tendency to increase the aggregate magnetomotive force and, therefore, to strengthen the field; in a motor, however, the effect of commutation is to decrease the magnetomotive force and to weaken the field. Iron is very sensitive to slight increases of magnetomotive force, while it is comparatively insensible to a considerable decrease of magnetomotive force. In generators, therefore, the danger of sparking due to improper setting of the brushes is much greater than in motors.

Curve 1, Fig. 6, shows the value of the resistance of a unit section of brush contact plotted against current density in that contact; the resistance decreases as the current density increases, and for higher values than 35 amp. per sq.in. it varies almost inversely as the current density, and the voltage drop across the contact becomes practically constant, as shown in Curve 2. Such curves

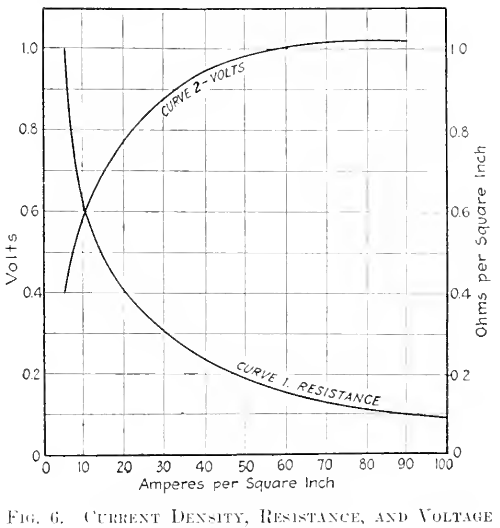

FIG. 6. CURRENT DENSITY, RESISTANCE, AND VOLTAGE DROP OF BRUSHES

of brush resistance are obtained by testing the brushes on a revolving collector ring and allowing sufficient time to elapse between readings to let the conditions become stationary. The resistance from ring to brush is generally greater than that from brush to ring by an amount which varies with the material of the brush.

It would seem that, by neglecting the effect of the variation of contact resistance with current density, the results obtained would be of little practical importance. It is found, however, that the variation in resistance is largely a temperature effect and that at constant temperature the contact resistance does not vary through such extreme limits; also that, due to the thermal conductivity of carbon, the temperature difference between two points on a brush contact is not very great.

Suppose that, having reached the value of 10 amp. per sq.in., and the resistance having become stationary at 0.06 ohm per sq.in. (see Fig. 6), the current density were suddenly increased to 40 amp. per sq.in. The resistance in ohms per square inch would not fall suddenly to 0.023, but would have a value of about 0.06, and this would gradually decrease until, after about 20 min., the resistance would have reached 0.023—the value which it ought to have according to Curve 1, Fig. 6. This explains why a machine will stand considerable overload for a short time without sparking, whereas if the overload be maintained it will begin to spark as the brush temperature increases and the contact resistance decreases.

Sparking is cumulative in its effect because slight sparking raises the temperature of the brush contact, which reduces the contact resistance and causes the contact to become worse.

The brush contact resistance is found to decrease as the brush pressure increases and as the rubbing velocity decreases, but these effects can be neglected in any study of commutation, since the change due to rubbing velocity is small, while the brush pressure is fixed by the service and is made as small as possible. The brush pressure is seldom less than 1.5 lb. per sq.in. of contact surface, because at lower pressures the brushes are liable to chatter, while if the pressure be too great the brushes will cut the commutator if they are hard or will wear down and smear it if they are soft. A brush pressure of 2 lb. per sq.in. is seldom exceeded except for street-car motors, in which the vibration of the machine itself is excessive, and pressures as high as 5 lb. per sq.in. have to be used to prevent undue chattering.

The average energy expended at the brush contact must also be limited, as may be seen from the following table:*

Kinds of Brush	Current Density	Volts across One Contact
Very soft carbon..........	50-70 amp. per sq.in.	0.6-0.4
Soft carbon	40-65 amp. per sq.in.	0.7-0.55
Fairly hard carbon........	30-45 amp. per sq.in.	1.1-0.9
Very hard carbon..........	25-40 amp. per sq.in.	1.5-1.2

The product of amperes per square inch and volts drop across one contact has an average value of 35 watts per sq.in. It must be understood that these figures are for machines which operate without sparking and without shifting of the brushes from no load to 25 per cent. overload by using the proper grade of brush.

From the preceding, then, it is evident that sparkless commutation will be promoted: First, by dividing up the armature into many sections so as to do the reversing of the current in detail; secondly, by making the field magnets relatively powerful, thereby securing between the pole tips a fringe of field of sufficient strength to reverse the currents in the short-circuited coils; thirdly, by so shaping the pole surfaces as to give a fringe of magnetic field of suitable extent; and fourthly, by choosing brushes of proper thickness and keeping their contact surfaces well trimmed.

The Velocity of Steam in Pipes commonly allowed for medium and high pressure is 6000 to 8000 ft. per min., but the tendency of the present is toward much higher velocities (even to double the figures given), especially where considerable initial superheat is given the steam.

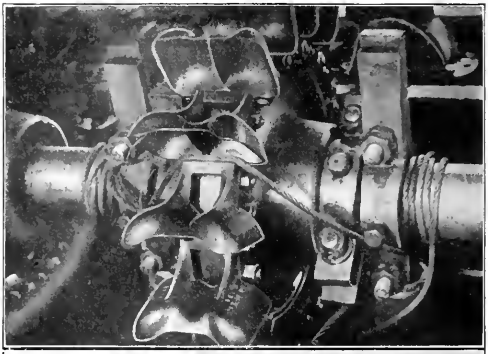
*Arnold, "Die Gleichstrom-machine," Vol. I, p. 351.

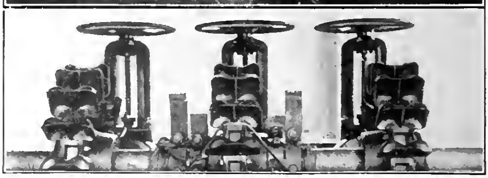
Repair to Waterwheel

By Walter Swaren

From far away Java comes an interesting example of a temporary repair. A waterwheel was shipped from San Francisco into the interior of Java to supply power for a tea plantation. It was necessary to sectionalize this wheel, and provision was made in the usual manner for a light press fit for attaching the hub to the shaft. The equipment for making the necessary press fit being rather difficult to obtain in the interior of Java, some refitting by hand was done. As a result, the fit of the middle spider (there being three spiders on the waterwheel shaft) was too light. After three years' operation it became loosened and worked endways on the shaft until it passed the key, thus rotating freely.

It was necessary that repairs be made quickly, as the accident occurred during the height of the season and





How the Wheel Was Made Fast

not more than two hours could be spared for the shutdown. It was obviously impossible, with the crude tools at hand, to arrange a new keyway or to put in setscrews; therefore, wire cable was drawn across the spider and wrapped tightly about the shaft by means of rough-forged clamps, as shown in the illustrations. It is interesting to note that but little more than two hours was required for making these repairs. The cure proved to be temporary, as in about a week the spider had again worked loose; then it was lashed in place in less than half an hour, which procedure had to be followed several times before the end of the season.

When the season was over, permanent repairs were effected by providing two clamps, one on either side of the wheel, with a notch in each which fitted about the boss on the hubs. These clamps carried bosses which in turn fitted into keyways sunk in the shaft, the whole repair being further held in place by setscrews. This left the spider held by two split-claw clutches.

All of the work was done by native Javanese laborers, under the direction of an engineer trained in the Netherlands.

Air Testing in the Refrigeration Plant

By A. G. Solomon

SYNOPSIS—The writer considers some of the dangers met in testing the refrigeration system with air. These dangers are not altogether absent when testing a new system. A special air pump should be provided always, so that the ammonia machine need not be used as an air compressor. Gage-glasses are not needed on the discharge gas receiver or on oil traps.

Using an ammonia compressor for pumping an air test on a plant is something that should be given considerable attention. It is customary to test the high-pressure side of a plant with 300-lb. air pressure and the evaporating coils and other low-pressure piping with from 100 to 150 lb. Many engineers seem to belittle the danger of using the ammonia machine as an air compressor.

Testing Newly Installed System

First, consider the risks in testing a new plant free from oil and ammonia. The machine is new and has been turned over by hand to ascertain that the clearance is right. Then it is turned over with steam, or with the motor if it happens to be motor-driven. With the steam drive the speed can be as slow as desired, but with the motor drive full speed is quickly reached. During this time the compressor does not draw anything from the evaporating side, as an opening is left so that the air is simply pulled in and forced out. Usually, much oil is put into the compressor to lubricate the valves and piston. Some of this lodges in small pockets in the valve cages and the globe valves in the pipes. After everything is ready the machine is turned into an air compressor and the test is begun. A full stream of water is turned through the water jackets, and often a hose is fastened to the discharge line and water allowed to flow over it to remove some of the heat of compression.

The machine should be stopped and allowed to cool after a discharge temperature of not over 250 deg. F. is reached. A thermometer should be inserted in the discharge line at this time, even if it is not left there for future use. The writer believes it would be a good thing to insist on discharge-temperature readings being taken during the test. The erecting engineer should be instructed as to what is a safe temperature and should keep within that limit. The oil for lubrication of the new compressor should be furnished by the builders, to avoid the danger of using an inferior lubricant or one with a too low flash temperature. This will mean that the thermometers and the oil will be a part of the erecting engineer's equipment. The lubricant used in many refrigerating plants is good as far as the low-temperature test goes, but when it comes to the question of gasifying under high pressure and temperature, that is another story. The danger of gas ignition and the resultant internal explosion is not any greater in the old system than in the new. The result of such explosion may be more serious in the former, owing to the possibility of ammonia being liberated.

Scale May Start Explosion

In one way, the writer thinks, a new system is more liable to explosion than an old one. The cylinder surface and the moving valves and piston are not worn to a smooth finish, and the friction is therefore greater. Minute irregularities in these surfaces may easily create friction which may cause a spark that will ignite the gas given up by the oil used for lubrication. In the old compressor this danger is not present.

Another producer of sparks may be the particles of scale in the pipes. However well the piping is cleaned, there is some scale which becomes loosened and may find its way into the cylinder. A small piece of hard scale, getting between the piston and cylinder wall, may cause a spark. Also small particles of scale and grit are sent through the compressor valves and the pipe work at high speed. These may cause sparks.

Soapy Water as Lubricant Prevents Explosions

There is one positive preventive for such explosions in testing a new plant. Do not use oil for lubrication. Use soap and water or some other material which will not give up a gas when subjected to heat. The amount of moisture thus introduced into the system will do no harm, as nearly all of it will be caught by the oil separator in the discharge line.

The proper way, and a way the writer believes should be insisted on, is the use of a special air pump for testing both new and old systems. Such an apparatus can be made to deliver air at a low temperature, and thus do away with the danger of explosion.

Where it is necessary to use a motor-driven ammonia compressor for pumping the air test, it should be stopped often and allowed to cool. This is annoying and takes a little more time, but it is safe. An hour or two more or less will not make any difference to the plant, whereas the bursting of a cylinder, receiver, valve or pipe work may delay the starting of the plant a week or more.

Glass Gages Not Needed

The proper way to handle the gage-cocks on ammonia gage-glasses needs some little discussion. There are two different ideas as to what is the best position for the cocks to be in—whether they should be left open all the time, or closed and only opened to see how much liquid is in the receiver.

The practice of placing the gage-glasses on the discharge-gas receiver or on oil traps should be discouraged. They are not necessary and are in most cases useless for the purpose intended. On the discharge side of a compression system the gas receiver or oil trap will be cold up to the level of the oil, and by simply placing the hand on it the amount of oil contained is readily ascertained. Glass gages usually become dirty on the inner surface and the oil level cannot be plainly seen.

So this leaves but two places where glasses are needed. The first is on the liquid-ammonia receiver. To successfully operate the plant the liquid level in the receiver must be known at all times. A glass gage is the only positive indicator. These glasses should be protected with a fine-mesh screen to prevent pieces from flying when the glass breaks. They should also be protected in some way from the danger of being hit by something dropping on them or by material being carried past the receiver. The writer knows of one case where the wheel from a valve directly above the receiver came loose and in falling it not only broke the glass, but also one of the cocks was broken off. Ladders and lengths of pipe are often carried around in the engine room, and they may come in contact with the glass. But besides such accidents, glasses often break in a seemingly mysterious manner. In one plant where a glass had been broken by being hit with something and a lot of ammonia lost before the cocks were closed, the chief engineer gave orders to keep the cocks shut except when the operator wished to see the liquid level. Several glasses broke during the following few weeks. This is easily explained. When the cocks were opened and closed, the liquid ammonia at the temperature of the condenser was bottled up. The heat of the engine room caused this liquid to expand and the pressure burst the glass. After a little study this was overcome by leaving the upper gage-cock open enough to keep the pressure from becoming high. Another scheme was tried with success in a plant where glasses had burst several times. If the cocks were left open it invariably happened that something hit the glass; when they were kept closed the pressure burst the glass. Finally, globe valves were placed between the gage-cocks and the receiver, and the core of the cocks was filed so that there was a small opening even when they were closed. The filing had the same effect as a leaky cock. Then the cocks were left closed and the two valves left open. If the glass broke, the amount of ammonia escaping was so small that a man could get to the valves to shut them.

There are on the market several styles of safety gage-cocks that are provided with ball checks and are supposed to shut the ammonia off in case the glass breaks. These can be depended on to a certain extent, but are like most automatic apparatus in that they are liable to fail when needed.

Gage on Brine Cooler

The other place where glass gages are used is on shell-type brine coolers where it is necessary to know the liquid level. These cocks are always left open and the glasses do not give much trouble by breaking. The pressure is seldom over 20 lb., and a man can get to and shut the cocks without much danger. But they should be provided with chains or chords so placed on pulleys that they can be closed from a point at least twenty feet away from the glass.

Electrically Operated Stop Valve

A large railroad company was handicapped by not being able to quickly stop the engine which operated the coal and ash conveyor, because this engine was located in a remote and inaccessible place. When something went wrong with one of the conveyor buckets, such as a section of the conveyor chain jumping the track, which, while not frequent, did occasionally happen, considerable damage was caused, because the engine could not be stopped quickly. Other accidents are likely to happen, such as workmen getting caught in the machinery. In coal breakers accidents caused by men being caught in the machinery are frequent. In most mines it is necessary for someone to ring a bell in order to have the engineer stop the engine.

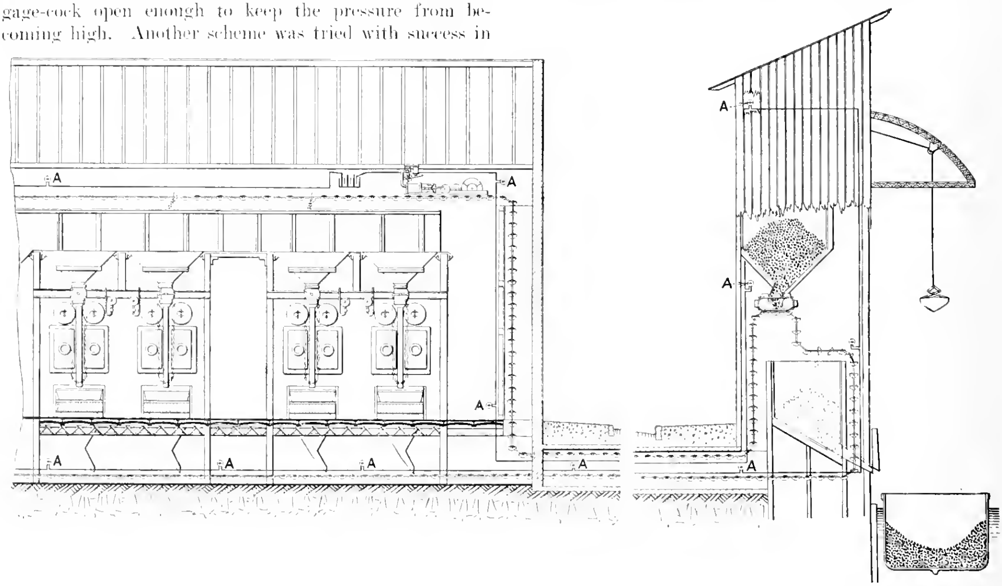


Fig. 1. Conveyor System, Push Buttons and Electrically Operated Valve

With the electrically operated valve herein described, anyone can quickly stop an engine by pushing a hand-push switch, any number of which may be located at intervals along the length of the conveyor path, as at *A*, Fig. 1. This device does not remove the cause of accident, but it does offer a means for preventing accidents such as mentioned from resulting seriously, as the conveyor can be brought to a stop within 6 in. of travel after a switch has been pushed.

Description of Valve

Fig. 2 shows a side and end view of an electrically operated valve of the inverted-lever type. It is fitted with

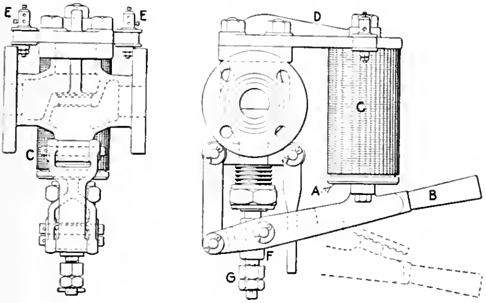

Fig. 2. Front and Side View of the Electrically Operated Valve

a hand lever *B* that carries an armature *A* by means of which the valve is held open by the ironclad closed-circuit magnet *C*, supported from the valve cover *D*. This carries heavy binding posts *E* on either side, which take the magnet and line terminals. The hand lever *B* is suspended from the valve body by a link and carries a trunnion *F* by means of which the valve spindle is held in its highest, or open, position. When the current is interrupted on the coil, a hand-push switch being operated, the hand lever drops to the position shown by the dotted lines, and as there is a clearance between the bottom of the trunion tee and the nut and check nuts *G* on the spindle, the weight of the lever strikes the spindle an impact blow, so as to insure closing against the stuffing-box friction. The pressure enters the valve body on the top seat side and acting on the valve disk, keeps the valve closed. aided by the weight of the disk spindle, and the hand lever resting thereon.

A guide is placed on the side of the body opposite the link, which fits into the crotch of the hand lever and relieves the spindle of any strain which might be caused by pulling the lever sideways. The two lugs on the body—one for the link and the other for the guide—are indentical and permit the hand lever to be turned to face the opposite way.

The cover can also be fitted on so that the magnet will face in an opposite direction, which permits the valve to be made either right- or left-hand to avoid interference with obstructions in restricted places.

The magnet can be wound for a 10-cell storage battery or 110-volt direct current. For 220 volts an outside resistance unit is used in series with the 110-volt winding. The current consumption is approximately $\frac{1}{4}$ ampere for the storage battery and $\frac{1}{10}$ ampere for either 110 or 220 volts, direct-current.

After the valve has been closed by the opening of the circuit on the coil, it is again opened by lifting the hand lever to its highest position, where it will be held by the attraction of the magnet, the circuit having been reëstablished immediately after having been opened, because the hand-push switches are of the self-resetting type.

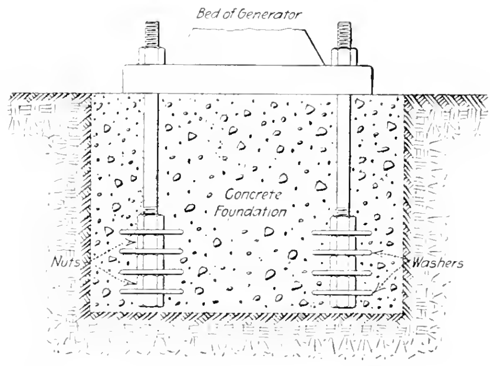
This valve must be used in conjunction with the existing stop or throttle valve on the engine, and should be placed between it and the engine cylinder. The valve is made in sizes from 1 to 2 in., inclusive. It is manufactured by the Schütte & Koerting Co., Thompson and 12th St., Philadelphia, Penn.

Anchoring Foundation Bolts in Concrete

By Terrell Croft

The effectiveness of the adhesion between an iron rod and the concrete in which the rod is embedded does not appear to be generally appreciated by many men who install concrete foundations for machinery. For example, the arrangement shown was used in a certain instance to provide an anchor for the foundation bolts of a machine. The series of nuts and washers on the lower ends of the bolts was entirely unnecessary, as will be demonstrated.

The maximum adhesion between a round iron rod and concrete amounts to between 250 and 400 lb. per sq.in. of contact area. A safe value for this adhesion may be taken as 75 lb. per sq.in. These values have been verified many times by actual tests. Working from these data, it can be shown that if a round iron rod is embedded in concrete to a depth equal to 30 times its diameter the rod will break before it pulls from the cement if force is applied to effect its withdrawal. Therefore, if a 1-in. diameter foundation



Unnecessary Nuts and Washers on Anchor Bolts

bolt with its surface perfectly smooth be set in concrete for a depth of 30 in., the rod will break before it can be pulled loose from the concrete. Roughening the rod by threading it or by chipping or by cutting fins in it has very little effect, one way or the other. However, as a matter of precaution it is always well to use for a foundation bolt a rod threaded and having a nut on the lower end. On this nut a cast-iron building washer or a square piece of wrought-iron plate can rest, which will insure against withdrawal if the bolt is not set 30 or more diameters in the concrete.

Air-Lift Efficiency

By E. M. Ivens

SYNOPSIS—Probably no mechanical device is as little understood in detail, or is subjected to so much abuse on one hand and praise on the other, as the air lift. Many engineers maintain that the air lift is inefficient, and should never be employed when anything else is obtainable; others credit it with a higher efficiency than is actually attained. Somewhere between the extremes is the proper place for the system.

Two descriptive theories of the air lift have been advanced—one by J. P. Frizell in 1880 and the other by Dr. Julius Pohlé in 1892. Each was granted a patent on a system of piping a well, and in each letters patent the theory is given.

Mr. Frizell says: "My present invention has for its object the elevation of water in a simple and convenient manner by the introduction thereunder of compressed air; and it consists in causing a column of water to ascend in a pipe or conductor by the injection therein, at or near its bottom, of compressed air, the weight of the air and water thus commingled being overcome by the weight of the external water which is thus utilized as a motive power to elevate the water." . . .

Dr. Pohlé says: "The object of the invention is to effect successfully and practically the elevation of the water to a much greater height than has heretofore been deemed economical with compressed air, and to avoid the results due to an ultimate commingling of the air and water, as well as to dispense with all valves, annular spaces and solid pistons. In accordance with my invention, the air is not directed into the water in the form of fine jets or bubbles, which would very readily commingle intimately with the water, but is delivered in mass, and the water and air ascend in well defined alternate layers through the eduction pipe."

Mr. Frizell claims a thorough aëration for his system, while Dr. Pohlé claims a piston-like layer formation of air and water for his. Fig. 1 is an illustration of the two principles.

Dr. Pohlé's idea was that the pistons or layers of air entirely filled the cross-section of the discharge pipe, but as shown in Fig. 1, in actual operation these air pistons only partially fill the cross-sectional area. Consequently, each ascending air piston cannot carry all the water before it; a certain amount (that contained between the air piston on the walls of the eduction pipe) is not raised and the air piston is said to "slip" by this water. This slippage loss is the most serious to be contended with in air-lift practice.

In a mathematical theory developed by Prof. Elmo G. Harris, it is shown that the air-slippage loss varies with the square root of the volume of the air bubble admitted to the water column, therefore it is advantageous to reduce the size of the bubbles by any means possible. This undoubtedly is nearly correct because it is only reasonable to suppose that the sum total of air-slippage losses will be considerably smaller in a rising column of air and water if a large number of finely divided bubbles are introduced than if a comparatively few large ones are employed. In other words, it is evident that, taken as a whole, the cross-sectional area of the pipe is more effectively occupied by the air in the Frizell aëration principle of operation than in the Pohlé piston-like layer principle. Experiment plainly indicates that this conclusion is correct.

Application of the Air

One of the first considerations in designing an air lift for any set of conditions is the manner of introducing the air, or the method of piping the well. Any system

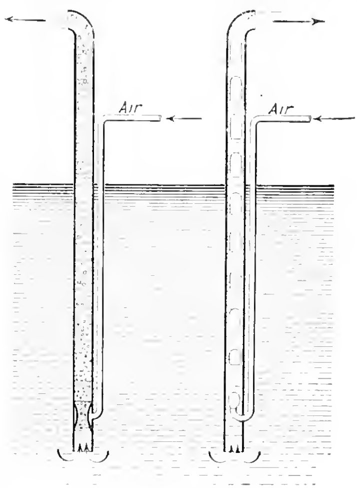

Fig. 1. Aëration Principles of Operation

that finely divides the air volume and provides a free passage for the mixed air and water will be found satisfactory. In Fig. 2 are shown a number of the systems of piping most frequently installed, the letters *A*, *B*, *C* and *D* referring to parts common to each system. Besides these there are several manufactured systems having specially designed head and foot pieces and for which broad claims of superior economy are made. In some of these dependence is put upon refined nozzles and deflector tubes for obtaining the efficiency claimed.

Submergence

Air slippage is also affected by the amount of submergence, or the distance below the surface of the water that the air is admitted to the discharge pipe. To thoroughly appreciate the importance of this feature in air-lift design, consider briefly the characteristics of the bored well and the water-bearing stratum that it penetrates.

Water-bearing strata usually consist of sand or gravel. At some point, which may be more or less remote, these strata reach the earth's surface, where they receive their supply of water from rivers, springs or rainfall. The ideal arrangement is the water-bearing stratum located between two impervious strata, so that there is no escape of water either upward or downward. No such perfect formation exists, but nearly impervious confining strata are found, so for the sake of simplicity of explanation we may assume that the water is held in the stratum in the same manner as in an underground pipe. This stratum we will assume to have a source of supply without an outlet.

Suppose now, that, as illustrated in Fig. 3, a well were drilled at A, piercing the upper strata and entering the water-bearing stratum. An outlet is now provided and the water, seeking its level, will rise up in the well until its surface at B coincides with a horizontal line drawn from the surface C of the source of supply. The distance from the ground surface to the water surface in the well is known as the *static head*.

If an air lift is installed in the well, as shown in Fig. 4, and operation begun with the static head h, there will be created a flow from the source of supply to the mouth of the well. Immediately the initial water level XB drops with a head loss XC due to the friction of the water in passing through the stratum and entering at the lower end of the well. Under the dynamic conditions, the head at the source cannot then maintain an equal head in the well, and the difference between the two is known as the *well head drop*. The *static head* plus the *well head drop* is known as the *pumping head* of the well.

Referring to Fig. 4, the air pressure introduced at A (pounds per square inch) necessary to start operation of the well is equal to the distance h_s in feet multiplied by 0.434, and the pressure necessary to keep the well operating after it has been started is equal to the difference in feet of h_s and the well-head drop multiplied by 0.434; so that the well-head drop in feet may be ascertained by noting the starting and running pressures on the air gage and dividing the difference by 0.434.

Besides the pressure reduction caused by actual falling of the head in the well, there is a slight pressure drop due to established column momentum. In other words, less energy is necessary to keep a column of water moving than is required to start the same column from a state of rest. This pressure difference is plainly equal to the velocity head, which is $\frac{v^2}{2g}$, multiplied by 0.434.

There is a certain amount of frictional resistance in the eduction pipe, and this increases the operating pres-

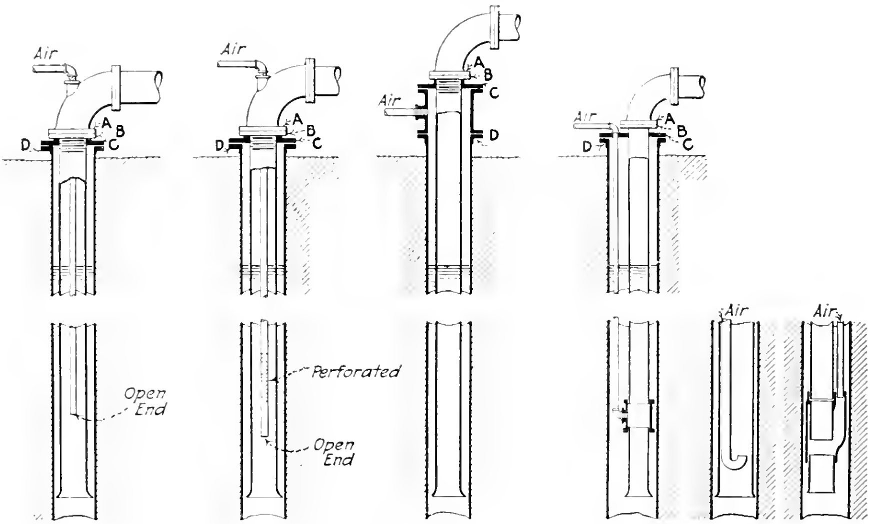

Fig. 2. Piping Systems Most Commonly Employed for Air Lifts

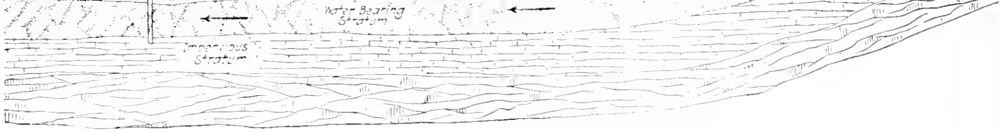

Fig. 3. Static Head of Well Bored to Water-Bearing Stratum

sure over that stated. It is usual to assume that this pressure increase cancels the pressure decrease due to column momentum. For all practical purposes, then, it is sufficiently accurate to say that the submergence in feet is equal to the air pressure multiplied by 2.31 or conversely, of course assuming that the air-transmission losses have been accounted for.

The air pressure that the compressor must operate against is dependent upon the amount of submergence (plus air-transmission losses) of the air line. Experience has shown that as the submergence is increased the air-slippage losses decrease, which means that a lesser volume but increased pressure of air is needed; on the other hand, decreased submergence requires increased air volume but decreased pressure Since these two factors (pressure and displaced volume) constitute work, it is important that the question of submergence be carefully considered.

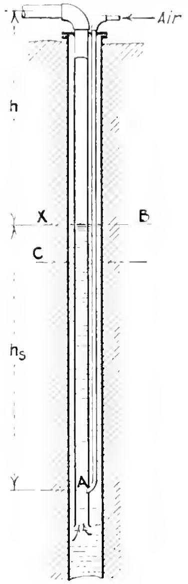

FIG. 4. STATIC HEAD AND WELL-HEAD DROP

There are no rules or laws that tell just what constitutes proper submergence; it is purely a matter to be determined by actual experiment in each case. A number of tests should be made with varying depths of submergence and the most advantageous depth selected. This is a very simple matter, indeed, and well worth the time expended. To show the effect of varying submergence on the efficiency of an air lift, there is reproduced in Fig. 5 a typical submergence curve. The curve was plotted from the results obtained from a test made on a well owned and operated by the City of Hattiesburg, Miss.* As will be noted, the efficiency falls off rapidly between 50 and 65 per cent. and between 75 and 95 per cent. submergence, but between 65 and 75 per cent. the difference in efficiency is only about 1 per cent. The most advantageous point of submergence is 70 per cent.

The proper percentage of submergence varies with the dynamic lift, decreasing as the lift increases. From numerous tests the writer has found the following to be about right, though, as stated, only a test can accurately determine the proper submergence in any particular case.

Lift	Submergence	Lift	Submergence
25 to 50 ft.	70 per cent.	201 to 300 ft.	50 per cent.
51 to 100 ft.	65 per cent.	301 to 400 ft.	45 per cent.
101 to 150 ft.	60 per cent.	401 to 500 ft.	40 per cent.
151 to 200 ft.	55 per cent.		

THE EDUCTION PIPE

Another factor which affects to a large extent the efficiency of operation of an air lift is the size and design of the discharge or eduction pipe. The small area of the well and the standard pipe diameters prohibit nicety of construction, even if enough were known to prepare an accurate design, but a material gain in efficiency can be made by exercising a little care and judgment in the use of our limited facilities and knowledge.

It must be remembered that the discharge pipe transmits a mixture of a practically incompressible liquid and a very elastic gas, and both are under a varying pressure. At the lower end of the pipe the pressure is equivalent to the depth of the submergence, and as the mixture rises the pressure reduces in proportion. The reducing pressure causes the air to expand and occupy an increasing area of the pipe. This causes the velocity of travel of the column to increase as the top is approached.

The demands of high efficiency for transmitting a mixture of air and water are conflicting. Air-slippage losses increase as the velocity of flow is diminished, and water frictional losses increase as the velocity squared is increased. In figuring the pipe diameter it is necessary to ascertain a velocity of flow where the sum of these two losses is least. Here, again, is the need of experience and experiment (for there is no other guide) and, unfortunately, we have neither. Then, too, we have the varying column velocity mentioned to contend with.

About all that can be said is that at no point in the discharge pipe should the column velocity be as low as

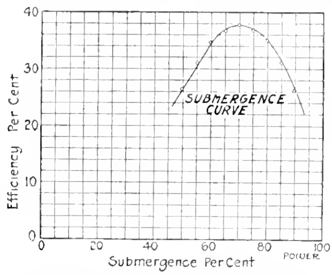

FIG. 5. VARIATION IN EFFICIENCIES FOR DIFFERENT PERCENTAGES OF SUBMERGENCE

that with which an air bubble will ascend in still water, and on the other hand at no point should it be so high that the water-friction losses overcome any gain obtained by small air-slippage losses. Also, the column velocity should increase as the air volume expands.

The writer has obtained good results with an initial velocity of 8 to 11 ft. per sec. and a discharge velocity of 22 to 24 ft. per sec. In high lifts and consequently long discharge lines, to prevent the velocity becoming excessive a gradually increasing pipe should be used. Initial and final velocities in each section of pipe of approximately 11 ft. and 22 ft. respectively will be found very satisfactory.

AIR PIPE

In a large percentage of air lifts the pipes for transmitting the air are too small. For obvious reasons these should be as large as possible, within reason. A velocity of travel of 30 ft. per sec. is considered good practice.

EFFICIENCY

If due consideration is given to the prevention of air-slippage losses and other economy essentials observed, the actual pumping efficiency of the air lift compares favorably with that of any other system of deep-well pumping.

*See page 116, "Pumping by Compressed Air," by E. M. Ivens.

When reliability and convenience are considered the air lift stands alone, and where conditions are suited it should be installed, by all means.

The very simplicity and reliability of the air lift have, however, gotten it into trouble a number of times. It has been installed where sufficient submergence was not available, and, consequently, the efficiency proved low. The one and only drawback to the air lift is the high percentage of submergence necessary to efficient operation.

The writer has obtained pumping efficiencies varying from 50 per cent. on lifts of 50 to 75 ft. to 18 per cent. on lifts of 900 to 1000 ft. These efficiencies were obtained, of course, after experimenting to ascertain the proper submergence.

Steam Generation in a Wood-Distilling Plant

By Lawrence Eddy

A battery of steam boilers burning six different substances—gas, liquids and solids—in the same fireboxes is rather unusual. Yet such are the conditions in the plant herein described, and which are quite typical of the wood distilleries in the East.

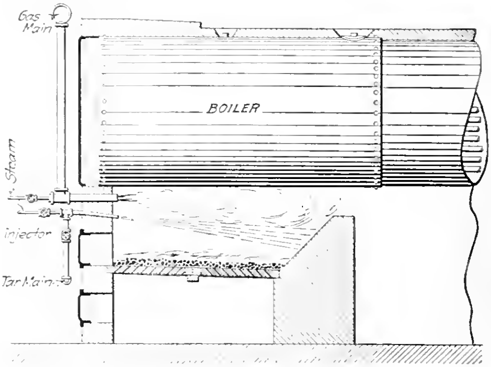
The steam for this plant is generated in three return-tubular boilers rated at 150 hp. each. They are set over stationary grates whose dimensions are approximately 6x6 ft. Air is supplied by a strong natural draft.

In the process of distilling hard woods several unmarketable products are obtained which are also combustible. They are burned, in this case under the boilers, as much for the sake of being rid of them as for the heat energy which they possess. When the wood is heated in the ovens about 20 per cent. of it, by weight, is converted into a noncondensible gas. In this plant, which burns 60 cords a day, this will amount to about 600,000 cu.ft. every 24 hrs. After washing, the gas is led in cast-iron mains to the upper corner of each firebox, as shown in the sketch. It merely escapes from the end of the pipe and mixes with the furnace gases, burning with a pale-blue flame in the top of the firebox. Its combustion is supported by the excess air which passes up through the fuel bed on the grates. A steam jet placed in the pipes just before they enter the fireboxes assists the flow of gas and prevents the furnace gases from working back into the mains and causing an explosion when the wood gas is not running. As there is no gas tank in the line, the supply at the boilers is intermittent and must be burned just as it comes, without any regulating valves which might cause a back pressure on the ovens.

The second class of fuels is the wood oils. These distill over with the alchohol and acetic acid, in the processes of purifying the wood vinegar or "raw liquor." They separate from the alcohol and acid by gravity, are washed, and run off to the tar sump where they mix with or float on the tar. They still contain a considerable amount of water and acid.

The residual tars which remain after the alcohol and acid have been distilled off resemble in appearance the familiar gashouse tar and have a very acrid odor, due to acid which cannot be entirely separated from them. Between 1000 and 2000 gal. accumulates every day, and is run off while still hot to the tar sump, together with the oils previously mentioned. Brass piping (to resist the acids) carries the mixture to the fireboxes, into which it is injected with considerable force by a steam jet, as shown. No attempt is made to atomize the liquid, it being merely hurled in large globules against the bridge-wall, spattering back and burning on top of the fuel bed. If fed too fast it builds up into a large mass which has often nearly filled the firebox. It will also run down into the fuel if fed too fast, and make a hard clinker in the grates.

In connection with the plant there is a sawmill which delivers the sawdust and refuse from 7000 ft. of lumber



Connections at Furnace Burning Solid, Liquid and Gaseous Fuels Simultaneously

a day to the boiler room. It is dumped into a bin by a chain conveyor and shoveled by hand into the fireboxes. When too green and wet to burn readily the sawdust is sometimes mixed with coal before firing. It is the practice to fire the sawdust all into one firebox; this is, of course, wrong, for since it is a much inferior fuel to the coal and the grate areas are the same, it follows that the two boilers fired by coal are overloaded, while the one fired with sawdust does not carry its share of the load.

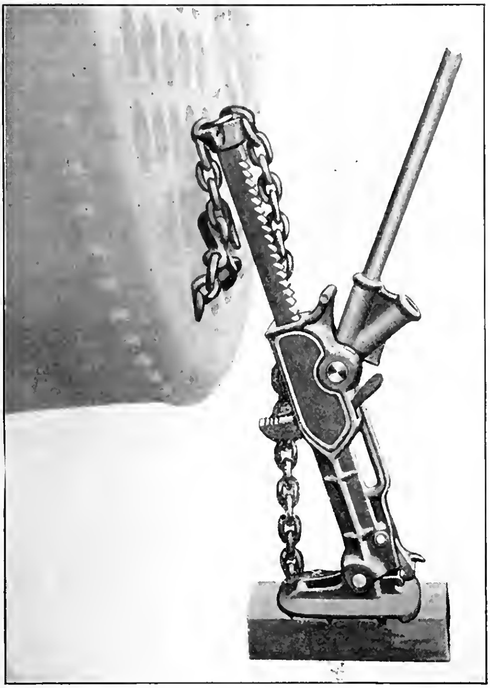
As the waste fuels do not furnish the necessary heat for all steam making, it is necessary to burn large quantities of fine pea anthracite coal on the grates. These fires must be raked off the grates periodically, and in kindling the new fire quantities of charcoal screenings are used. These screenings are a more or less waste product, and make excellent kindling. It is necessary to shut down the dampers when they are on the grates, to prevent them from blowing up the flue, they are so light.

The careful engineer will doubtless see much room for improvement in the arrangements mentioned, but owing to the extremely conservative spirit in the industry it is difficult to try out innovations; the coal bill is regarded as a necessary evil and, apparently, no further thought given to it.

Simplex Emergency Jack

The Simplex emergency jack, recently placed upon the market, is a tool of usefulness and utility wherever there are loads to be lifted or pushed. It practically combines a crane and a jack. The accompanying illustration shows the jack acting as a crane in changing the location of a boiler, wherein pushing at an angle and lifting are necessary.

The standard is a heavy malleable-iron casting ribbed for stress in every direction. The circular bottom of the frame rests with a machine fit upon two circular shoulders, which are a part of the large, well-proportioned base. In this way the base takes the load, and the steel pin acts to hold the frame in position. The rack bar and cap are heavy drop-forgings. The top of the cap is recessed for the chain, which is a part of the equipment. The double socket of crucible steel makes it possible to



SIMPLEX EMERGENCY JACK

handle a load with the jack at any angle. A heavy trunnion bearing supports the socket. The working angle of the jack is from 30 to 90 deg. to the horizontal. The trip at the back of the base either holds the frame in a rigid vertical position or releases it to pivot on the base. Five feet of chain and a 5-ft. steel lever bar comprise the equipment. The jack is manufactured by Templeton, Kenly & Co., Ltd., Chicago, Ill.

A Home-Made Cooling Tower

By A. D. WILLIAMS

An expense often overlooked in the operation of a gas engine is the cost of cooling water. This is particularly the case in city installations where the local water-supply is the only one available and meter rates must be paid. J. F. Kalb, chief engineer at the factory of the Willard Storage Battery Co., Cleveland, Ohio, was confronted with a problem of this kind several years ago. As the size of the power plant was increased by the addition of new engines the water bill increased until it was about $2300 per year, a part of the water being used in the factory, but the larger portion in the engine jackets. Mr. Kalb suggested that a cooling tower upon the roof of the engine room would enable him to use the water over and over again instead of wasting it to the sewer, and finally, he was authorized to build the cooling tower shown in Fig. 1, which was made entirely in the company's factory.

The base of the tower is a lead-lined sump or tank about 5x16 ft., supported on a rack upon the roof and deep

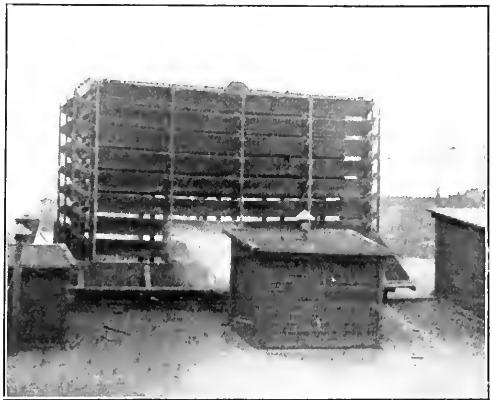


FIG. 1. GENERAL VIEW OF TOWER

enough to hold a foot of water. This tank is provided with an overflow to limit its water line and a ball-and-float valve to admit make-up water as required. The use of sheet lead avoided the necessity for making water-tight joints in the woodwork which might have been more troublesome. The bottom of the tank was built as a

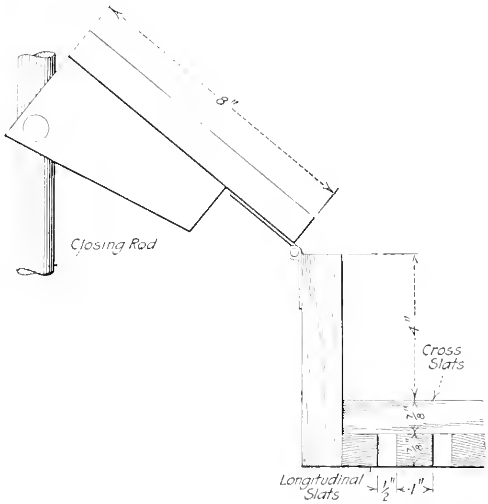

FIG. 2. DETAILS OF TOWER

platform, with heavy battens on its under side, and the sides rest on the platform and are supported by brackets. The joints in the lead lining are burnt, not soldered, and pipe connections are made to the lining by brass flanges soldered to it.

Above the sump there are nine trays about a foot apart, supported by posts that rest on the bottom of the tank.

the lowest tray being 8 in. above the sump. These trays are 4 in. deep and slightly smaller than the tank, their bottoms consisting of racks made up of 1-in. slats crossing at right angles and so arranged that the openings in one tray are not below the openings in the tray above. Water is delivered through a manifold and pipes to the top tray and to the fifth tray from the bottom, the latter arrangement being for use in cold weather. As originally planned, wind-shields were hinged to the top of each tray so that the windward side of the tower could be closed to prevent the spray being blown out on the roof. In practice, however, it was found that these shields became coated with ice and could not be closed in cold weather, except with difficulty. The construction of the trays is shown in Fig. 2.

The cost of this cooling tower, including erection, was slightly under $500, and the first year's operation showed a water bill of $300—a reduction of $2000 from that of the year before. This reduction in the bill caused the water department to test the meter used, after which the accuracy of the bill was not disputed.

Supporting Horizontal Return-Tubular Boilers

By F. W. Dean

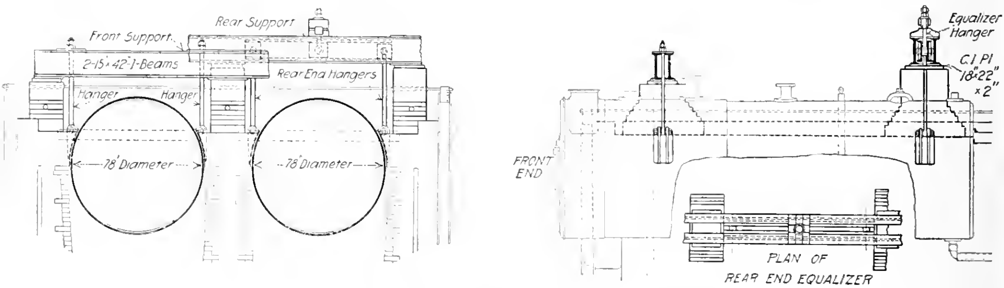
The manner of supporting horizontal return-tubular boilers is of considerable importance. Such boilers should be supported at no more than four points—on both sides near each end. If a boiler is of much length some builders support it at six points. Having an intuition that it is doubtful if the different supports will carry equal weights, they sometimes place springs under the middle ones, thus making the supports somewhat flexible without removing the uncertainty. This is only a makeshift, as even with the use of springs the inequality of supporting pressures is as great as ever.

It is a principle in mechanics that if a body rests on three points the pressure at each point can be determined, and will not change. A three-legged stool always rests properly on its legs and with unchanging pressure, even when it rests on an irregular floor; but a stool with more than three legs rarely presses equally on each, and if its feet were carefully fitted to bear equally on an ordinary floor, a little change in position would destroy the fitting. This illustrates that in supporting a horizontal return-tubular boiler the three-point principle should be applied. This, I believe, was first done by Orosco C. Woolson, and by him made public in a paper read before the American Society of Mechanical Engineers in 1898 and published in Power in November of the same year. If one end of the boiler is supported by two of the usual brackets, one on each side, or is suspended from above by two rods, one each side, and the other end is supported by two rods from above, one on each side, and connected to a hinged equalizing lever, the three-point principle is realized. When this is done the pressure on the brickwork and the strains in the supporting parts never change, even if the brickwork settles. If, instead of having an equalizing lever, the rear head were connected to an overhead beam by means of a hinged joint, the same principle would be applied. This may be a simple and good way to carry out the principle.

If it is doubted that a boiler can stand the strain of being supported at the ends, by treating it as a girder and knowing its weight when full of water, it will be found that the strain in the shell is next to nothing, and it will be seen that this method of support is safe for almost any horizontal boiler which is otherwise properly designed. In practice the case is not as bad as that just suggested, for the points of support are never at the extreme ends, and they can be so chosen that the boiler becomes a well proportioned continuous girder over the points of support, thus reducing the shell strains to a minimum.

Another feature of the usual method of supporting the type of boiler under consideration that merits criticism, is the design of the brackets. While I never knew of the brackets breaking or pulling away from the boilers, they should be designed with a row of rivets below the horizontal part that rests on the brickwork, thus reducing the stress on the bracket rivets.

The illustration shows how I have carried out the Woolson three-point principle since 1899. I first used it for 90-in. boilers for S. D. Warren & Co., but the illustration is that of some 78-in. boilers for Walter Baker & Co., Ltd., at their Montreal plant.



Rear Ends of Boilers Suspended from Equalizers

The Holding Power of Tubes, as shown by a series of tests, is given by J. M. Allen as follows: Tubes expanded but not flared or beaded, 5000 to 7500 lb. pull; tubes expanded and ends flared, 19,000 to 25,000 lb. pull.

Pipe Corrosion—In an effort to settle the important and mooted question as to which material better resists the action of corrosion, the National Tube Co. for years has made a practice of shipping with steel pipe wrought-iron couplings, so that the corrosion of each material could be judged by comparison under the same conditions of service. As a result they have concluded that there is no doubt as to the advantage of steel pipe and have abandoned the manufacture of charcoal and puddled iron for welded tubes.

Editorials

Weak Spots in Hydro-Electric Plant Design

Recent studies of water-power development for electric transmission disclose the need of broader operating knowledge in some instances, in order to realize the highest possible plant efficiency and the safest running conditions. Foresight in development cuts a greater figure in hydro-electric plants than almost anywhere else, in view of the costliness of changing such installations once they are completed. Both on the mechanical and the electrical sides improvements are desirable, as the following typical points illustrate.

Consider the problem of utilizing the available head. In this connection plant location is of decided importance, requiring thorough study by engineers of experience in order to avoid sacrificing a portion of the water drop which can be utilized easily without undue increase in investment. In one plant with a thirty-two-foot head, the available fall on the turbine runners might have been increased to forty feet had the station been located a couple of hundred yards down stream, and the output could have been increased accordingly, with still less service required of the auxiliary steam plant. The operating engineer in charge of the station pointed this out to a visitor familar with such work, and it was seen that the contention was true. The case was one where the company might have saved many thousands of dollars a year had its preliminary plans been shown to the operating staff for criticism. The adoption of the engineer's suggestions was in no sense obligatory, and there could have been no cause for dissatisfaction had the management decided, in the face of all the information before it, to proceed along the lines which it actually followed. Failure to realize the full possibilities of such a situation, however, is a misfortune, for day and night there is a loss of head below the tailrace in this station which might well have been turned into the wheels and made to earn revenue for the company.

Men who have to run plants of this kind realize the value of adequate hydraulic arrangement, including provision for getting at the rear bearings of turbine sets and ample sluice gates at the dam and forebay, so that the requirements of drainage can be met properly. Now and then only partial provision is made for emptying the forebay or for the removal of trash and leaves from the screens at the intakes. Ample lighting facilities here are as important as in the generator room itself. In one recently completed station a space of six feet wide has been set aside for reaching the rear bearings of the water-wheel units; and this, illuminated by a special circuit of tungsten lamps, means real comfort and resulting efficiency for the staff. It costs something in additional masonry or concrete to provide such a space, but in case of trouble, accessibility of such bearings is a valuable feature.

On the electrical side two points that deserve more attention may be emphasized. One is the practice of crowding too much switching and auxiliary apparatus into a limited space on a switchboard gallery, and the other is the need of better mechanical structures to support outgoing transmission and feeder lines. In one instance where the station design was studied in the light of operating experience, the potential transformers for various instruments were mounted on a frame above a concrete bus structure containing oil switches. The designer of the station probably never gave a thought to the danger of replacing fuses on these transformers in such a location, close to busses carrying high-tension energy and reached only by planking carried on pipe framing above the switch compartments. The fuses may be replaced with tongs, but nevertheless the position from which the operator must work is perilous, and had the designer consulted with men experienced in actually handling the type of plant in mind, it is probable that an entirely different location for the transformers would have been found.

Engineers and Supply Houses

One of the engineer's worst "good friends" is the supply house which takes back the articles he claims defective and replaces them without investigating whether the article was originally defective or ruined by misuse. This method of handling claims encourages an engineer to become more careless in his work and works a hardship on all concerned.

The supply houses, and their representatives, are great factors in educating the engineer, but if lax and careless in their business transactions he will gradually become the same in his work. For example, in place of catching the hexagon on the bonnet of a brass valve in the vise, then screwing a piece of pipe into the valve and using it as a lever to loosen the bonnet, he will catch the body of the valve in the vise and try to loosen the bonnet with a monkey- or perhaps a pipe wrench. Then, when the body slips in the vise he will tighten it up and squeeze the seat out of shape, and the valve will leak. This may be either ignorance or carelessness, but it makes no difference, he says the valve is defective and returns it. In order not to lose the business the supply man replaces the valve without a word and junks the ruined one.

How much better for all concerned it would be to take the valve back to the engineer, show him how it had been ruined and how to take it apart, and make him pay for it, as he should. Nearly all manufacturers test their valves before leaving the factory, consequently they have a right to look with suspicion on complaints regarding leakage through the seat.

Some time ago an engineer claimed that three automatic stop and check valves were leaking and didn't open as they should when cutting in a new boiler. They were taken apart and found to be covered with mud, which caused all the trouble. The engineer should have taken these valves apart himself before making complaint.

In another case, where a gate valve was placed in the header between two engines, the first time it was closed it "leaked like a sieve," and complaint was made. Another tested valve was sent, and this likewise leaked. An experienced man was sent, and he found that the expansion in the pipe line was springing the body of the valve. The piping was rearranged and the trouble disappeared. In a new pipe line there is always a lot of pipe scale cuttings, etc., that may lodge in the valve the first time the steam is turned on.

Returning material to obtain new when you are not justly entitled to it is dishonest. You might just as well break into a place of business after nightfall and take what you want. Besides, we pay the bill in the long run.

Definite Engineering Education

Attendance at commencement exercises this month brings many rewards to those fortunate enough to hear the distinguished speakers from far and near, but there is one striking consolation for the man who must stick to his daily task while others loll about the campus and drink in good advice in the auditorium. That is the eternal value of scientific principles, both pure and applied, as a mental resource and stimulus to the individual. Thousands of words have been spoken this month upon the subject of technical education and its relation to modern industry. Much of this has been interesting to hear, but a large part of it has been self-evident, with remarks of scarcely more than a commonplace value to the engineer, be he graduated from the school of experience or from the university of books and laboratories.

We have no quarrel with present methods of engineering education, but we do wish to emphasize the surpassing value of concrete studies in contrast to the ocean of generalities poured forth by many commencement speakers at this season. Some of these men rose to the occasion and drew appropriate lessons for the engineering profession from these epoch-making days in the world's history. Others—well the feeling of many a man after sitting through some of these exercises is one of thankfulness for the solid interest and profitableness of definite engineering principles and problems as a field for putting forth one's best powers of thought and expression. Those of us in, or closely allied with, engineering work can rejoice that we do not have to spend three-quarters or more of our waking hours groping about in the fogs of speculative theory which beset the footsteps of so many "educators." How much more interesting it is to stop leaks in the plant, to figure out a method of utilizing more heat units between the turbine-discharge outlet and the feed pump, to rectify a poor valve setting on the basis of a skillful indicator diagnosis—yes, to master the situation in dealing with that oil salesman, or to make the boss's jaw set with satisfaction in showing him an exceptionally good report of station performance!

A man may have gone back to his Alma Mater this year to celebrate some notable anniversary in his life, and yet he may have come away and gone straight to his job again with greater enthusiasm than ever for the principles on which his work is based and greater interest in its puzzling difficulties. He may have been given inspiration for taking up regular work again by speakers of international fame, or he may have been driven back into his own thoughts by the skill with which titled and "degreed" orators enunciated the perfectly obvious. However it may be, there is not the shadow of a doubt that one of the greatest blessings about working in the engineering field, with all that it implies in self and coöperative education, is the necessity of definite aims, of striving toward some concrete attainment. The lasting opportunities before the engineer for the mastery of specific principles and problems put the hypotheses and assumptions of people less accustomed to deal with realities far into the background as objects of tangible achievement.

Practical College Work

It is always gratifying to see a college or university with a decidedly practical trend. More and more is this becoming the spirit of the modern educational institutions, as contrasted with the learned, but not always useful, reputations which they once held.

The Oregon Agricultural College is making a first attempt to carry its engineering instruction out to the people of the state. During the past three months lectures and demonstrations have been given to the Portland branch of the International Union of Steam Engineers, with an average attendance by the members of over one hundred and fifty. In addition to the lectures, demonstrations have been carried on at various plants in the city, and a number of experiments and exercises have been conducted by individuals interested. One typical instance resulting from this instruction was a saving of eight per cent. in the cost of fuel in one of the largest plants in Portland.

The subjects taken up this year were "Combustion Control" in connection with the operation of heating plants, and "Refrigeration." This work was given by Prof. F. H. Rosencrants. There was also one lecture in "Electrical Engineering," by L. F. Wooster. The work proved so successful that it will probably be carried forward on a larger scale next year, according to a report of Prof. R. D. Hetzel, the Director of Extension.

While we do not wish to see the spirit of the age too commercial, real efficiency as measured in dollars and cents is, after all, the one for which it pays to strive, and if the colleges can teach us how to cut down the fuel expense in our steam plants eight per cent., it behooves us to give them an audience.

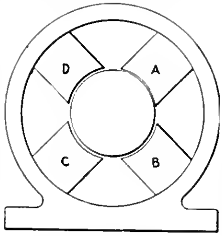
Of course, it does not follow that the savings will be general or that they are always possible. There are many engineers and steam-plant operators who could teach most college professors a great deal about economical combustion. At the same time, the college professors may have come from the ranks and, through the school of experience, know something about firing themselves.

There is a letter by one of our esteemed contributors on page 852 of this issue that nearly all should read—assistants as well as chiefs. It is about wage increases. Assistants should read it because it will reveal to many what the chief is "up against" when he tries to increase the wages of his subordinates. Chiefs should read it to either remind them of, or acquaint them with, the things they should consider before attempting to add to the payroll burden. Employers realize more and more that good wages attract high-quality labor, and most of them will increase wages when convinced it is deserved. But none will make weekly or monthly donations.

Correspondence

Hot Generator Bearing

On starting up a small belted generator that had not been in use for some time the bearing on the commutator end ran hot. The operator, thinking the bearing might be pinching, put liners between it and the cap. Then the bearing got hot quicker than before. When the cap nuts were loosened slightly with the machine running, the shaft was seen to rise out of the bottom bearing and follow up the cap; and the bearing got hot very quickly. This indicated that there was an unbalanced magnetic pull on the armature.



Showing Unequal Air Gap

An examination showed polepiece *A* to have a smaller air gap than *B*, *C* and *D*, which were all alike. There were a few shims back of the polepieces and by removing those back of *A* the air gap under *A* was equalized with those under *B*, *C* and *D*. The cap was then put back on the bearing without any liners and pulled down tightly, and the bearing did not go above a moderate operating temperature.

Child-Labor Laws

In a recent issue of one of my engineering magazines I noticed under the heading of "Court Decisions," the following statement concerning child labor in Alabama:

> Under a law enacted at the present session of the Alabama legislature and approved by the Governor Feb. 24, 1915, it becomes unlawful to employ any person under 16 years of age in operating or assisting in the operation of any steam boiler or dangerous machinery.

This evidently is a first step (and a rather weak one) in the right direction, for which the engineers in that state should be thankful, but if the law has only reached that stage where children are prohibited from acting in the capacity of engineers, then the engineers of that state have a long, hard road to travel before they can expect to get a safe and sane license and boiler-inspection law and the recognition which is due their position.

It is my opinion, and I believe that there are many others who will agree with me, that children of 16 years should be in school. Certainly, the work and responsibility of operating a steam boiler and engine should not be intrusted to a child.

In Alabama there are comparatively few boilers as compared with Massachusetts and other manufacturing states, and probably for that reason sufficient pressure has not been brought to bear to put through a reasonably safe law in regard to the operation of power-plant machinery. When we consider that Massachusetts, with its present rigid laws in regard to the construction, inspection and operation of boilers and examining and licensing those who are to have charge of them, is not satisfied with its present laws, and is trying to enact more adequate and in some instances more rigid ones; that Ohio, which now has rigid boiler-inspection and engineers' license laws is about to adopt the new regulations as proposed by the A. S. M. E.; that Wisconsin has already adopted these laws, and some other states and municipalities are contemplating the same step—it does seem that the present situation in Alabama is many years behind that of the other states.

These facts bring out the question, Are the boilers in Massachusetts, Ohio or Wisconsin more dangerous or the men as a rule less proficient than those of Alabama and some other states where there are no inspection and license laws? It is probable that the reverse is the case. Is there any right-thinking employer in any of the states which have any semblance of inspection and license laws (no matter how opposed he may be to the present laws of his state) who will admit for a moment that a boy of 16 or 17 years of age is a competent person to have charge of his engines and boilers? I think not. He may be satisfied to have these lax laws by means of which some other employer may hire the boy, and thus make it possible for him to get a man at boy's wages.

Then there is another phase of the subject which appeals to most employers, aside from the safety of the plant, and that is efficiency. It is well known that it often lies within the power of the engineer to regulate the cost of producing power. For this reason the progressive employer insists on having a man of mature knowledge, judgment and experience in the power plant, to say nothing of a 16-year-old boy who cannot possibly have acquired these qualifications.

It seems to be the aim of some of the employers in some of the states where the laws in this respect are rather lax or where there are none at all, to vigorously oppose legislative bills that come up in regard to boiler-inspection and license laws on the grounds that they are unnecessary and will cost them more money through the engineer's being able to control the supply of engineers to some extent, and of the necessity in some cases of getting other men. They can only see the almighty dollar that they may have to pay for the services of a competent man, to one who has to prove to an exacting board of examiners that he is competent to safely and efficiently operate this class of machinery before he is allowed to have charge of it. But they lose sight of the double eagles that will come to them through the more efficient operation of the plant by the man who can prove that he has the skill to do it.

As time goes on, the laws that govern the requirements of engineers become more exacting, and the employer, realizing the importance of the engineer's position, demands more efficiency in this department, and only those men who are persistent in their efforts to improve their conditions and who are willing to work conscientiously for their employer's interests, will succeed in holding the best positions in the engineering field

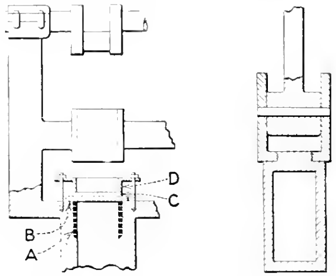
J. C. HAWKINS.

Hyattsville, Md.

Running a Crippled Pump

The threads on one plunger of a geared triplex pump gave way at the point where it screwed into the crosshead.

In order to keep the machine running, the disabled plunger, crosshead and connecting-rod were removed and the cylinder closed, as shown. In the illustration *A* is the



PLUNGER REMOVED AND OPENING CAPPED

plunger packing, which was not removed. *B* is a rubber gasket covering the opening in the end of the cylinder. *C* is a piece of sheet metal under the gland *D* to reinforce *B*. When these parts were assembled and tightened down, the pump was kept running with the two good ones until a new plunger could be made to replace the disabled one.

The construction of the plunger and crosshead is shown, in which the plunger screws into the crosshead which is cylindrical and runs in a bored guide.

EARL PAGETT.

Coffeyville, Kan.

Increasing the Mens' Wages

It sometimes falls to the lot of the chief engineer to approach his superior relative to an increase of pay, not for himself, but for the men of the plant. The task is not an easy one at best. Many a plant owner or manager who is personally a good boss to work for finds it necessary to put such requests "on file." Unless an engineer can show his superior why it will be good policy to increase the existing wage outlay, he will do well to refrain from asking for it.

Hard-headed business men do not increase wages without good reason. The engineer must never forget that to the man of affairs the power plant is usually incidental, and it is a mistake not to appreciate proportion when seeking to add to the payroll. The faithful work of an engineer through many years makes the presentation of recommendations a fairly easy matter so far as the continuance of friendly regard goes. "Bill says the firemen ought to have 15 cents a day more," says a manager of this kind, "and I guess he's right. He has been cutting the unit fuel cost 10 per cent. in the past six months. He tells me the peak is broadening and that we now have to run No. 6 and No. 7 boilers through the noon hour, when the boys used to ease off a bit more than they can today. Anyhow, it's Bill's job to know his men, and so long as the kilowatt-hour expense goes down, I'll back him in sharing the profits with the men."

This is not the kind of manager with which some engineers have to deal, as is shown by the following questions asked in a recent case where the chief thought his men ought to have a further advance in pay because of their faithful work, their punctuality, willingness to see the boss through any troubles and increasing familiarity with the service requirements.

"The work has not changed or increased since the last raise, has it? The men have had frequent raises in pay in the last decade, haven't they? Do you recall any class of men in your station that did not share in the previous increases? The hours have been reduced, have they not? Can you point to any specific increase in the men's efficiency since the last raise? Does the mere fact that your firemen understand English better justify this company in giving them more money? How many men have you today in this plant that were not on the payroll at the time of that last increase? Were not the men just as busy then as now? Have you any more or different machines now? Has the output increased enough to make it perceptibly harder for any man to do his daily work, and have you had to hire any more men to meet this condition? What sort of repair jobs have come up that have been handled quicker than before by the men as the result of their greater familiarity with the station and at how much less cost? Don't you pay the 'going rate' of wages in this station?"

By this time the engineer is likely to be reduced to a point where a reply is impossible unless he has anticipated just such objections. There is no use in considering the manager as a leather-hearted tight-wad, for he is only trying to protect the investor, although sometimes protecting the investor and sharing the profits may be parts of the same policy.

Operating a Pressure Pump without an Accumulator

Some time ago we installed a large pump to maintain a pressure of about 2200 lb. on the rams of a number of hydraulic presses. The accumulator on the line between the presses and the pump was weighted by building a cement block upon it. Subsequently, it was found that the weight was insufficient, and after some careful figuring the fact was brought out that it would be necessary to remove the whole cement block in order to get room to put on the pig-iron weights that our pressure called for.

This looked like a big and expensive proposition, so I advised running without an accumulator. This was objected to by the superintendent, and to my surprise the pump agent sided with him, but later they told me to go ahead and try it. I am pleased to say that after a year's operation in this way, the pump is giving good service, and I have less trouble with it than with its mate, which is attached to an accumulator.

I calculated that 88 lb. pressure per square inch, acting on the 10-in. steam piston (having an area of 78.54 in.), exerted a total pressure of 6911 lb.; operating a 2-in. plunger on the water end against 2200 lb. per sq.in. would just balance. It was therefore necessary to raise the boiler pressure slightly to overcome friction.

This pump is of the single-cylinder type, and we experienced no trouble with it until about two months ago, when the pressure fell at each stroke, and as a uniform and constant pressure is called for in our work, it was necessary to find the cause. The piping and joints were examined for leaks, the packing was renewed, the valves in the pipe lines were tested, and the pump valves were removed and inspected, but still the pressures varied. I decided that the trouble lay in the discharge valves, but was unable to see what it was.

On Sunday I thought it would not be amiss to give the valves a little grinding, although they did not seem to need it by any means. The next morning the pump acted much better and the variation in pressure was much less. Here was the cause, and a very small cause it was at that. Since then I have made a thorough job of the grinding, and the pump is giving splendid service.

While grinding does not appear to change the surface of these valves, results show that it does. I believe grooves are caused by the action of the water under high pressure, and while they are not to be detected by the eye or touch, under a glass they are easily seen. Engineers who have not had such experience will be surprised to know how rapidly water under high pressures can get through minute holes.

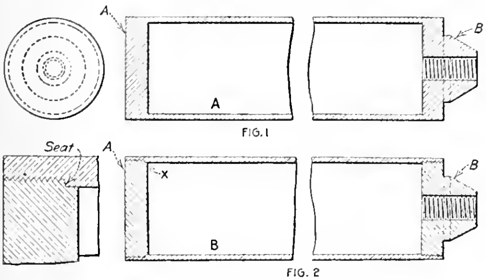
Dorchester, Mass

Renewing Pump Plungers

The illustration shows a method of renewing the plungers of an outside-packed plunger pump. Those furnished by the manufacturer are of cast brass, the shell being from 1/4 to 1/2 in. thick, according to the size of the pump and the working pressure. Fig. 1 shows the original plunger and Fig. 2 the new one. The heads *A* and *B* were cut off, turned and threaded as shown in



Pump Plunger Made of Pipe

Fig. 2. The shell was replaced by a length of extra-heavy seamless bronze pipe, seated and threaded to take the heads *A* and *B*.

The cost of the new plunger, including material and labor, is one-half that of the one furnished by the manufacturer. This difference in cost is due to the fact that in making the castings there is always difficulty in keeping them free from blow-holes, and another irregularity, the shifting of the core.

The life of the cast-brass plungers does not in any way compare with those of seamless bronze pipe, and when the latter is worn down, it is only necessary to replace the shell.

Brooklyn, N. Y.

Crankpin Failure

Referring to the article by F. F. Jorgensen, on the subject of crankpin failures in the issue of May 25, on page 720, I consider that the pin was not large enough in diameter for a cylinder of the size given (24 in.). There is an approximate moment of $2\frac{1}{2}$ in., therefore,

$$55{,}000 \times 2\frac{1}{2} = 137{,}500 \textit{ in.-lb.}$$

The section modulus of $1\frac{1}{2}$-in. diameter equals $0.98 \times 1\frac{1}{2}^3 = 8.91$, say 9.

$$138{,}500 \div 9 = 15{,}278 \textit{ lb. stress per sq.in. of pin.}$$

This is too high a stress for such work as hoisting. The normal stress should not be more than half of this, say 7000 lb. per sq.in.

The fillets are good and should be on all such pins. A still better design is to countersink the collar in the crank from one-quarter to one-half inch, and more where possible. I would suggest that a larger pin be made and put in before another accident occurs, because a larger pin is really necessary, and no doubt the crankpin box is of such design that the bore can be somewhat increased.

R. G. Cox.

Cleveland, Ohio.

The addition of fillets is undoubtedly an improvement on the old pin that failed, but the main trouble is that the pin is too small for the load. The information given indicates that the maximum pressure upon the pin was 54,000 lb. and the fiber stress in the pin at the point where it broke was 15,100 lb. per sq.in. As the stresses in a crankpin occur twice in each revolution, it is necessary to use a low fiber stress, generally between 8000 and 12,000 lb. per sq.in., according to the grade of steel. Assuming a fiber stress of 9500 lb. per sq.in., the new pin should be $5\frac{3}{4}$ in. diameter. Heat-treated or alloy steel may, of course, be subjected to higher stresses. The impact load is sometimes very high, and this is an added argument for designing the rods and pins of such engines for low fiber stresses.

A. D. Williams.

Cleveland, Ohio.

It is evident that the absence of a fillet contributed much toward the failure. In locomotive practice, failures occur even with liberal fillets. I recall a series of pin failures on 18x24-in. eight-wheel engines on a Middle West railroad at one time. The engines were some eight years old at the time, and well cared for. The back pins broke off just inside of the pin hub, and the fractures as a rule resembled the illustration shown on page 720, May 25.

The principal part of the fracture was toward the center of the wheel, a smaller break was on the outside of the pin, and the pin hub was chafed bright for one-half to three-quarters of an inch in from the face of the pin hub, indicating a bending of the pin for some time prior to fracture. The face of the fracture being quite smooth at the outside of the pin and gradually becoming coarser toward the place of final rupture, shows the characteristic fracture of the material of which the pin was composed. The original wrought-iron pins were replaced by either wrought-iron or forged steel in different engines, but both of the new kinds broke, some in as short a time as six weeks. They generally broke about one-quarter to one-third of the pin's diameter before the final rupture took place.

After the failure of the new pins of the same size as the original, the pin hubs were bored one-quarter inch larger and case-hardened pins of Low Moor iron were put in. There were no more failures for about a year afterward while I was working there. The cause of the fractures was evidently due to the thrashing of the rods at high speed, although on that type of engine we did not have any trouble from breaking main pins, notwithstanding they carried the two rods and had the piston pull to reckon with. On another road I saw a number of main-pin failures, and the fractures showed the same general features.

When the brasses are removed, a coating of white-lead paint on a freshly wiped pin will disclose cracks, the paint becoming discolored by the oil in the cracks. However, this test will be of no value where the fracture is within the pin hub.

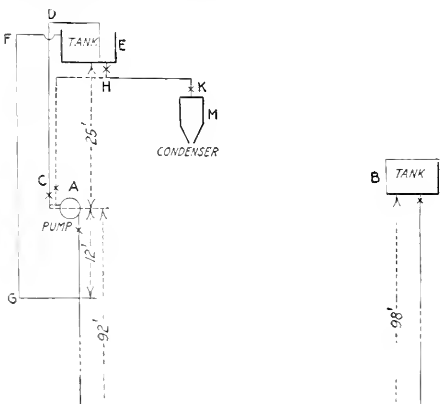
Rome, N. Y.

Centrifugal Pump Became Air Bound

The centrifugal pump *A* draws salt water from the tank *B*, through 590 ft. (400 + 92 + 98) of 12-in. pipe. When the machine is stopped there is about three pounds' pressure on the suction side at the pump.

The pump discharges through line *CD* into tank *E*. The latter supplies salt water to the condenser *M* through



Piping Diagram of Pump, Condenser and Tanks

pipe *HK*; *F* is an overflow pipe. This was intended to eliminate hand regulation of the pump discharge; if the quantity was too great it merely overflowed from the tank back through *F* into the suction of the pump. However, the water flowing back through *F* sucked in air. This was drawn through *F* into the pump, causing it to become air bound, and it would deliver no water.

Another thing contributing to the air binding was the fact that when the pump was working up to capacity there was a vacuum of about 15 in. at its suction due to the friction of the 590 ft. of piping. When this vacuum exceeded the head due to *BG*, air would be sucked in through the pipe *F*.

The above conditions were remedied by doing away with tank *E* and pumping directly to the condenser through pipes *CHK* (shown dotted) regulating the capacity by means of valve *K*.

Frank McMorrow.

New York City.

Sand for Hand Cleaning

Power-plant men usually have a hard time cleaning their hands. At our place we keep a supply of fine sand by the sink, which we apply to our hands after soaping them well. This takes the grease off without injuring the hands. I have always been troubled with chapped hands in the winter, but scouring them in the sand once or twice a day overcomes this trouble.

J. O. Benefiel.

Anderson, Ind.

An Unusual Piston Failure

In the issue of May 18, page 689, J. W. Dickson describes a unusual piston failure and asks to hear from readers who have had like experiences. A similar accident was related in Power about five or six years ago, and since then this has occurred twice in the plant of which I have charge. Both were in 22-in. pistons on low-pressure air compressors of different make. In neither case was any damage done to the compressor. In the first the damage was repaired in the way described by Mr. Dickson; in the second a new piston was required, which the builder supplied without charge.

No time was lost in finding the cause of the pounding, thanks to the article in Power, which was fresh in the writer's memory when the first failure occurred. The trouble in each case was due to core iron (used to stiffen the sand core) being left in the piston when it was cleaned, this cleaning out of the core being a difficult matter on account of the small opening provided for the purpose. The pounding was caused by the increased clearance volume.

P. L. Werner.

McKeesport, Penn.

One morning a number of years ago, a sudden loud "thump" inside of our 16x36-in. engine shook things up pretty well. The chief shut the engine down promptly, took off the cylinder head and found that a nut from one of the adjusting bolts between the bull ring and piston had worked off and worn a hole through one head of the piston and nearly through the other. These places were drilled out and plugged, after which the engine ran as well as ever.

Later we had an experience on a condenser pump similar to that described by Mr. Dickson and repaired it in the same way.

W. O. Perkins.

Bristol, Conn.

We had a very similar accident with a straight-line steam compressor. The piston in the steam end was of the built-up type, and two of the centering capscrews worked loose. One wore through the follower plate (which was one inch thick), fell out into the crank end of the cylinder, and broke the follower plate. A new cored piston was cast and put in place of the built-up type, and the compressor has since been running very satisfactorily.

P. F. OATES.

Santa Barbara, Chih., Mexico.

A Warning Sign

The illustration shows a safety or danger sign used in our plant. When the men go to work on shafting or belts they are instructed to hang this sign on the throttle valve and waterwheel gate as a warning to the engineer and others not to start any prime mover, and every man working on the job must sign his name on a pad near-by. When he has finished with his work he must cross out his name and the last man off the job is to take the sign or signs down. Our danger sign is 8x23 in., made of galvanized iron painted with aluminum, with a red border and red letters.

METAL DANGER SIGNAL

A. D. SKINNER.

Chadwick, N. Y.

Peculiar Induction-Motor Accident

I was called upon recently to repair a motor that had met with a rather unusual accident. It was a 100-hp., three-phase, 440-volt machine operating a gyratory crusher in a rock quarry. Heavy rains had caused a slide, and a rock had fallen from the quarry face through the motor room, breaking one of the leads to the auto-starter. This caused the no-voltage release to act, cutting out the motor at the auto-starter. A greater mass of rock was loosened by the first slide, and about five hundred tons crashed through the motor room, covering the motor entirely. In a short time smoke was seen coming up through the débris, and someone cut off the power at the quarry substation. Upon uncovering the motor, it was found apparently uninjured, but the auto-starter was seen to be in the "starting" position. Upon test, the motor showed forty badly burned coils.

Investigation showed that the first slide had cut out the motor safely, but the second slide (only a few seconds later) must have struck the auto-starter handle so as to throw it into the "starting" position, and to wedge it there. The motor could not start for at least two reasons: First, because one lead had been broken by the first slide, leaving the motor on single-phase; and second, because the machine was blocked by the rock from the second slide. The auto-starter was so wired that there were no fuses on the starting side, and the substation fuses were too large to relieve the motor, so it had to stand with the one phase hot, causing damage to forty coils. The auto-starter was uninjured.

The worst coils were cut out, and the others repaired so that the motor was put into commission 14 hours after the accident.

D. D. SMALLEY.

Bagley, Calif.

Single-Unit Power Plants

A short time ago the writer was asked to investigate the proposition of installing a municipal electric-light plant in a small town, and after determining as nearly as possible the probable load, it was decided that the conditions would warrant the installation of two 75-kw. units.

Several types of plants were considered, but the one which attracted special attention was the proposal to install a 125-hp. anthracite gas producer and a 100-kw. generator, to which would be connected two 2-cylinder gas engines of 70 hp. each, one on either end of the generator and connected thereto through a clutch. The principal advantage claimed for this arrangement was that, the gas engine being uneconomical at light loads, either engine could be used separately when the load was light, thus increasing the load factor toward the most economical point. Then, as the generator load rose above the capacity of one engine, the other could be cut into service and both run in parallel. It was claimed that this plan had been tried and found successful, even when running alternators in parallel, and that no trouble was experienced in the regulation.

The load to be handled was residence, store and street lighting with a small intermittent motor load on the water-works pumps. It would average about 50 kw. at the start, with a peak during the evening. The system arranged in this manner would allow one engine to be operated during the regular load, alternating every day and using both on the peak. This would also give time to keep the engines in good running condition.

Another advantage claimed was that, as only one generator would be used, the first cost would be less, including a smaller switchboard and less wiring. It was further proposed that when the load had increased to an average of 80 or 100 kw., a second unit consisting of one engine and one generator (with an additional producer) could be installed and operated at about full load. The combination unit would then be held as a reserve and used to help out on the peak load, running one or both engines as the conditions required. This plan would insure the engines' being fully loaded at all times and would reduce the coal consumption per kilowatt-hour to the lowest point.

Arguments that may be advanced against this plan are that the system consists of outside pole lines and there would be considerable danger from lightning. The generator and switchboard would of course be protected by lightning arresters, but there is a possibility that the generator might be damaged from this source, which would put the entire plant out of commission. An alternating-current generator as a rule is not as liable to be damaged, in the machine itself as a direct-current machine, there being no commutator; but trouble might develop, either in the machine itself or in the exciter, which would put the entire plant out. It is probable that no breakdown service could be provided, as the idea is to take the load away from the central station at the expiration of the franchise.

Another proposition was to install two 100-hp. boilers and one Corliss engine to operate at 125 lb. and 150 r.p.m., and direct-connected to the generator. The builder claimed that this arrangement could be depended on to run 18 or 24 hr. a day, 7 days a week, and with only a few minutes' stop once or twice a week for keying up and other minor adjustments. This would fill the requirements of the plant for several years to come or until money was available for a second unit. It must be remembered that these plans were not advocated as being the best, but to get a plant with the money available at the time the central-station franchise expired.

The greatest objections to this single-unit steam plant in addition to generator trouble is that in order to carry the peak and the increasing average load, it would be considerably underloaded a greater part of the time, and the steam consumption would be correspondingly high.

The matter has not yet been settled. Usually, it has been considered poor policy to depend on one unit for continuous operation, although the writer knows of several instances where this was done for a number of years, and the engine, as a rule, was stopped only half an hour at noon once a week, running 24 hr. a day and carrying approximately full load.

J. C. Hawkins.

Hyattsville, Md.

Another Combustion Suggestion

There appear to be two principles that might be used to improve the action of boiler furnaces in addition to those already utilized. They have been used in analogous arts and might be availed of to make the combustion of the fuel used with boilers more efficient.

The first is based on the old method of brightening a fire by means of a poker or iron. It consists in placing the iron in a dull fire where the combustion is most prominent and leaving it there. The iron accumulates and stores the heat and not only prevents the fire from dying out, but conveys the heat to other parts of the fuel. It also takes up heat that would otherwise pass off in the gases. When the iron becomes red-hot it acts like a burning coal, except that it does not burn out and stop heating.

This principle could be used in boilers by placing a number of rods across the furnace so they would come in contact with the fuel above the grate. They could even be extended along the path of the furnaces through the boiler parts, so that the gases would have heat supplied to them during the entire period. The rods, being conductors, would supply heat to the gases at all points at about the same temperature as they (the rods) were at, in the furnace. The rods would deteriorate, but that would not of itself be an argument against their use.

If the rod was hollow, particularly in the portion that was in the furnace, it could be used to convey the draft or air to the furnace where it was needed and without cooling the fire, and at the same time the air would tend to keep the rod sufficiently cool to prevent melting.

The second principle consists in using materials that will raise the temperature of the fire and that do not burn themselves—for instance, chalk, unglazed ware, etc. This principle is like that used in an incandescent gas burner. It might be employed by mixing the material with the fuel or by installing it in some back part of the furnace so as to heat the gases or promote combustion in some special part of the boiler. In any case, it would serve to increase the efficiency of the fuel used and to stabilize the operation of the boiler in somewhat the same way that a flywheel does the action of a reciprocating engine.

These are theoretical suggestions. Can they be made of practical use?

A. P. Connor.

Washington, D. C.

Differential Draft Gage

Differential draft and air-supply gages are inexpensive in comparison with the saving they represent. Time is well spent in their upkeep. Imperfect connections to furnace or ashpit thwart their purpose.

Water has too variable a capillarity to be employed as an indicating fluid. Kerosene may be used in an emergency. The best liquid is a mineral oil of 39 degrees gravity, Baumé scale, at 60 deg. F. and specific gravity about 0.834. This oil evaporates slowly, is a good lubricant and will recede to the zero mark. To set the differential gage both ends should be free to the atmosphere. The liquid should be poured carefully into the reservoir end until the zero mark has been reached.

No set of rules can be laid down as to the amount of draft to be carried, as load, fuel-bed thickness and other factors affect each case differently. A near approach to a balance seems to be the aim in many plants. It is true that a high degree of perfection in combustion can thus be attained and a high CO_2 record made, but for practical operating conditions I prefer at least 0.02 or 0.03 in. of water over the fire. Of course, a pressure of 0.06 or 0.07 in. or even 1.02 in. under the fire will do no harm if the firebed is well sealed.

Edward T. Binns.

Philadelphia, Penn.

Removing Scale from Oil-Engine Jacket

Operators of oil engines often experience trouble with the cooling water scaling up the cylinder jackets; in fact, in some localities the jacket almost fills with scaly deposits in a few weeks. The method usually employed is to allow a dilute sulphuric-acid solution to remain in the jacket for a few hours, thereby loosening the scale. This is effective, but rather severe on the cylinder walls.

A short time ago the writer met with this trouble and eliminated it by using graphite mixed with oil and placed in an ordinary hand oil pump connected to the cylinder jacket. The engineer operating this engine gives the pump two or three strokes a few times each day. It seems that the graphite acts upon the jacket in the same manner as on boiler tubes.

L. H. Morrison.

Fremont, Neb.

Inquiries of General Interest

Estimating Piston Speed of Duplex Pump—In a duplex pump how is the piston speed determined from the length of stroke and the number of revolutions per minute?

F. P. K.

The term, piston speed, has reference to the average velocity of the water pistons, and when each side makes the same length of stroke the average piston speed in inches per minute would be found by multiplying the length of stroke in inches by two, and by the number of revolutions per minute. This product divided by 12 would be the average piston speed in feet per minute.

Drilling Small Holes in Glass—What is a good method of drilling small holes in glass?

G. W. K.

Small holes can be drilled in glass by employing a flat drill lubricated with turpentine. In drilling small holes through thin glass, care should be taken that the drill does not break through and therehy shatter the glass. Where possible, the drilling should be done from both sides. Another method is to employ a drill made of brass pipe having its end cut off square and one or more slots in its side for the introduction of flour of corundum.

Stability and Isochronism of Governors—What is the difference between stability and isochronism of steam-engine governors?

G. R.

A governor is said to be stable when it assumes a definite position for each particular speed and when a change of speed is necessary for a change of position, while a governor which is in equilibrium at but one speed is said to be isochronous. Perfect isochronism would be impractical, as the slightest increase in speed above the normal would result in cutting off the steam, accompanied by a sudden decrease of speed, following which the steam valve would open wide, thus giving rise to extreme fluctuations.

Water Hammer in Steam Pipes—What is the explanation of water hammer in spaces containing steam, and particularly the snapping and cracking noise often heard in steam pipes?

R. W. R.

Water hammer is attributed to the impact of particles or slugs of water upon each other or against the sides of a pipe or other containing vessel, due to the formation of vacuous spaces that result from cooling and condensation of the steam. Water is comparatively incompressible, and a continuation of the high velocity of the steam toward such a vacuous space after condensation has taken place and the movement of slugs of water toward those spaces at high velocity by the elastic force of the steam result in violent impacts, similar to those occurring when inelastic bodies impinge upon each other at high velocities.

Size of Steam Pipe—Allowing a velocity of 5000 ft. per min., what diameter of steam pipe would be required to pass 6500 lb. of steam per hour at a gage pressure of 80 lb. per sq.in.?

B. E.

Referring to the steam tables, it is found that the specific volume of dry saturated steam at 80 lb. gage, or 95 lb. absolute, is 4.65 cu.ft. per lb., and as the flow would be

$$6500 \div 60 = 108.33 \text{ lb.}$$

of steam per min., the volume flowing per minute would be

$$108.33 \times 4.65 = 503.73 \text{ cu.ft.}$$

and the required cross-sectional area of the steam pipe for a velocity of 5000 ft. per min. would be

$$\frac{503.73 \times 144}{5000} = 14.5 \text{ sq.in.}$$

which corresponds to

$$\sqrt{\frac{14.5}{0.7854}} = 4.28 \text{ in.}$$

diameter, and therefore 4½-in. steam pipe would be the nearest commercial size suitable.

Relative Merits of Belt Dressings—In what particulars should the relative merits of belt dressings be considered, and how can they be practically compared?

E. W. C.

The leading merits of belt dressings consist in (1) increasing the coefficient of friction between the belt and the pulley, enabling transmisison of a given power with a lower belt tension; (2) increasing the pliability, and (3) prolonging the life of the belt. The relative friction can be practically determined by treating each half of the length of a belt with one of the dressings or by applying the dressing to only one half for comparison with an untreated half, and, with the belt in use, observing which half first shows slippage when the belt is gradually loaded to its transmitting capacity. Or, after use for some time, the relative coefficients of friction can be approximately determined by alternately hanging the belts over the same pulley, and determining which condition requires the greater load to be suspended from the belt over one side of the pulley to slip the belt in raising a given weight suspended from the belt over the other side of the pulley. Relative pliability is made apparent by observing which belt forms a smaller loop when folded over on itself, or when equal lengths of each belt are gathered and suspended. The effect of dressing on durability of a belt can only be determined by test of time and usage.

Volume of Air for Burning a Pound of Coal—What volume of air is required for combustion of a pound of coal?

J. R.

The weight of air required is given approximately by the formula,

$$\text{Weight of air in pounds} = 12C + 35 \left(H - \frac{O}{8}\right)$$

in which C, H and O represent the parts of a pound of carbon, hydrogen and oxygen in a pound of the coal.

Applying the formula to the analysis of most coals will show that about 12 lb. of air is required for combustion of a pound of the fuel, and as one pound of air at 62 deg. F. has a volume of 13.14 cu.ft., then 12×13.14, or about 158, cu.ft. of air will be required to burn each pound of the fuel. For certainty, however, that the carbon will meet with an abundance of oxygen, it becomes necessary to admit an excess of air, depending on the draft, and the weaker the draft the more the excess required. Hence, with chimney draft it is usual to supply about 300 cu.ft. of air per lb. of coal, and with forced draft about 200 cu.ft. of air per lb. of coal.

Discharge of Water from Hydrant—What quantity of water would be discharged per minute through a short 2-in. pipe connected to a fire hydrant in which the pressure is 60 lb. per sq.in.?

M. A.

The rate of discharge would depend upon the roughness and length of the pipe and the pressure at the entrance of the pipe. Assuming that the pressure 60 lb. per sq.in. is maintained while discharge is taking place, then as 60 lb. per sq.in. would be equivalent to

$$60 \times 2.3 = 138 \text{ ft. head}$$

and as the theoretical velocity in feet per second due to the head would be given by the formula,

$$v = \sqrt{2gh}$$

in which

v = Velocity in feet per second;
g = 32.16, the acceleration of gravity;
h = 138;

then,

$v = \sqrt{64.32 \times 138}$, or about 94.2 ft. per sec.

If the pipe has a smooth bore and a length 3 to 3½ times its diameter, that is, 6 to 7 in. long, and has a smooth, square entrance end, then the actual velocity of discharge will be about 81 per cent. of the theoretical, and as the cross-sectional area would be

$$2 \times 2 \times 0.7854 = 3.1416 \text{ sq.in.}$$

the discharge would be approximately

$$\frac{0.81 \times 94.2 \times 12 \times 3.1416 \times 60}{231} = 747 \text{ gal. per min.}$$

It is assumed that the pressure at the entrance of the 2-in. pipe is ascertained from indication of an accurate pressure gage during the discharge, as that pressure is not to be confused with the static pressure which exists only when no discharge is taking place.

National Electric Light Ass

With a registration of over one thousand, the thirty-eighth annual convention of the National Electric Light Association at San Francisco, June 7-11, was an unqualified success. The eight-story building, "Native Sons of the Golden West," served as headquarters for registration and meetings, and the Hotel St. Francis, adjoining, cared for most of the delegates and was the center of the social features of the convention, especially the reception given on Monday night by the president, H. H. Scott. On the same evening was dedicated the "Temple of Light," an Ionic colonnade erected around the Dewey monument in Union Square. This was turned over to the visitors by John A. Britton on behalf of the local members, and President Scott accepted it on behalf of the convention.

At the opening session on Tuesday morning, the visitors were greeted by Mayor Rolph, of San Francisco, and by John A. Britton, general manager of the Pacific Gas & Electric Co., who briefly outlined the progress of the Pacific Coast States, with special reference to the important part played by electricity in their development.

Response was made by President Scott, who in the course of his address pointed out the great decrease in the price of electric service during the past 15 years, whereas the price of most commodities had increased. This had been due to increased efficiency in production and to more efficient lighting, the public having derived the benefit.

The remainder of the morning was taken up with the reports of the secretary and of several committees. T. C. Martin, as chairman of the Committee on Progress, dealt with the present conditions of the electrical industry, pointing out a steady increase in spite of the recent business depression, although there have been practically no additions to the number of large central stations during the past year. The second part of the report (read at the hydro-electric session) was devoted to hydro-electric and transmission work, and discussed the pending national legislation on conservation. It suggested that the law be framed so that the banker shall know reasonably well to what extent the investor is protected and to what extent he must accept risk. Opinions were quoted from a number of men associated with hydro-electric work, notably Hugh L. Cooper, who stated that within the past 10 or 12 years hydro-electric plants aggregating over 600,000-hp. capacity had either been through receivership or had proved bad investments.

FIRST TECHNICAL SESSION

The first technical session was held on Tuesday afternoon, at which were read the reports of the committees on Meters, Electrical Apparatus, and the Grounding of Secondaries, as well as two papers—one on "Application of the Diversity Factor," by H. P. Gear, and the other on "Features of the Lighting of the Panama-Pacific Exposition," by W. D'A Ryan, illuminating engineer of the Exposition.

In the report on electrical apparatus, attention was called to the introduction of the phase-advancer in performing the same functions as the synchronous condenser in connection with inductive motor loads. While condensers serve primarily for regulating a complete installation, the phase-advancer provides an economical means for regulating the power factor of an individual motor. Among the recommendations of the committee were the use of electrolytic arresters with rotary converters and suitable methods of grounding the converter frames. Modifications of the rules of certain member companies to conform to those of the majority with regard to motor connections was urged, as this would greatly simplify the problems of manufacturers and distributors of standard commercial motors.

FIRST ACCOUNTING AND COMMERCIAL SESSIONS

Simultaneously with the first technical session were held the first accounting session and the first commercial session. The order of business of the former included an address by the chairman, H. M. Edwards, and reports from the Library Committee, the Question Box Committee, the Committee on Uniform System of Accounts, and a paper by L. R. Reynolds on "Some Opportunities of Public-Utility Accountants."

The commercial section, after listening to an address by the chairman, Douglas Burnett, heard the reports of the committees on Foreign Relations, Finance, Publications, the Education of Salesmen, and the Commercial-Department Terminology.

On Wednesday morning the association listened to an address by President Moore of the Panama-Pacific Exposition, who reviewed the hydro-electric development on the Pacific Coast and spoke of the electrical illumination at the Exposition. He said that about 850 conventions had chosen San Francisco for their place of meeting this year.

Following President Moore's address were held the first hydro-electric and second technical sessions, the second commercial session and the second accounting session. Chairman Wagner called to order the hydro-electric and technical sessions and the report of the Hydro-electric Committee was read by Mr. Downing, in the absence of the chairman, R. Bump.

REPORT ON PRIME MOVERS

The report of the Committee on Prime Movers was next read by Mr. Coldwell, in the absence of Chairman Moulthrop. The report called attention to the improvements in the design of surface condensers during the past year and also to the increased economy obtained by large steam turbines. Two new stokers of the underfeed type for high capacity were described, and considerable space was devoted to the subject of economizers. The steady increase in the rate of evaporation, with a consequent increase in the volume and velocity of the flue gases and a somewhat higher temperature at the boiler exit, together with the improvement of condensing apparatus, producing lower vacuum and lower hotwell temperatures, have created conditions more favorable to the use of economizers. Under "Gas Power," figures were quoted to show that there are vast quantities of fuel-oil in the United States and in Mexico and that there is much activity in Diesel-engine work among American manufacturers. The gas-engine situation however, seems to be little changed from that of last year; this also applies to the gas producer.

In discussing the report, Henry Hull, of the Puget Sound Traction, Light & Power Co., of Seattle, stated that it had been the experience of his company in burning low-grade, highly volatile lignites, such as are available on the Pacific Coast, that the best results were obtained by the use of continuous chain grates of large area installed in furnaces with dutch ovens. He believed it imperative that the coal be of uniform size to prevent occurrence of holes in the fuel bed and to secure a uniform fire; also that it is necessary, in using a chain grate, to employ a free-burning coal, as any tendency to coke will give trouble from jamming and piling up at the back of the furnace.

ciation At The Exposition

In the speaker's opinion, the use of economizers depends entirely upon the individual conditions. In plants operating with steam-driven auxiliaries and where leaks in boiler settings are minimized and baffling kept tight, the advisability of installing economizers appears doubtful. He believed that if more attention was given to utilizing the heat in the boiler itself, the results would tend to offset the desirability of the economizer.

A written discussion by Professors Rosencranz and Phillips, of the Oregon Agricultural College, dealt with the control of combustion when burning oil fuel. The authors pointed out that the combustion of oil is practically an instantaneous process, and assuming the ratio of oil to air to be correct with a uniformity of mixture and the proper combustion space, maximum efficiency of combustion will result. An instrument showing the instantaneous rate of flow of the air and oil to the furnace would go far to solve this problem. The CO_2 recorder has been a big help in this respect, but it is handicapped by the fact that it is from three to ten minutes late in its indications, which is a disadvantage on variable loads. It was pointed out that the boiler itself could be made its own gas or air meter by attaching a differential draft gage, one end to the combustion space and the other end beyond the last pass. This would measure the boiler resistance, which will be different for every rate of flow, and hence be an indication of the rate of gas flow through the boiler.

Mr. Philip Torchio, in discussing economizers, gave the results of some observations made in Europe about a year ago, to the effect that a considerable saving, probably as high as 8 per cent. in fuel consumption, was possible under certain conditions by the use of economizers. However, the whole equipment of the station must be laid out for such use of economizers. He believed that in this country it would probably be difficult to apply the economizers without changing the auxiliaries and drafts of the boilers, which would make the problem quite expensive. In new stations, however, he believed that economizers could be used profitably by designing them for use with the stacks of the Epozee type, in which air is blown into the stack and creates a draft as in the case of a steam injector. He called attention to the difference between European and American practice, in that the former employed motor-driven auxiliaries almost exclusively.

F. H. Varney, of the Pacific Gas & Electric Co., discussed the use of soda ash in the boilers, his contention being that if air is kept out of the boilers there is no need for soda ash to prevent pitting. For this reason his company has adopted the open type of heaters.

Appended to the Prime Movers' report was a paper by C. M. Allen, which discussed weirs, current meters, pitot tubes, venturi meters, floats, waterwheels and meters, the moving-screen method of measurement, and the salt-solution method. Briefly, the latter method consists of discharging a known amount of salt solution into the water before it passes through the wheel, then analyzing the water as it discharges from the wheel, and from accurate chemical analysis determining the total amount of water discharged by the wheel. Another method was also cited, of injecting color into the conduit close to the forebay and measuring the time elapsed until the color appears in the tailrace.

Professor Peaslee, in discussing Mr. Allen's paper, described a conductivity meter for measuring the flow by the salt-solution method without chemical analysis.

The next paper was entitled "Practice in High-Head Hydraulic Plants," by J. P. Jollyman, of the Pacific Gas & Electric Co., who reviewed the present practice along the Pacific Coast, pointing out that this favors the use of steel pipes with either riveted or welded joints. Expansion is usually provided for by long-radius bends, rather than slip joints, which are employed only where the pressure is not excessive. For heads up to 700 ft. and specific speeds as low as 12, Francis turbines were recommended, and impulse wheels for heads up to 3000 ft. or over, with specific speeds as high as 4 for heads up to 2000 ft. He considered the most desirable speed for waterwheel-driven generators of 3000 to 15,000 capacity to be about 400 r.p.m.

In discussing Mr. Jollyman's paper, M. T. Crawford referred to two 10,000-kw. generators in the White River plant of the Puget Sound Traction, Light & Power Co., which were originally fitted with the usual fan type of rotor for sucking air along the shaft and forcing it out through the windings on the stator. With this equipment the machines carried a rated load with a normal temperature rise of not over 40 deg. C. above the incoming air. It was found, however, that on warm summer days the temperature of the air to the generator room reached as high as 35 deg. C., and any overloading of the machines would give a fairly high temperature in the windings. Accordingly, the generators were inclosed and the incoming air taken from inclosed spaces above the tailrace outside the building. A number of spray nozzles are kept playing in these inclosed spaces, so as to greatly increase the humidity, and the air goes in at a temperature of about 17 deg. C. The generators can now be operated satisfactorily at 40 per cent. overload, and the temperature is cut down to 40 deg. between the laminations and the incoming air.

"Analysis of Waterwheel-Governor Efforts" was the subject of a paper by E. D. Searing. This gave a résumé of an interesting series of experiments made in analyzing a governor problem at one of the hydro-electric plants of the Portland Railway, Light & Power Co. Steam-engine indicators were connected to each end of the governor cylinder of the waterwheel unit, and continuous records of the varying pressures from each side of the governor piston throughout one cycle of operation were obtained. An analysis of the effort of separating friction and unbalance was made, and the rise of pressure in the wheel casing, high pressures in the governor cylinder, overspeed devices and wicket gates themselves, were thoroughly studied.

The next paper was on "Oil-Burning Standby Plants," by C. H. Delany, of the Pacific Gas & Electric Co. This paper will be abstracted in a later issue. In discussing Mr. Delany's paper, E. A. Weymouth mentioned an installation at the plant of the Inspiration Copper Co., in which the boilers are equipped with steel casing and most thoroughly insulated. The boiler efficiency at three-quarters load is higher than at full rating, and at one-half load it is higher than at three-quarter load. This is explained by the fact that radiation is much greater in the case of the ordinary brick setting; and as it is a practically constant quantity for all loads, at light load it will be proportionately greater. The absorption of heat by the heating surfaces is better at light load, but with a brick setting the radiation loss offsets this. With the steel casing, however, and a proportionately less radiation loss, this does not hold true to such an extent, with the result that the efficiency is nearly 2 per cent. better at half load than at full load.

The last paper of this session was by D. M. Downing, on the "Water-Power Development on the Pacific Coast." This gave a general review of the whole subject and was fully illustrated.

SECOND COMMERCIAL AND ACCOUNTING SESSIONS

The second commercial session, also held on Wednesday morning, took up the report of the Committee on Sales Development in the West, and that of the committee on Merchandising and Recent Development of Electric Appliances. At the second accounting session, an interesting paper on "Workmen's Compensation Insurance" was read by Walter G. Cowles, vice-president of the Travelers Insurance Co. He expressed the opinion that the stock-insurance system is the only one that furnishes reliable means for reducing future losses to present fixed values. "European practice," he said, "along compensation lines, can teach us little or nothing, because the conditions there and here are widely different."

Following this was a paper on "Electric-Vehicle Cost Accounting," by W. P. Kennedy, and another on "Record of Property or Construction Expenditures," by T. R. Ferguson.

SECOND HYDRO-ELECTRIC AND THIRD TECHNICAL SESSIONS

The hydro-electric and technical sessions were continued on Wednesday afternoon, the order of business including the report of the Committee on Overhead Line Construction, a paper on "Electric Line Distribution in the Pacific Northwestern States," by J. C. Martin, the reports of the Hydro-Electric Sub-Committees on "High-Tension Transmission and Construction," on "High-Tension Apparatus," and on "Main-Line Electrification of Railroads."

On Thursday morning the fourth and concluding technical session took up the report of the Committee on Terminology and that of the Committee on Street Lighting, the latter prepared by J. W. Lieb, of the New York Edison Co., covering a digest of the information made available through an investigation of the street illumination which has been conducted in New York during the past year. M. J. Insull presented the report of the Committee on Accident Prevention, and Mr. Torchio that of the Committee on Underground Construction. The final paper of the session was on "Opportunities of the Public-Service Company in General Accident Prevention," by C. B. Scott, of the Chicago Middle-West Utilities Co.

The third accounting session considered the report of the Committee on Cost Accounting, a paper by O. B. Coldwell on "Analytical Accounting for Central-Station Purposes," and another paper by W. E. Freeman, on "Statistical Machines."

Reports of the Rate Research Committee and the Power Sales Bureau were considered at the fourth commercial session, as well as three papers—"The Commercial Application of Resistance Furnaces," by C. W. Bartlett, "A Stassano Furnace Installation at Redondo," by W. M. McKnight, and "Electric Furnace Power Loads," by F. T. Snyder.

On Thursday evening the Public Policy meeting was held, at which the report of the Public Policy Committee was presented by W. W. Freeman, and addresses were made by Max Thelen, of the Railroad Commission of California, and by John H. Roemer, a former member of the Wisconsin Railroad Commission.

ENTERTAINMENT FEATURES

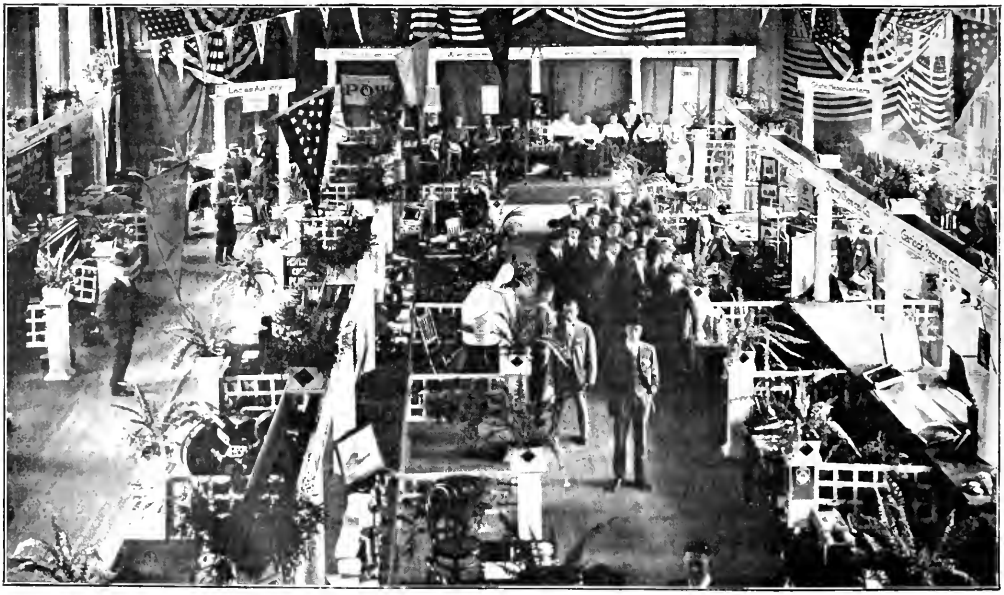
Members of the National Electric Light Association attended the Exposition in a body on Thursday afternoon, where a photograph was taken in front of the Tower of Jewels. The ceremonies were held in Festival Hall, and addresses were made by President Moore of the Exposition, President Scott of the Association, Samuel Insull, Arthur Arlett and Mayor Rolph; and greetings were read from Thomas Edison, Alexander Graham Bell, Elihu Thomson, Frank J. Sprague, Charles P. Steinmetz, Charles M. Brush, and J. J. Carthy. President Moore presented President Scott with a bronze medal commemorative of the convention.

The entertainment features also included a musicale and tea for the ladies on Wednesday afternoon, an automobile trip Thursday morning and luncheon at the Cliff House, after which they joined the men at the Exposition in the afternoon. Friday was spent on an all-day sightseeing trip to Mount Tamalpais and the Muir Woods. Special credit is due to F. H. Varney, chairman of the local entertainment committee, for unusual thoughtfulness in providing for the comfort and convenience of the guests.

E. W. Lloyd, general contract agent of the Commonwealth Edison Co. of Chicago, was elected president of the association for the coming year.

New Jersey N. A. S. E. Convention

While it was generally known that the Trenton convention of the New Jersey N. A. S. E. would consider important association affairs, no announcement had been made that the exhibit was to be one of the best-arranged and attended displays of engineering supplies ever connected with a state convention of the association. The exhibit, held in Masonic Hall, was opened to the public on Thursday, June 3, by Mayor Frederick W. Donnelly, with an address of welcome. A feature of the opening evening was an automobile tour of the



New Jersey N. A. S. E. Convention Exhibit Hall city "engineered" by the Mayor and Frank V. Tuthill, of the McLeod & Henry Co., and enjoyed by a number of engineers and supplymen.

The business sessions were held June 5 and 6 in the Trenton House, with Charles Sumner, president of the association, in the chair. About a hundred delegates attended. National Vice-President Walter Damon, of Springfield, Mass., and James Taylor, secretary-treasurer of the Life and Accident Department of the association, addressed the delegates during the Saturday session.

The Educational Committee reported that depressed business conditions had caused a slight lull in the educational activity of the various local associations; this was not serious, however, as the state committee had made special efforts to keep the smaller and most-in-need-of-help associations interested, with the result that their educational work on the whole was more commendable than that of the larger associations. The committee expressed the belief that there was no more thorough and inexpensive way of creating educational interest than by question-and-answer contests held by each association. Many associations have received valuable assistance from a pamphlet written by the instructor for Newark No. 3 Association. These "Examination Questions" are to be obtained by addressing No. 3 at 103 Market St., Newark, N. J.

The Legislation Committee handed in a short report at the Sunday session. A. L. Case, chairman of the board of examiners of the State Engine and Boiler Operators' Bureau, pointed out some of the defects in the present license law and read passages from a proposed bill that was vetoed by the governor. The law as it now stands reads that "the provisions of this act shall not be construed to include or apply to men holding marine licenses or to men in plants under the jurisdiction of the United States Government, or to locomotive engineers." Many of these engineers were refused licenses because the attorney-general handed down an opinion that they could not be lawfully given to them. The law needed amending when an engineer holding a license to run a dinky tugboat could operate the largest plant in the state and be immune from any action the license bureau might take. The vetoed bill also provided for a well-deserved increase in the salaries of examiners, from $1200 to $2000 a year. The convention adopted a resolution introduced by Newark No. 3 which embodied the amendments needed in the present law and stated that the governor's veto of the bill was the result of snap judgment. This resolution was ordered printed and circulated.

The next convention of the New Jersey State Association will be held in Paterson, N. J

Both Joseph Carney and William Reynolds, members of the National Board of Directors, refuted the rumor that the "National Engineer" was subsidized by central-station interests. A resolution was passed and ordered circulated embodying their denials.

Saturday a smoker and cabaret were given by the supplymen under the direction of Frank Martin, of Jenkins Bros., at which, among others, appeared the well-known but always entertaining trio—Jack Armour, Billy Murray and Herbert Self. The new officers elected are: President, Dennis Bartley, of Jersey City; vice-president, Thomas Brown, of Newark; secretary, James S. Heath, reëlected; treasurer, William Krause, of Passaic. During the convention the ladies sold cigars, candy and tags and otherwise added to the pension fund for indigent engineers. Mrs. McCoy, state deputy for the ladies' auxiliary, gave an interesting report of the doings of the state and national bodies.

A list of the exhibitors follows:

Albany Lubricating Co.
Cherry Chemical Co.
Corbett, E. A.
Crew, Levick & Co.
Crook & Son, A M
Dearborn Chemical Co.
Dick, R. & J.
De Laval Steam Turbine Co.
Engineering Supply Co.
Fisher & Norris.
France Packing Co.
Garlock Packing Co.
Greene, Tweed & Co.
Home Rubber Co.
Homestead Valve Co.
Industrial Requirements Co.
Jenkins Bros.
Johns-Manville Co., H. W.
Keystone Lubricating Co.
Lunkenheimer Co.
McArdle & Co.
McLeod & Henry Co.
Morehead Manufacturing Co.
"National Engineer"
Ohio Blower Co.
Otis Elevator Co.
Peerless Rubber Manufacturing Co.
Philadelphia Grease Co.
"Power."
Quaker City Rubber Co.
Reeves-Cubberley Engine Co.
Clement Restein Co.
Richardson Scale Co.
Robinson Co., W. C.
Roto Co., The
Roebling's Sons Co., John A.
Squires Co., C. E.
Stahl, Harry E.
Standard Regulator Co.
Steam Appliance Co.
Underwood & Co., H. B.
Webb & Sons Co., Elisha.
Zurn Oil Co.

Following the schedule of fittings and flanges published on page 782, June 8, 1915, the address of the National Association of Master Steam and Hot Water Fitters should have been given as 260 West Broadway, New York City.

Seventh Annual Convention of National District Heating Association

On June 1, 2 and 3, the seventh annual convention of the National District Heating Association was held at the Sherman Hotel, Chicago. The meeting was a great success. The papers and committee reports presented were of a high quality and indicated a vast amount of work in their preparation by practical men engaged in the heating business. The material presented was received with enthusiasm and discussed at length. The association has made wonderful progress since its inception six years ago, and a continuation of the present interest and enthusiasm will insure results of inestimable value to the field of district heating.

On Tuesday morning President H. R. Wetherell called the first session to order. Harry Miller, prosecuting attorney, in behalf of the mayor, welcomed the visitors to the city. The response was made by D. S. Boyden, first vice-president of the association. In his presidential address Mr. Wetherell believed the day had come when steam heating should not be regarded as a byproduct of the electrical end of the plant. It was up to the association to put heating on a paying basis. The public-service commissions of the various states were already insisting that the heating be made independent of the electrical plant so that the low rate formerly made in connection with lighting would be eliminated. By putting customers on a meter basis the consumption of steam would be greatly reduced over the old flat rate and the cost would be lowered to a reasonable figure. It was important to give strict attention to service and in every way possible satisfy the customer.

Secretary Gaskill reported the association in better financial condition than ever before and an increase of 44 members, which was 14.66 per cent. of the membership in 1914. He advised the election of honorary members and recommended that a suitable badge be presented to the retiring president. At the end of the session A. P. Biggs, chairman, presented the report of the station record committee. This dealt principally with franchises. Copies of franchises under which 25 different companies were operating had been obtained and the contents had been spread on a large data sheet, which was available at the convention. A collection and comparison of such data, it was thought, would eventually result in a standard franchise. A table on the steam consumption of various classes of building and the cost of trenching was in course of preparation and would be appended to the report before it appeared in the "Proceedings."

At the opening of the afternoon session J. F. Gilchrist, vice-president of the Commonwealth Edison Co., of Chicago, gave an interesting address on steam heating and the advantages of concentration in the generation of electricity and steam. As heat was one of the requirements of the race, it was evident that the heating business was founded on a solid foundation. It was one of the fundamental things human beings required, and in this respect was a little ahead of its big brother, the lighting and power business. In establishing central heating in Chicago, there had been no special foresight. The company had been forced to it. When they attempted to displace the isolated plant, it became evident that they must know something about the heating business and be in a position to furnish heat. The speaker explained how the Illinois Maintenance Co. had been founded in 1899 and how it had been built up to its present proportions. No comprehensive system had been laid out. It was arranged so that the electric-light contract for a building included the right to operate the plant in the basement to furnish steam for heating and to connect the plant with the piping of the adjoining building. Eventually, the piping was carried across alleys and in some cases streets, so that at the present time there are several plants taking care of a number of buildings. Mr. Gilchrist touched upon the importance of metering the steam, so that it would be to the interest of both the seller and user to minimize the consumption.

Although the possibilities of concentration in the heating business were not so great as in the generation of electric current, the following advantages were enumerated: The reduction of smoke, the possibility of obtaining high-grade labor from which higher economy might be expected, a decrease in the fire hazard and a reduction in the expenditure for handling fuel and ash.

In the United States 517,453,000 tons of coal was consumed per year. Of this amount central stations used 17,375,000 tons, street- and electric-railway plants, 10,078,000 tons; steam railways, 100,000,000 tons; and all other uses, 390,000,000 tons. Electric light and power and street railways only consumed 5 per cent. of the fuel. If the hydro-electric output was reduced to a steam basis this would account for 17,-

000,000 tons, so that the entire electrical output would only require 44,000,000 tons per year, or less than 10 per cent. of the total. The speaker expressed a desire to see a comparison of the work done in the different fields. It was certain that outside of the electric light and power business the coal is burned much less efficiently. Coal for domestic use was estimated at 50 to 100 million tons, leaving the remainder for heating and industrial purposes. By concentration much of this coal could be saved or at least be held to the same figure notwithstanding the increase of population. It was the speaker's opinion that there will in the next few years be a great development in the heating business. The importance of this service in connection with light and power will become greater in the years to come. The distribution of heat was a natural monopoly, and it should be permitted to act as such. It should be made independent of lighting and power and should come under the same regulating bodies as the central-station companies.

REPORT OF PUBLIC-POLICY COMMITTEE

Recognizing the desirability of all utilities following some form of general policy, the association has a standing committee on this subject. In the report presented the following items were briefly considered: Education of the public as to cost and advantages of heating service, extension, appraisal, rates, municipal ownership, legislation and franchises. The comments were general, leaving it to future years and committees to elaborate and definitely design the policies that should be pursued as conditions change and future developments require.

UNDERGROUND CONSTRUCTION

At the Wednesday morning session H. A. Woodworth presented the report of the underground construction committee, which was prepared to give the society the benefit of the best practice that the present day affords in the selection of materials and the installation and operation of district heating mains. Letters had been written to various companies affiliated with the association asking for particular data which they possessed. The replies showed a wide variation in the methods used throughout the country, and a study of the data indicated that these variations were not due to the geographical location or climatic conditions. It was clear that one of the greatest needs was a closer attention to standardization. In the report the various items relating to the design, construction and operation of mains were discussed briefly. Most of the data had been drawn from the letters, but other data had been received from outside sources. Items requiring research work, such as the design of high-pressure steam feeders and tests on automatic valves as they affect line capacity, were turned over to authoritative persons to insure accuracy in the results. In an appendix to the paper, descriptions were given of the underground insulations and conduits as they are placed upon the market by the various engineering and manufacturing companies.

BLEEDER TURBINES

Following an extended discussion on Mr. Woodworth's paper, F. W. Laas read a short paper on operating experiences with bleeder-type turbines. As a preliminary the author related an experience he had had with a 1500-kw. turbine of this type, also an experience with a cross-compound condensing engine supplying steam from the receiver for heating and eventually from the exhaust of the low-pressure cylinder against a maximum pressure of 25 lb. Mr. Laas enumerated the features a successful bleeder turbine should possess, some of the points to be watched in its operation and by means of data from specific cases explained the operating advantages of this type of turbine.

EDUCATIONAL COMMITTEE REPORT

At the afternoon session Wednesday, D. S. Boyden summarized the report of the educational committee. The work had been divided among the various members of the committee as follows: The establishment of a standard for transmission losses from buildings of all constructions, Reginald Pelham Bolton; the establishment of standard methods of proportioning direct radiation and standard sizes of steam and return mains, James A. Donnelly; the establishment of a standard coefficient for heat losses affected by wind movement, H. W. Whitten and R. C. March; the establishment of standard heating elements for cooking apparatus, with special reference to low-pressure steam, D. S. Boyden.

Mr. Bolton's contribution to the report brought out the wide variation in the hitherto accepted bases of computation. The various transmission losses through building materials were presented in tabulated form, with several suggestions for further observation, which may help to determine these losses definitely.

Mr. Donnelly's report was devoted mainly to the data required in estimating the heat requirements for buildings. It opened with tables of heat losses through building materials, including the losses through various thicknesses of concrete. These were followed by rules for estimating the amount of air required for ventilation. Under transmission from radiating surfaces a useful table was incorporated giving the relative surface in pipe coils and wall radiators. Another table showed the comparative transmission from a standard direct radiator at various steam temperatures. This was followed by a table giving the proportionate amount of radiation required to heat a room to 70 deg. F. from various outside temperatures, with steam in the radiator at 210 deg. F. A feature of many of the tables was that proportional requirements were given for conditions varying from the usual standard of 0 deg. outside and 70 deg. inside. Considerable space was devoted to the operation of gravity hot-water heating systems, vacuum-steam heating systems, forced hot-water heating systems and vacuum-vapor heating plants. In the section devoted to standard sizes of steam mains, a table of steam-pipe sizes based on the Unwin formula was included. Another table gave the comparative carrying capacity of pipes, so that after one size is figured for a certain condition, capacities of all other sizes may be readily obtained. At the conclusion of the report data were given on standard sizes of radiator connections and return mains, with a table showing the standard rating for steam mains as well as the standard for wet returns and for various percentages of steam carried in dry returns, figured for a drop in pressure of 1 oz. to 100 ft. of straight pipe.

A close study of the records of the Public Service Co. of northern Illinois for the past two years, in connection with other data referred to in last year's report, enabled the members of the committee having the work of determining the effect of wind on heating to obtain data from a large group of buildings of varied construction. The constant given last year was modified and now may be used safely, allowing for certain factors which may affect isolated cases.

The report by D. S. Boyden on standard heating elements for low-pressure cooking apparatus was one of progress only. Much remains to be done in this line. The report indicated, however, that apparatus in the kitchen and elsewhere that had formerly operated at pressures of 40 to 60 lb. will do the work satisfactorily on pressures as low as 3 lb. provided the heating elements are properly designed.

ELECTION OF OFFICERS

The commercial end of the heating business was discussed in a paper by C. F. Oehlman, and immediately after its presentation the election of officers took place, with the following results: D. S. Boyden, president; B. T. Gifford, first vice-president; George W. Martin, second vice-president; W. S. Monroe, third vice-president; D. L. Gaskill, secretary and treasurer; Thomas Donahue and C. F. Oehlman, members of the executive committee.

HOT-WATER HEATING

At the fifth session, Thursday morning, W. D. Carlton read his paper on "The Hot-Water Heating System at the Grand Central Terminal" in New York City. The paper was brief, giving in outline the arrangement and general construction, some of the operating features and capacities and the method of computing rates for the service.

REPORT OF STATION-OPERATING COMMITTEE

The report of the station-operating committee was then read by Byron T. Gifford, chairman. It included results of a boiler test conducted along lines suggested by last year's committee; statistics on operating costs, with tabulated results from a number of typical plants; the accounting of operating costs; general information regarding coal, with a table giving the designation, origin and analysis of a great variety of fuel; meters and their uses, including a description of the new Republic flow meter; and miscellaneous points of interest, such as the reason advanced by the New York Steam Co. for softening water that originally contained only 3½ grains of total solids per gallon.

EXHAUST VS. LIVE STEAM

At the last session of the convention, on Thursday afternoon, C. C. Wilcox read a paper comparing the use of exhaust and of live steam for heating. Tests were conducted on the heating systems of Peoria and Pekin, Ill. From a study of the tests, the following conclusions were derived: The heat consumption for the heating system under similar weather conditions was found to be the same for either live- or exhaust-steam operation; the rate of steam sent to the heating system is increased as the heat content of the steam is diminished; the carrying of an electric load in addition to the heating load cannot be accomplished without an increase in fuel; the main condensation with live steam is less than with exhaust steam; the pressure drop between the station and the end of line is more with exhaust than with live steam, which may be accounted for by the increased amount of steam delivered to the system; pulsations in pressure caused by the engine exhaust are not propagated very far from the source. A paper by George W. Martin on the same subject was read in abstract as a part of the discussion on the paper by Mr. Wilcox. Mr. Martin stated that it seemed to be the opinion of many engineers that in heating a building with exhaust or live steam a less quantity of the former was required. A number of instances were cited to show that this was not the case, provided the same temperatures were maintained in the rooms and equal attention given to obtaining economical results from the boilers. Investigations in several buildings had disclosed the fact that the bypass for admission of live steam into the heating system had been too small, so that enough steam could not pass through to the system. It gave the impression that the boilers were not large enough to supply the demand. By enlarging the bypass the difficulties were overcome, and the live steam gave as satisfactory service as the exhaust from the engines.

This concluded the papers, some of which will be abstracted more fully in these columns at a later date. Before adjournment the convention discussed the advisability of publishing a quarterly bulletin devoted to association affairs. A unanimous vote gave the board of directors power to act if the proposition was found feasible.

ENTERTAINMENT

Special entertainment for the ladies was provided in the way of a musical and card party, shopping excursions, automobile sightseeing rides, and a lake excursion on the United States training ship "Isle de la Luzon." On Tuesday evening a theater party was attended by all, and on Wednesday evening the banquet, followed by professional entertainment and dancing, was a great success. Fully 160 sat at table and all spent a most enjoyable evening.

EXHIBITS

The exhibits were more numerous than usual and presented an interesting variety of meters, pipe coverings, valves, steam traps and other equipment used in district heating. Following is a list of the firms represented: American District Steam Co., American Radiator Co., Armstrong Cork Co., V. D. Anderson Co., Boylston Steam Specialty Co., Cannelton Sewer Pipe Co., Central Station Steam Co., Consolidated Engineering Co., G. M. Davis Regulator Co., Detroit Lubricator Co., G. T. Hornung, Jenkins Bros., H. W. Johns-Manville Co., Michigan Pipe Co., National Air Cell Covering Co., Republic Flow Meters Co., E. D. Tyler, Westinghouse Electric & Manufacturing Co. and A. Wickoff & Sons Co.

Worcester Polytechnic Celebrates Fiftieth Anniversary

Fifty years of engineering instruction at the Worcester Polytechnic Institute was fittingly celebrated on June 8 and 9 by exercises preceding the annual commencement, this arrangement affording an opportunity for both undergraduates and alumni to attend and listen to the many prominent engineers and educators who participated.

Starting with a reception by President and Mrs. Hollis at the Bancroft on Tuesday evening, the principal exercises were held on Wednesday morning in Mechanics Hall, the speakers, besides President Hollis, including Governor Walsh of Massachusetts; Doctor Brashear, president of the American Society of Mechanical Engineers; President Lowell of Harvard; and Booker T. Washington, the well-known negro educator. On the platform with the speakers was a large number of delegates from engineering societies and colleges.

President Hollis, in his opening address, sounded a warning against carrying efficiency methods to extremes, claiming that "anyone can understand the application of good sense, good will and system in the mills and factories, but no American can approve any plan that lessens the responsibility of the individual by turning him into a machine."

Doctor Lowell was of the opinion that control over the forces of nature, as gradually worked out by the engineer, had more to do with human prgress, and especially the abolition of slavery, than any change in morals. He pointed out how, in the days of the Roman Empire, the ships were rowed by slaves, but as soon as other and better methods of propulsion were worked out through control of nature's forces, the necessity for these slaves ceased. He cautioned, however, against the misuse of engineering knowledge in lines that would be detrimental to humanity.

The Governor extended to the Institute the congratulations of the State, and was followed by Doctor Brashear, who in his characteristic humorous strain touched upon the human element in engineering work, emphasizing that education should not be for the good of the individual alone, but more particularly to enable one to better aid mankind. Doctor Washington told of the work being done in the negro trade schools with which he is connected in the South.

On Wednesday afternoon the local and visiting members of the American Society of Mechanical Engineers listened to a paper by Professor Alden on the history of the Washburn shops. These shops, in which the students of the Institute receive their practical training, consist of forge, foundry and machine shops and are carried along on a strictly commercial basis, the student working as an apprentice along with a paid journeyman.

In the evening a banquet was held at the Hotel Bancroft, about 600 attending. The speakers included Senator Weeks of Massachusetts; Major-General Wood; Howard Elliott, president of the New York, New Haven & Hartford R.R.; Arthur D. Little, of Boston; Mayor Wright of Worcester; and Francis W. Treadway, ex-lieutenant-governor of Ohio.

Water-Power Discussion at a Conference of Western Governors

The outstanding feature of the conference of Western governors held in Seattle during May was the discussion on legislation for the use of water power. Those who took part in the conference were the governors of Oregon, Washington, Idaho, Montana, Nevada, Arizona, Utah and Colorado. Governor Carlson, of Colorado, read a paper entitled "Unlocking the West."

That satisfactory results will follow the regulation of water-power sites by the Federal Government rather than the states was questioned by Governor Carlson. He did not favor the adoption of legislation by Congress along the lines of the Ferris bill, which provides that permits for the use of water power situated on government land shall be granted for fifty years, carrying the right of the Government to take over the property at the end of that time at a reasonable price for its physical value.

"We can't trust the state to manage water-power resources as well as we can trust the Government," Governor Boyle said in reply. "States are clamoring now to give away their resources, and while they may pretend to have the door closed, nevertheless their natural resources will be packed out of the windows."

"It is an outrage and shame the way our reasources in Oregon have been managed," said Governor West. "The plan of Secretary Lane for the leasing of water-power sites is a just one. The bill he proposes does not take away any of the sovereign rights of the states. They cannot be taken away by an act of Congress. What is a granted privilege today becomes a vested right tomorrow, and that is why the leasing system is best."

The argument was advanced that the royalty paid to the Government would be borne by the consumers of power and light, as it would be counted by the managers of the hydro-electric projects as a proper item of operating cost.

Governor Carlson outlined his position clearly and forcefully in his paper:

So long as the Department of the Interior revoked power permits only for misuse and nonuse, millions of dollars were put into power plants upon the public domain. The moment this principle was departed from, all development ceased. It is now proposed to remedy the situation by giving permits that will run for fifty years and carrying the right of the Government or the state or municipality to take over the property at the end of the term upon a basis of physical valuation. The plan also proposes to regulate the price of power and to divide the taxes assessed against the property between the Government and the state. For the sake of argument only, conceding the right of the Government to pass such a law, and supposing that it will pass, I do not believe any great development will follow. It is entirely unlikely that investors will put money into projects where no title passes; where the property might be subject to the onerous rules and regulations which thereafter might be promulgated; where there is possibility of conflict between the laws of the state and the rules of the Department of the Interior.

Investors are not likely to take kindly to a plan that would keep a property upon their hands if the venture be a losing one, or that might be taken from them if it proved a profitable one. The power of eminent domain inherent in every sovereign state has been used again and again when it has been found necessary to beneficially use the waters of a stream. Private property has always been subject to the exercise of this power by the state or delegated agents, and the only theory that would prevent its exercise by the states upon government lands is that such are not held by the Government in a private proprietary capacity, but as a superior sovereign power within a sovereign state. There is not a line in the Federal Constitution giving the Government a right to set up an independent sovereignty within the borders of a state, and I believe the time is not far distant when Congress will pass legislation declaring the inherent rights of Western states. Our greatest obstacle at the present time is to bring the East to our view. This is not as difficult as it was ten years ago. The multiplication of cases where millions of dollars of capital were planned to be expended in Western states for the development of its low-grade ores, of lighting plants, power plants, interurban lines, irrigation projects, etc., that have been diverted to Mexico, Bolivia and other foreign countries will strike home sooner or later to the Eastern manufacturer, and he will undergo the inevitable disillusionment of the enchanting theories of the ultra-conservationist.

"I think the policy of the Government holding title and leasing power sites to individuals, giving them only temporary control, is opposed to the best interests of the states," said former Governor Hawley, and he recited several cases that have gone to the highest courts of the land, upholding the sovereign power of the states in the management of their resources.

The conference, however, before its adjournment did not come to a definite agreement on legislation for the use of water power, as it was the sentiment to postpone action until the water-power conference to be held in Portland, Ore., Sept. 21-23, which the governors will attend. This question is also expected to be one of the leading features of the national conference of governors of the country to be held the last week in August, at Boston, Mass.

Rating of Diesel Engines

In the course of a lecture before the Junior Institution of Engineers, W. A. Tookey, the well-known English authority on internal-combustion engines, referred to the high rates asked for insurance against breakdowns of Diesel engines and to the occurrences reported from time to time in the technical press, in which broken crankshafts, seized pistons and similarly serious accidents are mentioned. These occurrences, he thought, proceeded mainly from the overstressing of cranks and the excessive heating of pistons, due to a prevalent tendency to over-rate the permissible output from given cylinder dimensions. He was inclined to lay the blame, not upon the technical men responsible for the details of construction, but upon those who are intrusted with the negotiations with prospective purchasers and who are particularly interested in claiming as small a ratio as possible between horsepower developed and initial cost. Cases had occurred in which lack of appreciation of this point had led to the engines working overloaded, or where it was found necessary to reduce the load originally contemplated, in order to avoid risk of breakdowns. Thus it had happened in a number of cases that the Diesel engine had not enjoyed the reputation that its high thermal efficiency and general reliability so amply merited when properly selected, erected and maintained.

Proceeding further to discuss this phase of the subject, the speaker pointed out that while the limit of power in an internal-combustion engine cylinder is definitely established and recognized, the rating of electrical machinery is purely arbitrary and apparently, therefore, much more elastic. Experience had dictated that a "rated" output about 10 per cent. below the permissible maximum, or overload rating of Diesel engines, is satisfactory and convenient. In smaller cylinders this could be based on a higher mean pressure than is advisable with cylinders of larger sizes.

He concluded with references to the manipulation of details in starting, running and stopping, and many valuable practical hints were given in this connection, both for single- and multi-cylinder engines. Particular emphasis was laid upon the paramount importance of scrupulous cleanliness and conscientious management, a matter which depends quite as much upon the personal attribute of the attendant as upon his technical ability.

OBITUARY

CLAUDE H. HUNTINGTON

Claude H. Huntington died May 21 after a brief illness. At the time of his death he was president of St. Louis Association No. 2, National Association of Stationary Engineers.

HARRY H. WHEELER

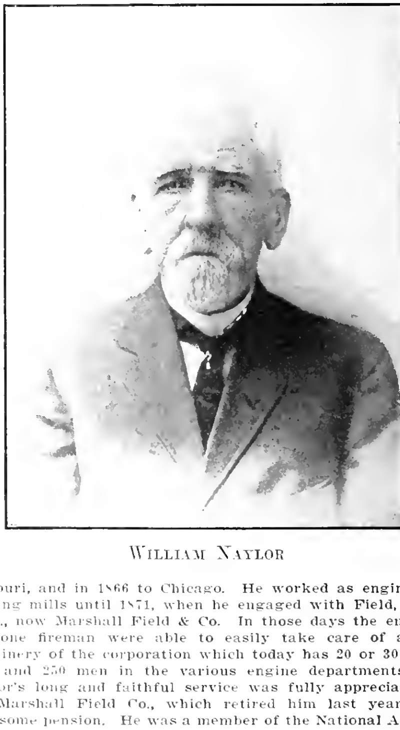
Harry H. Wheeler, of St. Louis, Mo., died suddenly on June 2, from injuries received in an automobile accident. He was a past-president of St. Louis Association, No. 2, N. A. S. E., and was a brother of William Wheeler, of New York, a Past-National President of the organization. About twenty-five years ago he left New York City to make his home in St. Louis. He is survived by a widow and three daughters.

JOHN F. FARLEY

John F. Farley, who died June 6 in Brooklyn, had for many years been employed as an engineer in the Department of Water Supply, Gas and Electricity of the City of New York, and for the last four years had been with the Department of Sewers. He was a member of the N. A. S. E. and the International Union of Steam Engineers.

WILLIAM NAYLOR

William Naylor died June 13 in Chicago at the age of 83. He was born in Lancashire, England, and seven years later began work operating hand machines in a calico-printing mill. He was apprenticed as machinist's assistant in the railroad shops at Bradford at the age of 9 and worked continuously until he retired last year. After serving several years as a locomotive driver on roads running between Yorkshire and Liverpool, he left England in the fall of 1858, and reached America by way of New Orleans, after a voyage of seven weeks on a combination steam and sailing vessel. He came by boat up the Mississippi and Ohio Rivers, and was employed as a sawmill operator and flour-mill engineer in Wabash County, Illinois. At the close of the Civil War he moved to



WILLIAM NAYLOR

Missouri, and in 1866 to Chicago. He worked as engineer in flouring mills until 1871, when he engaged with Field, Leiter & Co., now Marshall Field & Co. In those days the engineer and one fireman were able to easily take care of all the machinery of the corporation which today has 20 or 30 buildings and 250 men in the various engine departments. Mr. Naylor's long and faithful service was fully appreciated by the Marshall Field Co., which retired him last year on a handsome pension. He was a member of the National Association of Stationary Engineers since 1890, treasurer of the Robert Fulton Association continuously for 22 years, and was also a member of the Chicago Steam Engineers' Club. He was married to Ann Haigh before he left England and was the father of Charles William Naylor, Past National President, N. A. S. E. It was said that he was a friend of almost every operating steam engineer in and about the city of Chicago.

CHARLES E. CHINNOCK

Charles E. Chinnock, a manufacturer of telegraph instruments and one of the pioneers of the electric-light and telephone industries, died June 11 in Brooklyn, N. Y., in his seventieth year. When the telephone and electric light were still in their infancy he became associated with Thomas A. Edison, was later the superintendent of the first central station of the New York Edison Co., and as the vice-president of the Edison United Manufacturing Co., the parent Edison company, he was largely responsible for the founding of the Edison Electric Illuminating Co. of Brooklyn. The Edison United Manufacturing Co. was merged with the Thomson-Houston Co., which afterward became part of the General Electric Co. Mr. Chinnock was also chief electrician of the Metropolitan

Telephone Co., now the New York Telephone Co., and he patented many electrical inventions, among them an automatic transmitter, for teaching telegraphy that was adopted by the U. S. Government. Another of his inventions used by all the telephone and telegraph companies is a method of suspending aerial cables.

AUSTIN LORD BOWMAN

Austin Lord Bowman, one of the foremost bridge builders and engineers in this country, died June 3, at his home in New York City. He was born in Manchester, N. H., in 1861, and studied engineering at Yale, graduating in 1883. He engaged in engineering work continuously until the time of his death, specializing in design and heavy construction in both railroad and bridge work. Of his more important work, the construction of the Kings County Elevated Railroad in Brooklyn, his service as engineer in charge of construction for the American Bridge & Iron Co., and his reconstruction of the bridges on the Central Railroad of New Jersey are especially worthy of mention. He was made a member of the American Society of Mechanical Engineers in 1899 and was also a member of a number of other engineering societies. In 1907 he entered the service of New York City as consulting engineer of the Bridge Department, and in a few years was made chief engineer of the department, the position he held at his death. Commissioner Kracke, of the Bridge Department, and the chiefs of thirty departments under him, drew up suitable resolutions expressing their condolence, which will be embossed on parchment and presented to the family of their associate.

PERSONALS

S. H. Viall, assistant chief of the Chicago smoke department, has severed his connections with the city and is open for engagement.

Robert H. Kuss has severed his connections as sales engineer with the Edge Moor Iron Co. and will devote his time to advisory engineering.

J. A. Carson, better known as "Jack" Carson, formerly with the Durabla Manufacturing Co., is now connected with the Home Rubber Co., Trenton, N. J.

Hill & Ferguson, consulting engineers, 100 William St., New York City, have opened a laboratory for analyzing water and chemicals used in water treatment, as well as coal, oils and boiler compounds, and for testing the calorific value of coal.

S. F. Jeter has been appointed chief engineer of the Hartford Steam Boiler Inspection and Insurance Co. This is a recently created office, the holder to have general charge of the mechanical work for the company. Mr. Jeter for the past four years has held the position of supervising inspector in charge of the inspection service of the company.

ENGINEERING AFFAIRS

The Connecticut State Association of the N. A. S. E. will hold its annual convention at Hartford, on Friday and Saturday, June 25 and 26. The Engineers' Committee, assisted by the officers of the Supply Men's Association, has about completed the final arrangements, and a successful meeting is looked forward to.

The American Society of Refrigerating Engineers will hold its fourth Western meeting at San Francisco on Sept. 23 and 24. A special train, leaving Chicago Sept. 15 and arriving in San Francisco Sept. 21, has been arranged for the members, their families, and friends. Those attending the meeting will have the opportunity of attending the International Engineering Congress, which takes place from Sept. 20 to 25. Details of the trip may be obtained from the secretary of the association, W. H. Ross, 154 Nassau St., New York City.

The American Railway Master Mechanics' Association held its 48th annual convention, June 9-11, at Atlantic City, N. J. During the sessions committee reports were presented relating to locomotive stokers, smoke prevention, locomotive boilers, fuel economy and boiler washing. The Committee on Locomotive Stokers reported that the device was withstanding the test of continuous service with remarkable durability. Nothing novel has been presented during the past year, but a great deal of good work has been done in redesigning and improving detailed parts to better withstand the service. Data gathered from the scatter-type stokers in more extensive use show that the cost per 100 miles ranges from 43 to 68c., and the miles run per failure from 1000 to 5000. The committee felt unable to point to any rule in terms of weight of engine or train load, or to general conditions where the stoker will always be applicable or necessary. This is owing to the wide range in physical and operating conditions and in the character and price of fuel. According to the Committee on Smoke Prevention, continued use of the steam-air jets and quick-action blowers has further demonstrated that locomotives thus equipped may be kept comparatively free from smoke, provided the engine crews are properly instructed and carry out such instructions at all times. The report also presents a brief description of the Joint Smoke Inspection Bureau of the railroads operating in Chicago, and states that the record books of the City Smoke Department show a reduction in density of railroad smoke from 22% in 1910 to 7% in 1914. The committee on locomotive boilers recommended rules for determining stresses in such apparatus. These rules are the result of an analysis of existing practice of a number of representative railroads and locomotive builders. Since fuel economy depends not only upon the use of locomotives designed to have maximum efficiency, but to a large extent on their proper operation, the Committee on Fuel Economy presented a standard manual of instruction for enginemen and firemen. It is intended that this manual, while embodying all the essential points of efficient locomotive operation, should be brief and free from technical data. Superheaters, properly maintained and efficiently operated, are by far the most valuable mechanical aid to fuel economy ever applied to locomotives, and by their use savings of from 20 to 25 per cent. in coal and water are obtainable. The committee believed that to obtain the best results from the superheater a temperature indicator is desirable. The Committee on Boiler Washing gave an outline of the general practice of washing locomotive boilers. Many railroads have found that the use of hot water for boiler washing results in a saving of time, water and fuel. Chemical means of preventing incrustation are largely used. The chemicals are placed either in engine or wayside tanks, preferably the latter. The use of water-softening plants has resulted in an average increase in mileage between flue-setting and boiler repairs of over 100 per cent. In a paper on "Variable Exhaust," J. Snowden Bell stated that while these devices have effected an economy in fuel, none has proved sufficiently satisfactory or desirable, and it is not believed there are any at present in railroad service in the United States. In Europe, however, the early introduction of the variable exhaust has been followed by its general application. As an appliance designed to operate in the direction of economy of fuel, the variable exhaust merits careful consideration. If this be given, no doubt a variable exhaust can be produced to satisfy the requirements; that is to say, it would be properly constructed, automatically operable and fool-proof because independent of the human factor.

NEW PUBLICATIONS

DYNAMOMETERS. By F. J. Jervis-Smith and Charles V. Boys. D. Van Nostrand Co., New York. Cloth, 267 pages; 5½x9 in.; 119 illustrations. Price, $3.50.

DISTRICT HEATING. By S. Morgan Bushnell and Fred B. Orr. Heating and Ventilating Magazine Co., New York. Cloth, 290 pages; 6x9¼ in.; 82 illustrations; tables. Price, $3.

LOCATION OF CARBURETION TROUBLES MADE EASY. Chart arranged by Victor W. Page. Published by the Norman W. Henley Publishing Co., New York, 1915. Price 25c.

A plate showing a typical gasoline system as applied to an automobile motor, with a section through the carburetor. Motor troubles traceable to poor carburetion are diagnosed and the remedies prescribed; also general directions are included for the adjustment of carburetors. The automobilist will find the chart very useful.

HANDBOOK OF MACHINE SHOP MANAGEMENT. By John H. Van Deventer. Published by the McGraw-Hill Book Co., New York. Cloth, 374 pages; 4x6¾ in.; 244 illustrations. Price, $2.50.

This book is a careful effort to collect the best available information and data upon the details of management and to present them in concise form for the convenience of managers of machine shops and similar undertakings. To use the author's analogy, the book bears the same relation to those treating of systems of management that a book giving the fundamental data bears to books on the general theory of machine design. There is little that is speculative, and the information for the most part relates to data and elements of management that have been tested in actual practice. The book is arranged in handbook form, with seven sections. Under Section I are collected material and data on organization and system. Details pertaining to drafting-room systems, standardization of drawings and filing methods are given in Section II. The information in Section III relates mainly to the selection and installation of equipment, while Section IV contains data on shop and production orders and methods. Section V deals with timekeeping, payroll methods and cost-keeping. In Section VI are given data on shipping, transportation and tracing methods. In the last section information on safety mechanism, fire prevention and sanitation is given. While the beginner will find much of interest and profit in the book, because of the necessarily abbreviated treatment it will prove of more value to those who have already given some attention to these matters, and who can therefore use discrimination in selecting material.

EL INGENIERO Y CONTRATISTA

The title given applies to a new Spanish engineering periodical, the first number of which was issued in June. While the publication is begun in a small way, it is hoped to make it really useful in advancing the interests of American engineering practice in Spanish-America. It is published by Dodwell & Co., Ltd., 135 Front St., New York City.

TRADE CATALOGS

McNab & Harlin Mfg. Co., 55 John St., New York. Bulletin. Regrinding valves. Illustrated, 20 pp., 5x7 in.

Scranton Pump Co., Scranton, Penn. Bulletin No. 102. Duplex plunger pumps. Illustrated, 12 pp., 6x9 in.

BUSINESS ITEMS

The Sullivan Machinery Co., Peoples Gas Building, Chicago, Ill., has moved its Boston office from 35 Federal St., to Room 1010, Unity Building, 185 Devonshire St.

The Kern Commercial Co., 114 Liberty St., New York, has received an inquiry from a client in Scandinavia for various steam specialties, such as lubricating apparatus and cups, injectors, valves, manometers, etc. The company is inviting figures.

The Terry Steam Turbine Co., Hartford, Conn., has appointed Joseph Battles as district sales manager for Denver, covering States of New Mexico, Colorado, Wyoming and the western portion of Nebraska. Mr. Battle's address is 326 First National Bank Building, Denver, Colo.

The McIntosh & Seymour Corporation, Auburn, New York, has appointed V. E. Raggio, 1107 Nevada St., El Paso, Texas, to represent the company in Arizona, New Mexico, Texas west of a line drawn north and south through Del Rio, and the States of Sinaloa, Sonora, Chihuahua, and Durango, in Old Mexico.

The Ingersoll Rand Co., 11 Broadway, New York, has recently issued a catalog, form 3031, descriptive of the new "Ingersoll-Rogler" Class "FR-1" Steam Driven Single Stage Straight Line Air Compressors. The catalog is profusely illustrated showing the details of the machine in section and is sent on application.

Ice Making Plants in the U. S.—We are advised by the editor of "Ice and Refrigeration" that the number of ice-making plants in the United States is not 12,500, as given on page 659 of our May 11 issue, but 4245, as given in the "Ice and Refrigeration Blue Book."

The World Bestows Big Prizes, both in money and honors, but for one thing. And that is initiative. Initiative is doing the right thing without being told; but next to doing the thing without being told is to do it when you are told once. Next, there are those who never do a thing until they are told twice; such get no honors and small pay. Next, there are those who do the right thing only when necessity kicks them from behind, and these get indifference instead of honors, and a pittance for pay.—Elbert Hubbard.

NEW EQUIPMENT

ATLANTIC COAST STATES

It is reported that the Athol Gas & Electric Co., Athol, Mass., contemplates extending its transmission lines to Petersham, Mass., if sufficient business is guaranteed. The estimated cost of building the line and installing the distribution system is from $10,000 to $15,000. George MacKnight, Athol, is Supt. and Ch. Engr.

The City Council of West Newbury, Mass., is considering the installation of a municipal electric-lighting system. The present service is furnished by the Newburyport Gas & Electric Co.

It is reported that the City Council of Lindenhurst, N. Y., is considering the installation of an electric-light plant in connection with the municipal water-works system.

The Diamond Match Co., Oswego, N. Y., has awarded the contract for the construction of its new power house in Oswego. The equipment will include two 500-hp. boilers (with space for a third one of the same size) and two 1000-kw. generators. The boilers will be equipped with automatic stokers.

SOUTHERN STATES

It is reported that contracts will soon be awarded by the Town Council of Dayton, Va., for the installation of a municipal electric-light plant. Bonds to the amount of $24,500 were recently sold for this purpose and the construction of a sewer system.

The People's Light, Heat & Power Corporation, Westpoint, Va., contemplates the construction of an addition to its plant and the installation of another unit. Samuel MacWatters is Supt.

The City of Hertford, N. C., is considering a bond issue of $12,000, the proceeds of which will be used for the installation of a municipal electric-light plant.

The City of Warsaw, N. C. has granted a franchise to Oliver Pettit, Clinton, N. C., for the installation and operation of an electric-light plant.

Plans are being prepared for the construction of a municipal electric-light plant at Ocala, Fla., estimated to cost $75,-000. H. C. Sistrunk is City Clk. Twombly & Henney, 55 Liberty St., New York, N. Y., is Engr.

The City of White Castle, La., will install a municipal electric-light plant to cost about $25,000. Xavier A. Kramer, Magnolia, Miss., is Engr.

It is reported that E. B. Jones and John E. Green are interested in the establishment of an electric-light plant at Crossville, Tenn

It is reported that E. H. Crump, Mayor of Memphis, Tenn., is agitating a project to build or buy a municipal electric-light plant. A bond issue of $1,500,000 is said to be available for the purpose.

The Commercial Club of Harlan, Ky., is reported to be promoting the establishment of a $250,000 electric plant in Harlan, to be built by an association of Cincinnati capitalists.

CENTRAL STATES

It is reported that the Canton Electric Co., Canton, Ohio, has purchased a site for the construction of an addition to its power station. The company has authorized improvements to its system to cost about $250,000. W. C. Anderson, Canton, is Mgr. and Supt.

The Board of Education of Cincinnati, Ohio, Charles Handman, Business Mgr., has engaged an engineer to prepare plans and estimates of the cost of installing electric generating stations in a number of the larger school buildings of the city.

A special election will be held June 22 at Painesville, Ohio, to vote on the question of issuing $35,000 in bonds for the purpose of improving the municipal electric-light plant.

The Ohio Light & Power Co., Tiffin, Ohio, has made application to the City Council of Granville, Ohio, for a franchise to supply electricity for domestic and commercial purposes in the latter place.

C. C. Outland, Mayor of Zanesfield, Ohio, and E. Huntzinger, Piqua, are preparing to organize a company to install and operate an electric-light plant in Zanesfield.

It is reported that the Mohawk Mining Co., Calumet, Mich., plans to install an electric-light and power plant.

WEST OF THE MISSISSIPPI

According to press reports, bids will soon be asked for the installation of a municipal electric-light plant in Davenport, Neb. Charles F. Sturtevant, Holdredge, Neb., is Consult. Engr.

At a recent special election in Tekamah, Neb., the citizens voted to issue $15,000 in bonds to be used for extending the municipal electric-light plant to furnish 24-hr. service. M. S. McGrew is Secy. and Cont. Agt. of the plant.

It is reported that arrangements are being made for the installation of an electric-light plant in Michigan, N. D.

The Town of Chilhowee, Mo., has voted a bond issue of $6800 to be used for the installation of a municipal electric-light plant.

It is reported that W. B Rollins & Co., Midland Bldg., Kansas City, Mo., is preparing preliminary plans for the installation of a municipal electric-light plant at Harrisonville, Mo. The estimated cost is $15,000.

It is reported that the Sterling Consolidated Electric Co., Sterling, Colo., will shortly install a 250-kw., three-phase, 60-cycle, 2200-volt generator and engine. The company will purchase stokers for three boilers, poles and wire. H. L. Titus is Mgr.

POWER

Vol. 41 NEW YORK, JUNE 29, 1915 No. 26

That Peak Load Problem

By Berton Braley

WE'VE rustled for power contracts and landed a lot as well,
We've hunted the country over for fancy outfits to sell,
We've peddled electric irons, we've boosted electric pots,
And gathered up fans and sold 'em in regular carload lots,
We've hinted and preached and threatened and advertised year on year
And talked to the folks like Uncles and written 'em plain and clear,
But in spite of our ceaseless efforts, our labors almost sublime
Full half of our power units are idle most of the time.

And that's the fault of peak load
(It never is a weak load)
Which jumps upon the backs of us at certain times of day
A bold and not a meek load,
A make-you-swear-a-streak load,
Oh, if it weren't for peak load our labor would be play.

THE sun goes down in the western sky and the stars come into sight,
And the homes of the busy city are drawing on us for light,
The theaters glow in glory, the signs and the street lights glare,
And here at the central station we've worry enough to spare,
For the straining boilers tremble, the laboring engines throb
And we start up the whole equipment to handle the heavy job,
It's trouble enough on week days to manage the problem well
And then when Saturday Night comes round—say, SATURDAY night is Hell!

And so we cuss the peak load
The big load, the freak load,
Which jumps upon the backs of us at certain times of day,
A strong and not a weak load
A make-you-swear-a-streak load,
Oh, if it weren't for peak load our labor would be play.

IF only the load were steady each hour of the twenty-four
We wouldn't be fretting and fuming and figuring any more
On boosting the "off hour" business by every kind of scheme;
But the peak load still is with us and life is no idle dream.
For all of the new inventions we've brought to the public's view
Electric curling irons and vacuum cleaners, too,
For all of our advertising, our urging in prose and rhyme,
Full half of our power units are idle most of the time.

And that's the fault of peak load
(It never is a weak load)
Which jumps upon the backs of us at certain times of day,
A not at all unique load
Yet, in a way, a freak load
Oh, if it weren't for peak load our labor would be play.

Washington Avenue Power Plant, Scranton, Penn.

By Warren O. Rogers

SYNOPSIS—This plant has been remodeled at a cost of $2,000,000. Six new water-tube boilers, each with 5580 sq.ft. of heating surface, have been installed. The generating units consist of three turbo-generators and two reciprocating engine-driven units, the latter exhausting to a district heating system during cold weather. Culm fuel having an average calorific value of 10,500 B.t.u. is burned in the boiler furnaces. This fuel has been through the washery twice and contains approximately 5.02 per cent. volatile matter, 74.98 per cent. fixed carbon and 20 per cent. noncombustible matter. At 163 per cent. of boiler rating 6.07 lb. of water is evaporated from and at 212 deg. in the old boiler plant. A test of one of the new boilers gives an evaporation of 8.38 lb. of water from and at 212 deg.

The City of Scranton, Penn., is situated in the heart of the Lackawanna Valley, one of the greatest anthracite producing regions in the country. The mines are dotted here and there all along the valley and range in size from those requiring 50 or 100 hp. in their operation up to those requiring from 2000 to 3000 hp. Many, in fact most, of these mines still use steam power and their electrification is for the future.

Naturally, in this region the greatest competitor of a central station is cheap coal, and in order to obtain and keep its business it must be in a position to sell electrical energy at an attractive rate and to give reliable service.

When the American Gas & Electric Co. took over the Scranton properties eight years ago, there were six companies supplying electric service from four generating stations to consumers, the combined yearly output of these plants being about 11,000,000 kw.-hr. Today the yearly output of the company generated in its two stations is more than 60,000,000 kw.-hr., which is distributed over 70 square miles, furnishing current to 16 cities and boroughs, ranging from 200 to 130,000 in population.

The old properties were becoming obsolete, and to meet the increasing business both for the present and for the

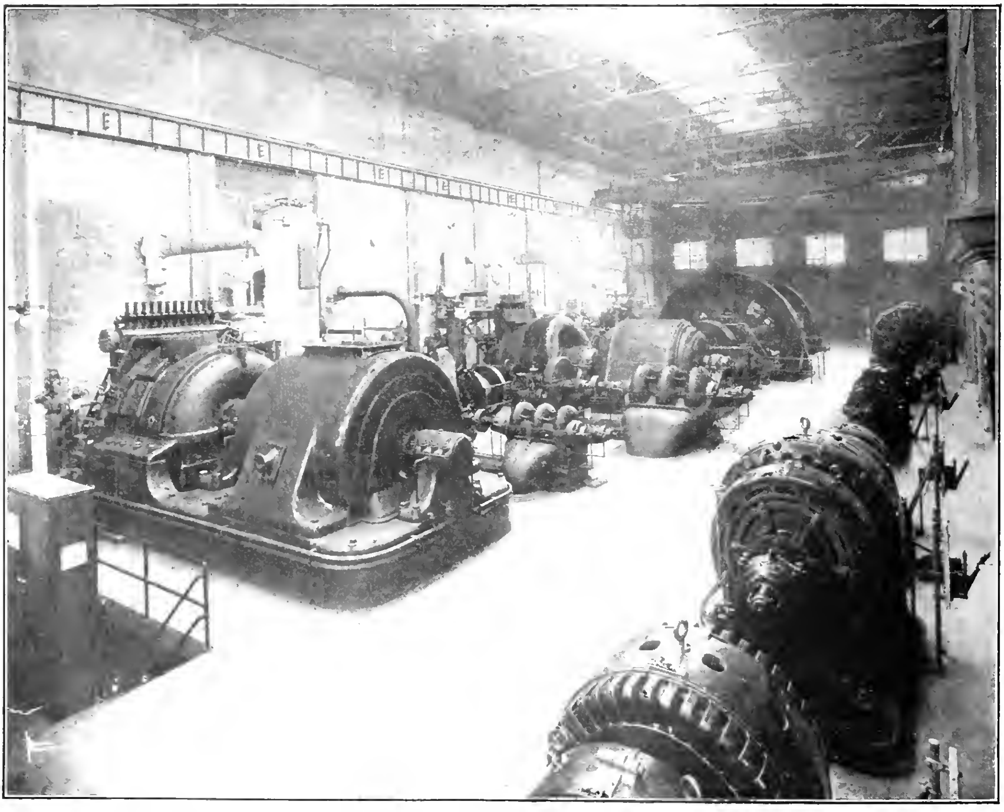

Fig. 1. General View of the New Washington Avenue Power Plant, Scranton, Penn.

future the suburban power plant on Washington Ave. has been rebuilt with the exception of the old boiler room. The new power house is 200 ft. long, 64 ft. wide and 37 ft. high to the steel roof trusses. The basement is 14 ft. 6 in. deep and contains the condensing apparatus. A new fireproof boiler house 120 ft. long, 115 ft. wide and 40 ft. high to the roof trusses, forms an ell with the old building.

The plant, before being remodeled, contained three 300-kw. alternating-current generators, two being belt-driven from two engines, from which alternating current was secured, and one was motor driven. These units were run separately with a total load of 1200 kw. The old station, with its belt-driven units, was typical of the old-time plant.

New Turbine Room

A view of the present turbine room is shown in Fig. 1, two of the three units being in the foreground. There are two Curtis-Rateau 10,000-kv.-a. horizontal turbo-generators and one 4500-kv.-a. unit, both generating current at 4000 volts. Two of the original 3500-hp. engines are retained. One, a cross-compound with cylinders 36&66x48 in., is directly connected to a 4000-volt, 2000-kv.-a. three-phase, 60-cycle alternator, and runs at 100 r.p.m. This engine is arranged to run condensing, to the atmosphere, or to exhaust into a heating system working against an average back pressure of 8 lb. The other reciprocating unit is a twin engine with cylinders 36x48 in., and runs at 100 r.p.m. It is directly connected to an alternator of the same size as that of the compound unit. This engine, which has been in service about four years, is designed to operate against a 40-lb. back pressure, as that was the pressure carried on the commercial heating system at the time it was installed. The weight of each flywheel is 65 tons.

The compound engine is piped to a surface condenser containing 6000 sq.ft. of cooling surface, or 1.7 sq.ft. per hp. The volute circulating and the hotwell pumps in the basement are turbine-driven. The 8x20x12-in. air pump is on the main floor. The condensers for the turbines are connected by expansion joints. The 10,000-kv.-a. turbine condenser has 20,000 sq.ft. of cooling surface, or 2.66 sq.ft. per kw. The condenser for the latest 10,000-kw. turbine installed is of the usual design, but it has a special arrangement of the tubes. It contains 30,000 sq.ft. of cooling surface, or 3 sq.ft. per kw. of turbine capacity. That for the 1500-kv.-a. unit has 11,000 sq.ft. of cooling surface, or 2.7 sq.ft. per kw.

The 20- and the 28-in. triplex volute circulating pumps for both condensers are turbine driven, and are on the main floor, as are also the 12x30x16-in. and the 8x20x12-in. dry-air pumps for the 10,000- and the 1500-kv.-a. units. A vacuum within 2 in. of the barometer is maintained with injection water at 70 deg., and within 3 in. at 80 deg. F.

Circulating water flows to the pumps by gravity from eight cooling towers at the rear of the plant and 50 ft. above the basement floor. The return water is through a 42-in. diameter cast-iron pipe, and is controlled by motor-driven valves.

Cooling Towers

The cooling towers, Fig. 2, are of the combination fan and natural-draft type. They are built over a covered concrete reservoir with concrete columns extending above the reservoir on which the towers rest, and leaving openings between the columns for the entrance of air when the towers are operated on the stack-draft principle. The air spaces below the towers are separated by concrete aprons extending from the under side of the top of the reservoir down to a point below the water level, thus making each tower independent of the others, so far as operation is concerned. The stacks are built of sheet steel riveted and are cylindrical in form, the lower parts being 24 ft. in diameter and the towers 70 ft. high from the top of these supporting piers.

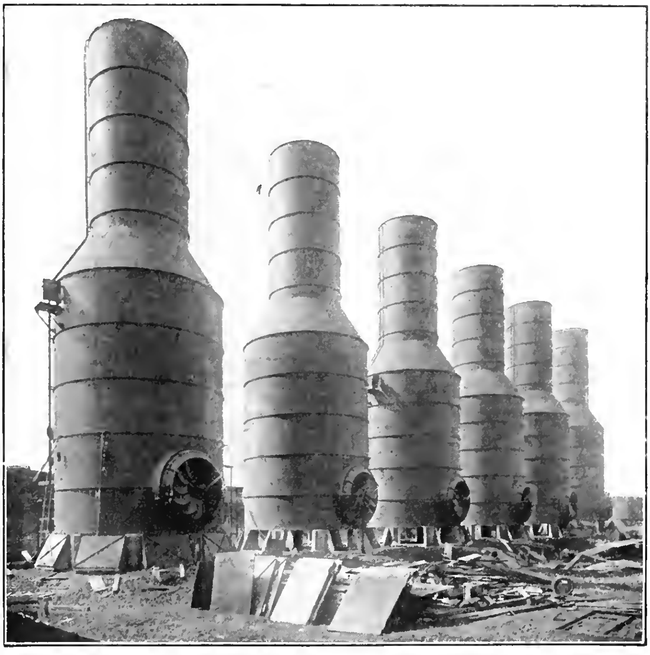

Fig. 2. Combined Fan and Natural-Draft Cooling Towers

Each tower is provided with two 10-ft. diameter fans mounted on one shaft and driven by a motor in a concrete housing close to the tower. The cooling surface consists of dressed cypress boards set on edge, each course being arranged at right angles to the course below.

Warm circulating water is brought to each tower through a 14-in. discharge pipe entering at a point just above the fans and extending up through the center of the tower to a point just over the cooling surface. On the top of this discharge pipe is a self-rotating water distributor, which is revolved by the reaction of the jets of circulating water and rotates on a lignum-vitæ bearing which, being lubricated by a part of the circulating water, requires no attention.

The special openings between the supporting piers at the base of the tower are provided with steel doors hinged

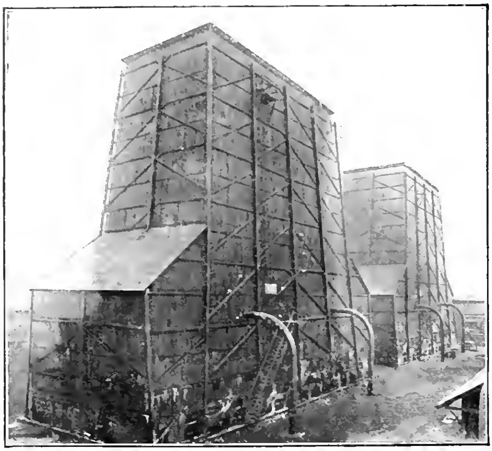

FIG. 3. TWO COOLING TOWERS, CAPACITY 5000 GAL. PER MIN.

at the top and partly counterweighted with chain and weight to facilitate opening and closing. The lower part of the tower can be entered through one of these draft doors, and the distributor and upper part of the cooling surface are accessible through a door arranged at the side of the stack. A ladder extends from the ground to the top of the tower, passing close to the platform in front of the upper opening.

This battery of towers is capable of cooling the circulating water from the condensers serving a power plant of 14,500 kw., when maintaining a vacuum within 3 in. of the barometer, and during summer weather conditions with forced draft.

In cold weather, or when the load on the power station is light, the fans are stopped, the draft doors are opened and the towers allowed to operate on a stack-draft principle, thus saving the power necessary to operate the fans.

There are also two natural-draft cooling towers working in connection with a 10,000-kw. turbine. These towers are shown in Fig. 3. They are about 250 ft. long, and 100 ft. high, and are of the all-wood natural draft type, built under a license from the Balcke Co. of Germany. So far as known, these are the largest natural-draft cooling towers installed in the United States.

The condensate and circulating pumps are mounted on a single bedplate and driven by a steam turbine through a common shaft. Fig. 4 shows the unit in part. The pump *A* is a combined hydraulic-air and condensate pump. There is but one connection to the condenser—the condensate and non-condensible vapors being separated in this pump. In case the hurling water used in the air pump becomes too hot it can be cooled by city water.

The centrifugal circulating pump *B* is of standard type. An interesting fact concerning this installation, as shown by the readings for a day herewith given, is that the vacuum is better than 29 in. practically throughout. It is understood that this showing is a record in this country, and there are no data available from foreign plants showing such results. The readings are as follows:

SCRANTON ELECTRIC COMPANY Feb. 25, 1915

Time	Load, Kw.	Circ. Inlet	Circ. Outlet	Condensate	Temp. Atmos.	Humidity	Corrected Vacuum	Hurling Inlet	Water Outlet	Cooler In	Cooler Out	Speed Pump

The combined condensate and turbo air pump* is driven by the same auxiliary turbine that drives the circulating pump. This arrangement is compact and requires less attention than the general arrangement of condensing apparatus. The exhaust steam from the pump turbine is connected to the second stage of the 10,000-kw. turbine. The exhaust pipe from the pump turbine is fitted with an automatic trip throttling valve close to the connection to the large turbine. There is also a back pressure valve set at 15 lb. pressure absolute. The pressure in the first stage of the turbine is 30 lb. and that of the second stage is 13 lb. absolute, therefore the exhaust steam enters the second stage of the large turbine at a pressure of 2 lb. above that existing in that

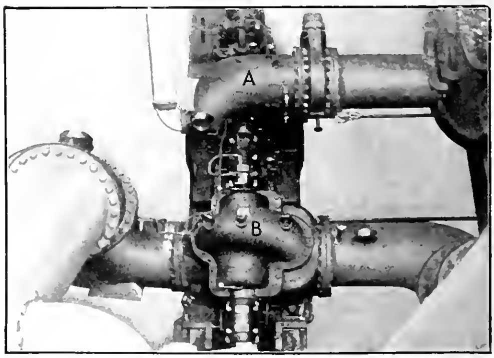

FIG. 4. TURBO-AIR AND CONDENSATE PUMP ON SHAFT WITH CIRCULATING PUMP

portion of the turbine. In the near future the exhaust steam from the other turbine auxiliaries will be connected to their respective turbines and the exhaust steam used in the second stage.

The makeup water is taken from the city water mains. The feed water is taken from one 4000-hp. open

*Details of a test of one of these air pumps were published on page 442 of the Mar. 30, 1915, issue.

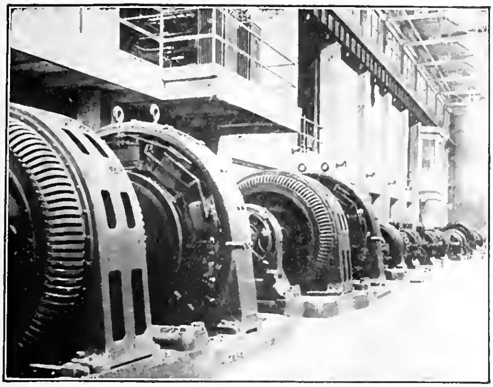

FIG. 5. A LONG LINE OF MOTOR-DRIVEN UNITS

heater by two 16x10x18-in. outside-packed pumps controlled by a pump governor and from one 5000-hp. heater by two 500-gal. capacity centrifugal boiler feed pumps. Exhaust steam from the auxiliaries is used for heating the feed water, all, with two exceptions, exhausting into a common header. The circulating pumps on the 10,000-kv.-a. turbine units are arranged to run either condensing or noncondensing, assuming that with both main turbines in operation more than enough exhaust steam would be obtained for feed-water heating.

AUXILIARIES

Along the switchboard side of the turbine room is a row of motor-driven units, shown in Fig. 5, consisting of the following:

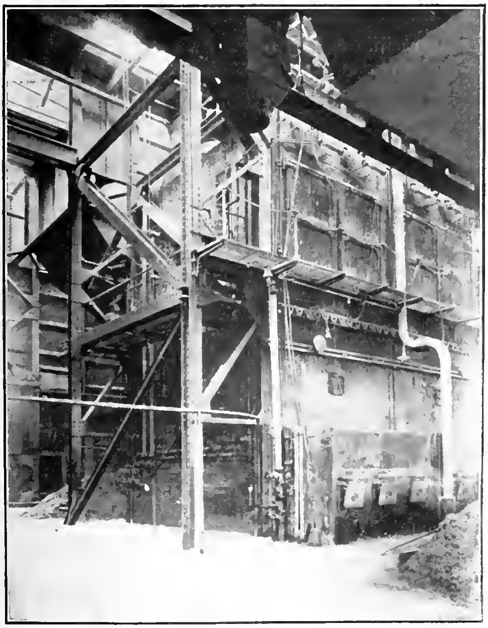

FIG. 6. ONE OF THE NEW DOUBLE-DECK BOILERS

Two 1400-hp. synchronous motors directly connected to two 1000-kw., 550-volt railway generators, speed 514 r.p.m. These units have a 125-volt exciter mounted at one end of each shaft.

Two 250-hp., 4000-volt synchronous motors, each directly driving three 6.6-amp. arc-light machines at 514 r.p.m.

One 186-hp., 4000-volt synchronous motor directly connected to two 6.6-amp. arc-light machines at 514 r.p.m. motor circuits.

One 150-hp. induction motor driving 100-kw., 250-volt, direct-current generator at 580 r.p.m.

One 300-hp. induction motor driving a 200-kw., 250-volt, direct-current generator at 580 r.p.m.

There are three exciter units: One is a 150-kw., turbine-driven set generating 125-volt direct current at 3775 r.p.m.; one is an induction, 250-hp. motor-generator set generating 125 volts at 720 r.p.m.; and the third is a 10&18x10-in. marine engine directly coupled to a 150-kw., 125-volt, direct-current generator, at 340 r.p.m.

BOILER ROOM

The old boiler room contains only water-tube boilers, of which four are of 180-hp. capacity, four 600-hp., and

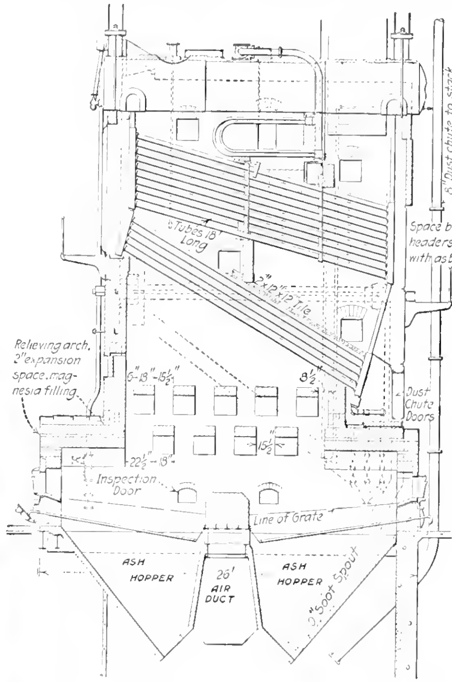

FIG. 7. SECTION THROUGH ONE OF THE BOILERS

five 300-hp. The eight largest are equipped with dutch-oven furnaces and dumping grates. The five small ones have shaking grates. All are equipped with regulators, and but two have superheaters.

In the new room, Fig. 6, there are six special-type, double-deck, water-tube boilers with two banks of 18-19-ft. tubes, each 18 sections wide; the upper one is 10 and the lower 5 tubes high. These boilers are double-end and are at present hand fired. Mechanical stokers are to be installed in the near future capable of handling the grade of fuel now being burned. Each boiler contains 5580 sq.ft. of heating surface and is rated at 558 hp. The grate surface is 217 sq.ft., which gives 2.57 sq.ft. of heating surface per square foot of grate surface. Washed buckwheat and anthracite culm are used.

Fig. 7 is a section through one of the new boilers. Forced draft is used, the main air duct being between the ash hoppers and opening to a blast box which is equipped with hand-operated dampers for controlling the volume of air admitted below the grates. The staggered arches are 18 in. wide and spaced 15½ in. This arrangement is to provide a baffling which, with its high temperature, will cause the furnace gases to burn before striking the comparatively cool tube surface; also, to diffuse the heat currents so that they will reach the heating surface of the lower bank of tubes from end to end.

This method of arch construction has developed trouble in that the arches have been found difficult to keep in place. To preserve them in place a pillar 2x4 ft. in size has been built between the bridgewall and an arch 11 ft. long, 9 ft. high and 6 ft. cross-section, and arched 15 in. at the center. This arch replaces the bottom one, Fig. 7, and the brick column has proved satisfactory. The six new boiler furnaces will be so equipped.

Resting on the top row of the lower bank of tubes is a tile baffle wall, which extends 10 ft. 9 in. from the lower end of the tubes. The upper bank is baffled for three passes of the gases, the superheater being placed between the first and second pass.

In order to facilitate cleaning the space between the two banks of tubes, provision has been made to remove the dust to the ash hopper through a 10-in. dust chute. Dust from the stack is taken care of by an 8-in. chute which is brought down to a point convenient for discharging into a tile drain running to the ash accumulating pit.

Following are the results of tests recently run on two of these boilers:

BOILER TESTS AT THE WASHINGTON AVENUE PLANT

Boiler: Babcock & Wilcox W. S. V. II. Special. 18 Sections, 10 High, 18-ft. Tubes. 18 Sections, 5 High, 19-ft. Tubes. Two 42-in. Drums—5580 sq. ft. H. S.-Rating 558 hp. Babcock & Wilcox Superheater. Furnace Double End. Hand-fired. 217 sq.ft. G.S.
Coal: Washed Buckwheat No. 2—Slush—Bituminous—"Shawmut."

The capacities secured in the tests are interesting in view of the poor quality of coal used, and this is also true of the efficiencies. Heat balances which have been worked out from three of these tests show the following results:

	Date		
	Aug. 19	Aug. 21	Aug. 28
Heat absorbed by boiler...........	65.54	52.57	64.79
Loss due to moisture in coal........	1.02	1.92	0.80
Loss due to burning hydrogen	2.35	2.71	2.34
Loss due to chimney gases	11.31	11.71	10.91
Loss due to moisture in air.........	0.54	0.33	0.46
Loss due to incomplete combustion.	0	0	0
Loss due to carbon in ash..........	14.62	25.22	15.18
Loss due to radiations, etc.........	4.62	5.44	5.52

Air assumed to have 60 per cent. saturation in all cases.

Air for the forced draft in the old boiler room is supplied by two 14-ft. and one 10-ft. steel-plate blowers and in the new boiler room by two turbo- and one motor-driven fan. Ashes and soot in the old boiler room are removed and discharged into a tank 70 ft. above the basement floor, by means of a 5-ft. exhaust fan which runs at a speed of 1440 r.p.m. and is driven by a 100-hp. motor.

Ashes from the new boilers are dumped from the hoppers into half-round tile drains in which they are flushed by mine water into a pit, from which they are taken by a crane and loaded into railroad cars (Fig. 12).

An interesting method of getting rid of ashes from this plant was used about two years ago. As is well known, under the City of Scranton are many coal mines that have been worked out to a large extent, and this power plant is over a mine, the top vein of which is about 130 ft. below the surface. Pillars had been left to support the roof.

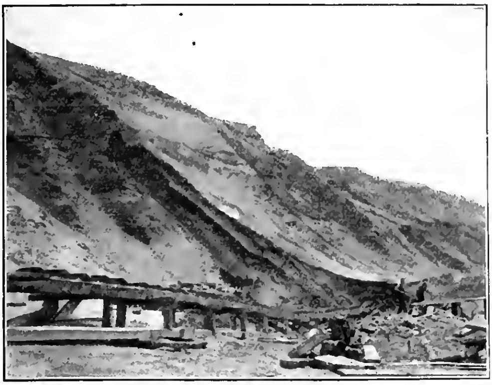

FIG. 8. CULM BANK AND SCRAPER CONVEYOR

huge piles is being reclaimed by passing it through washeries, and is sold in the market in the various sizes of buckwheat. The fine dust, dirt and bone were looked upon as of no particular value, and in some cases were discharged to any stream handy or returned to a bank for rewashing.

The fuel used at the Scranton suburban plant has been through the washing process twice and is so fine that a dry sample taken from the bank and passed through a $\frac{7}{16}$- and over a $\frac{1}{4}$-in. mesh screen gives 8 per cent.; through a $\frac{3}{8}$-in. and over a $\frac{1}{8}$-in. mesh, 6 per cent.; through $\frac{1}{8}$-in. mesh, or dust, gives 76 per cent.. An approximate analysis showed volatile combustible matter 5.02 per cent., fixed carbon 74.98 per cent., noncombustible matter 20 per cent., and a calorific value of 10,500 B.t.u.

This fuel is so fine and dust-like that it is necessary to thoroughly wet it before firing to prevent its being carried over back of the bridgewall before it has had a chance to become completely ignited.

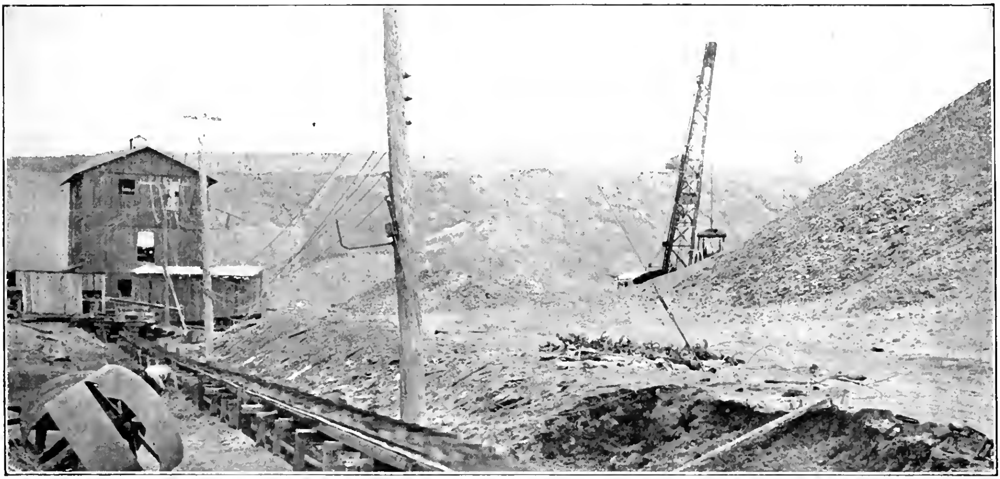

FIG. 9. CULM BANK, ELECTRICALLY OPERATED JIB CRANE AND CRUSHER HOUSE

To prevent the ground from settling under the plant, two 8- and one 10-in. bore holes were drilled through to the three veins, which were worked out, and the ashes from the boilers were flushed into the chambers and passages; thus making a solid support for the plant.

It is proposed to return to this method of ash disposal as the company has about 30 acres of mine surface which is available for filling in. A bore-hole will be drilled in one corner of the ashpit and the ashes flushed to the abandoned mine. There will also be an ash-storage tank of a size to hold about six days' ash accumulation. This is so that the contents of the ash basin and that of the bin can be sent to the mine at one flushing and so decrease the labor cost, as it is necessary to employ men at the outlet of the flushing pipe. It is estimated that with this arrangement one man will do the work formerly performed by six.

FUEL

Culm banks are common in the anthracite region, as up to a few years ago there was no demand for the finer grades of anthracite. Today the coal contained in these

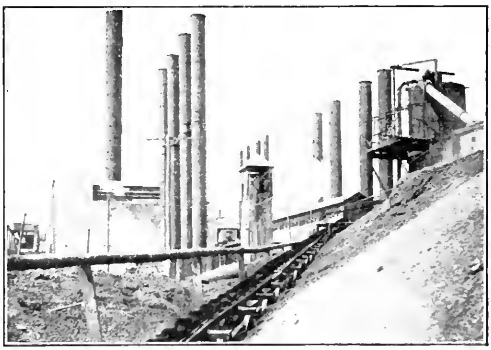

FIG. 10. SCRAPER CONVEYOR DISCHARGING TO OLD BOILER HOUSE

The casual observer would hardly believe that this grade of fuel could be burned to advantage. That it can be utilized in a boiler furnace with good results is shown

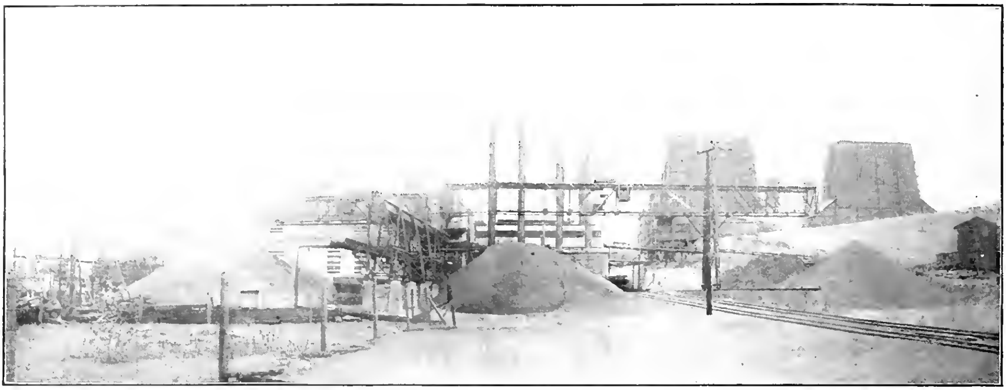

Fig. 11. General View of the Plant, Showing Coal-Conveying Apparatus and Water-Cooling Towers

by a test run on four 480-hp. boilers in the old boiler room. The grate surface per boiler is 168 sq.ft., with 12.5 per cent. of air space. An air pressure of 1.72 in. of water was carried in the ashpit, with a draft over the fire of 0.02 in. and a draft under the damper of 0.45 in. of water. The boiler horsepower developed was 163 per cent. of the boiler rating, with an equivalent weight of water evaporated from and at 212 deg. F. of 6.07 lb. per pound of fuel.

Fuel is carried from the culm bank at the rear of the plant by a 6-in. reinforced chain with scraper every 2 ft. The conveyors, which travel at a speed of about 65 ft. per min., are shown in Figs. 8 and 10. The culm is taken to a crusher house shown at the left in Fig. 9, and as it contains considerable rock, it is taken to the top of the building and dumped into a $^3/_4$-in.-mesh revolving screen. The material passing through goes to the conveyor line, Fig. 10, which discharges to the boiler house where it is hand-fired to the furnaces. What does not pass through the screen goes to a pair of 24x24-in. chestnut rolls, and then drops into a second set of rolls of the same size, which reduces it to pea-coal size. It is then returned to the elevator and passed through the screen in order to mix it with the finer fuel coming from the culm pile. An electric jib crane with a 2-ton clamshell bucket is used for handling the culm from the pile to the conveyors.

Fuel for the new boiler room is obtained by rail from another culm pile owned by the company, and is stored in the yard close to the boiler house. Here it is handled by a 10-ton, three-motor traveling crane equipped with a two-ton grab bucket, Fig. 11. This takes the coal from either the cars or the bins and discharges it into a crusher, which passes it to a 30-in. belt conveyor, Fig. 12. The latter de-

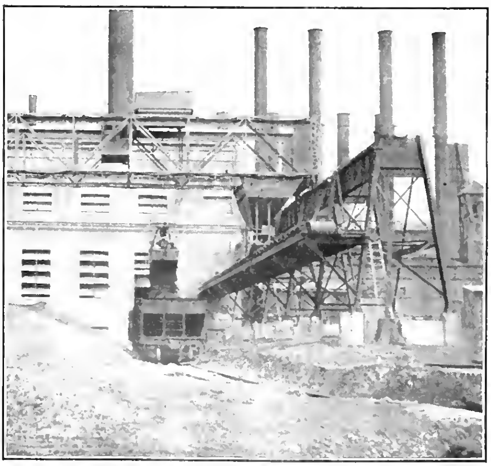

Fig. 12. Ash- and Coal-Handling Apparatus

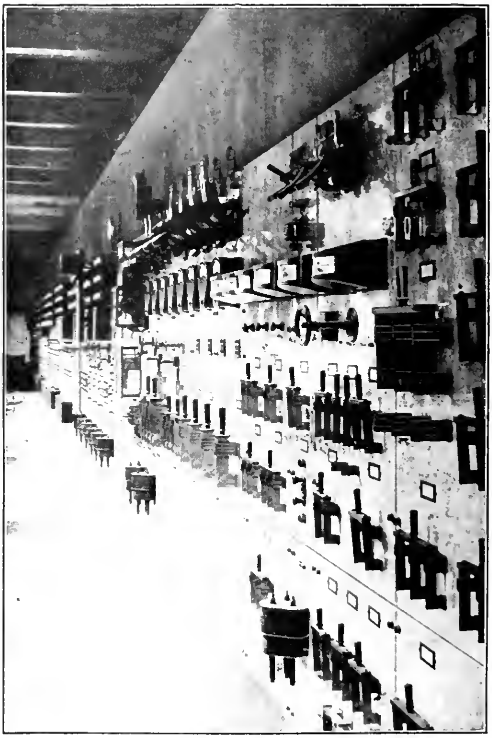

Fig. 13. Station Switchboard

posits the coal onto a 32x32-in. overlapping bucket conveyor, which elevates it to the top of the building and dumps it into either one of three 24-in. belt conveyors that discharge into the bunkers. These conveyors have a capacity of about 120 tons of coal per hour and are equipped with automatic self-reversing traveling trippers arranged so that their travel may be controlled by hand.

Steam Heating

The exhaust-steam system of the company is one of the largest in the United States. It comprises over 15 miles of mains ranging from 2½ to 22 in. in size. Both the illuminating and suburban plant supply steam to the system, and it has been found advisable to carry the heaviest back pressure on the illuminating plant, which is nearest the center of distribution. With a winter temperature of 25 deg. F., the pressure at the suburban plant is carried at twice that at the illuminating plant. With lower atmospheric temperatures down to 10 deg., the pressure gradually changes until the suburban plant has three times that of the other, and below 10 degrees the difference in back pressure is four times greater than that at the illuminating plant.

One pound pressure is carried at the point of delivery to a building. If the pressure drops below this the engineer is at once notified. With the beginning of the heating season, the exhaust steam from one cylinder of the twin engine at the illuminating plant is turned into the heating main; exhaust steam from the compound engine at the suburban plant is turned into the main, but the back pressure on the low-pressure cylinder is not increased above 15 lb. In case it is necessary to carry more than 15-lb. pressure, owing to a drop in atmospheric temperature, the twin engine is used instead of the compound. If it is necessary to carry more than 15 lb. at all times, the piston of the low-pressure cylinder is removed, the valves are placed in the open position, and the piston-rod hole plugged. This allows any desired pressure to be carried. An auxiliary supply of live steam can be had, if for any

PRINCIPAL EQUIPMENT OF THE WASHINGTON AVENUE POWER PLANT, SCRANTON, PENN

No.	Equipment	Kind	Size	Use	Operating Conditions	Maker
1	Turbo-generator	Horizontal, 12-stage	4500-kv.-a.	Main unit	150 lb. steam, 1200 r.p.m., 4000 volts, 3-phase, 60-cycle	General Electric Co.
2	Turbo-generators	Horizontal, 8-stage	10,000-kv.-a	Main units	150 lb. steam, 1800 r.p.m., 4000 volts, 3-phase, 60-cycle	General Electric Co.

cause the exhaust-steam supply should be insufficient, by reducing the live-steam pressure from 150 to 5 lb. With 10-lb. back pressure about 130,000 lb. of steam is furnished to the system per hour by the suburban plant, and about 50,000 lb. by the illuminating plant at 10-lb. back pressure.

Fig. 13 is a view of the suburban-station switchboard, and Fig. 14 the busbar compartments. The two plants and the substations are connected by tie lines, of which there are four between the two power stations, four from the suburban plant to the Dix Court substation, and one from the latter to the illuminating plant. This arrangement, in connection with the motor-generator sets, makes

Fig. 14. Busbar Compartments

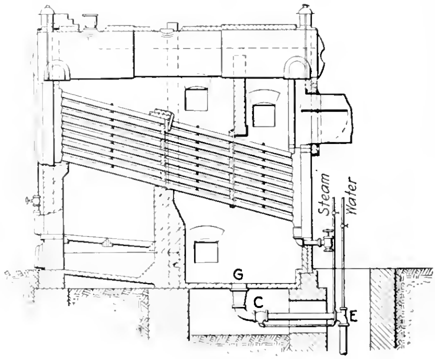
a flexible combination, because in case of an interruption in service the motor-generator sets can be used to generate either alternating or direct current.

There are also two tie lines from the Dix Court substation to the Hampton power plant of the Delaware, Lackawanna & Western R.R. Co., which provide a breakdown arrangement to the advantage of both companies. The conditions are that the Hampton plant has a heavy day load and the illuminating company a heavy night load, and either is supposed to help the other to the extent of 2500-kw. per hr., or more if desired when it is possible to do so.

In building the new power house the principal problems encountered were those of keeping the service up to the standard and at the same time tearing down the old building and constructing the new one over the old. Foundations for new units were built and old ones dismantled, requiring planning weeks in advance. The remodeling was carried on with but one complete shutdown, and that for only about 15 minutes, which reflects great credit upon the engineer in charge. The work cost not far from $2,000,000.

Schutte & Koerting Soot Conveyor

When the soot from the tubes of a boiler is blown down, most of it collects in the dust-settling chamber, from which it is occasionally removed through the clean-out doors. This operation necessarily involves labor and time out of service for the boiler. The illustration shows the application of a conveyor to a boiler setting for removing the soot each time the tubes are cleaned. It is operated by steam pressure and is installed in a pipe line that has connections to the combustion chamber of the



Steam-Operated Soot Conveyor

various boilers, as at *C*. Each connection is furnished with a slide gate, as at *G*, to cut in or out any particular boiler. Only the slide gate to the boiler being cleaned is open. Steam is then admitted to the conveyor, creating a high vacuum, and floating particles of soot are drawn into the system.

Sometimes the amount of soot to be handled is considerable, and as the steam consumption of the conveyor is the same under all conditions, after leaving the conveyor it makes a mixture not readily discharged, and for this reason a special elbow *E* is used. The boss is tapped to take a centrifugal spray nozzle, which injects water to wash the soot down the discharge pipes.

As the water is under pressure and as the nozzle is connected to the discharge in the direction of the flow, it not only helps to wash out the soot, but the water issuing from the centrifugal nozzles gives added velocity sufficient to overcome any reasonable counter pressure.

This soot conveyor is manufactured by the Schütte & Koerting Co., Thompson and Twelfth St., Philadelphia, Penn.

Painting Boiler Drums—In a plant equipped with B. & W. boilers developing 8400 hp., the interiors of the drums were scalded, painted both above and below the water line with silica-graphite paint, and allowed 48 hr. to thoroughly dry. This treatment was repeated every ten months. Pitting stopped, and where it had previously taken six men seven days to clean the drums of one boiler, two men now clean them in a day. This experience is quoted from a letter of the chief engineer of the New York Life Insurance Co., in the April issue of "Graphite."

The Southwark-Harris Diesel Engine

SYNOPSIS—A two-stroke-cycle engine with no scavenging or starting valves in the head, employing a stepped piston for both starting and scavenging and possessing unusual means of fuel control.

The impetus given the heavy-oil-engine industry in this country by the expiration of the original Diesel patents in 1912 has been marked particularly by the number of steam-engine builders who have entered this field. Some, choosing to follow foreign practice, are building under license from foreign firms with modifications to suit local conditions; others have developed what may be termed distinctly American designs. Among the latter may be mentioned the Southwark-Harris Diesel engine, built by the Southwark Foundry & Machine Co., of Philadelphia, from the designs of Leonard B. Harris.

This is a two-stroke-cycle type intended primarily for marine service, but also adapted to stationary work, the engine being somewhat simpler for the latter service, as no reversing is required. Because of the ingenious, yet simple and flexible, control for maneuvering, the marine type will be described.

Unlike most two-stroke-cycle Diesel engines, there are no starting nor scavenging valves in the head, the only opening being for the fuel atomizers, of which there is one to each cylinder in both marine and stationary types. There are two atomizer-actuating levers in the marine type, one for ahead and the other for astern; in the stationary type there is, of course, only one atomizer-actuating lever. This arrangement makes possible a very simple cylinder-head casting.

The pistons, as shown in Fig. 3, are stepped, the lower part serving as a scavenging pump besides acting as a guide in the place of a crosshead. The cylinders are in pairs and each scavenging piston serves the adjacent cylinder of that pair through the passage A, valve V_2, manifold M and port D. This will be understood when it is

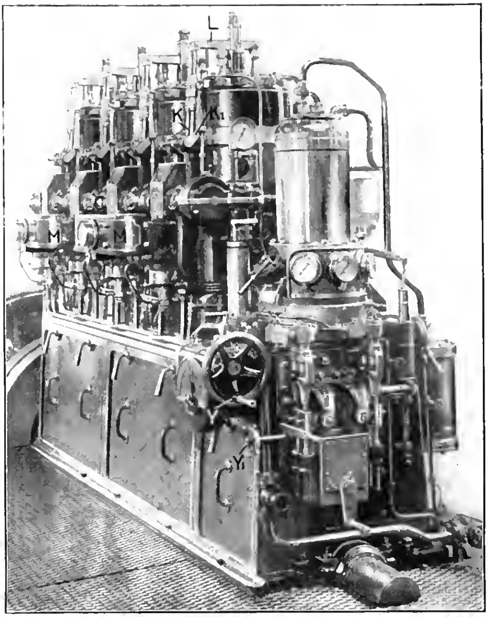


FIG. 2. END VIEW SHOWING PUMPS

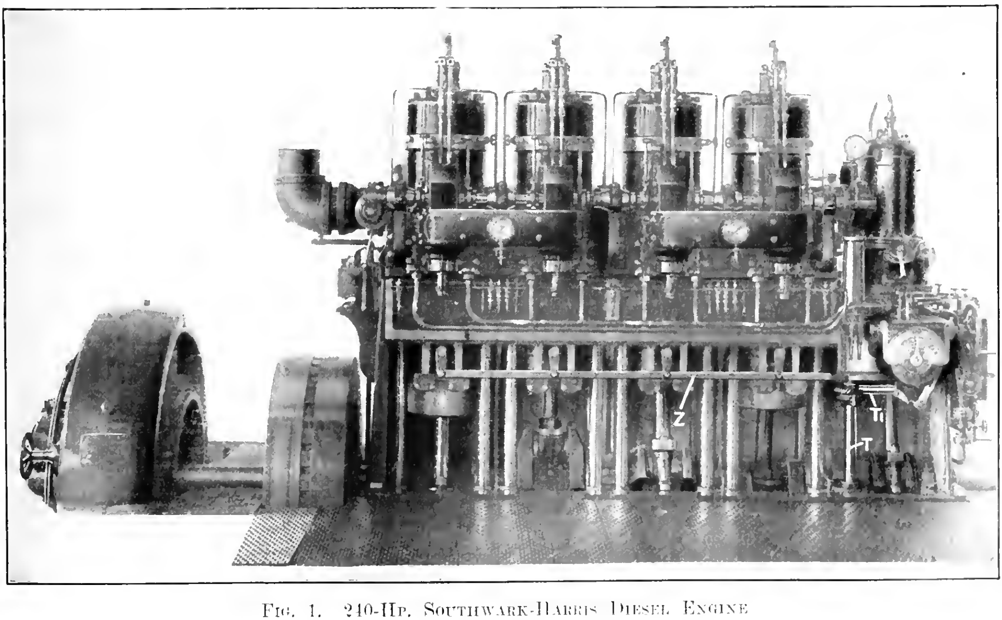

FIG. 1. 240-HP. SOUTHWARK-HARRIS DIESEL ENGINE

remembered that the cranks of a pair are set at 180 deg. Therefore, when the scavenging piston of cylinder No. 1 is traveling upward, compressing the air in the scavenging cylinder, ports and manifold, the pistons of No. 2 are traveling downward, and when No. 2 working piston has uncovered its port *D*, the scavenging air, under a pressure of about 7 lb., will rush in and force the spent products of combustion out through the exhaust ports *E*. The air-delivery valve of cylinder No. 2 prevents the scavenging air of No. 1 from being forced into the scavenging cylinder of No. 2 while its pistons are on the down stroke.

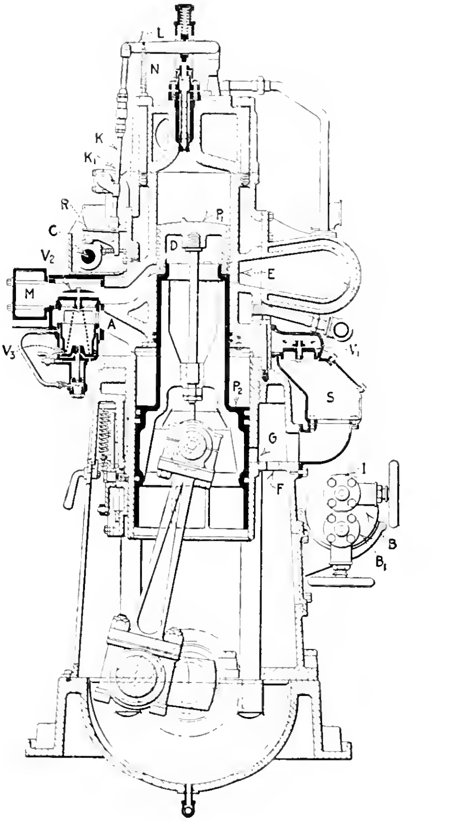

Fig. 3. Sectional Elevation

P_1 is the main piston; P_2, the scavenging and air-starting piston; V_1, scavenging-air inlet valve; A, scavenging-air outlet passage and starting-air inlet passage; V_2, scavenging-air delivery valve; M, manifold; D, scavenging-air inlet ports; V_3, the air-operated intercepting valve; O, outlet for starting air; S, silencer; F, vents; B, injection-air storage bottle; C, camshaft; R, atomizer-actuating rockers; K, push rods; L, atomizer levers; N, atomizer spindle; E, exhaust ports; I, injection air from compressor; B, bypass to starting bottles; K_1, bell crank.

An unusual feature of this stepped piston is its use for starting the engine—a most important factor in marine work, as it avoids admitting cold starting air to the highly heated working cylinders and pistons when reversing and maneuvering. Moreover, as the area of the stepped piston is greater than that of the working piston, starting air of relatively low pressure, 175 lb., can be employed. Since the starting is independent of the working cylinders, the fuel can be admitted to the latter while the starting air is still on. This will be found advantageous when starting under load, as the starting air can thus be used to help out until the momentum has been built up.

Of interest in this connection are the diagrams of Fig. 4. No. 1 is from the scavenging cylinder when starting

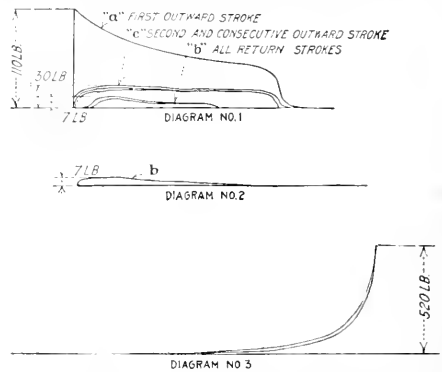

Fig. 4. Indicator Diagrams from Working and Starting Cylinders

with air, while No. 3 was taken simultaneously in the working cylinder. Line *a*, diagram No. 1, represents the first outward stroke, *b* the return stroke, and *c* the successive outward strokes until the starting air is shut off. It will be noted that after the first stroke, a pressure of only 30 lb. is required, owing to the power given back in the working cylinder by the expansion of the compressed

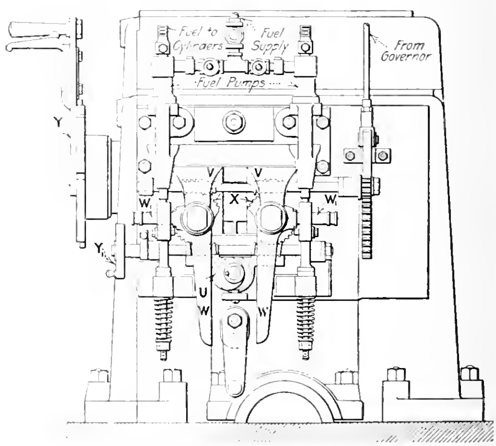

Fig. 5. Showing Fuel Control

air within it. Diagram No. 2 shows the normal working of the scavenging piston.

Starting and fuel-injection air is furnished by a two-stage compressor driven off the main shaft and having a control valve on the suction. The compressor delivers the high-pressure air for fuel injection directly to a steel air bottle mounted at the back of the engine frame. The starting air is supplied to the starting bottles through a reducing valve.

There is a separate fuel pump for each cylinder, making four in all in the engine shown. These are mounted at the end of the engine (see Fig. 2) and the stroke is varied by the governor.

A better idea of the operation of the fuel pumps will be gained by reference to Fig. 5. First, however, it will be necessary to revert to Fig. 1, which shows the pump shaft T_1 driven from the main crankshaft through the vertical shaft T and worm gears. At the end of T_1 is mounted a cam U, Fig. 5, which acts laterally upon the bell-crank levers W; these in turn work the pumps through the arms W_1, working in yokes on the pump stems. The fulcrum pins of the bell cranks are carried on laterally sliding plates V, the movement of which is effected

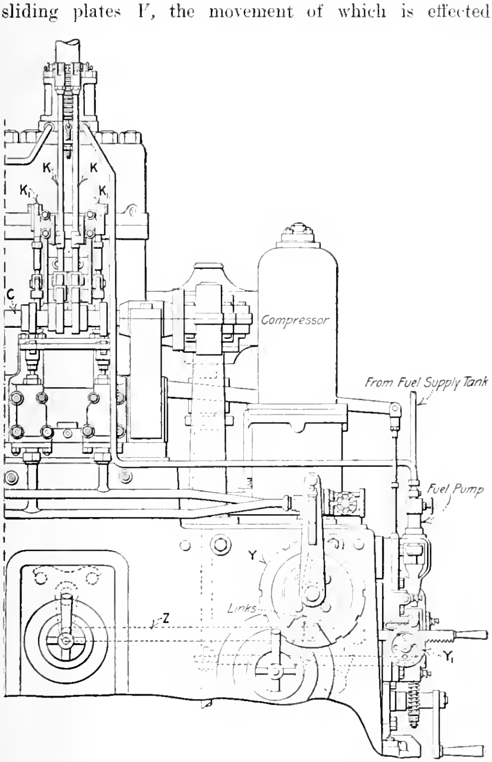

Fig. 6. Partial Side Elevation, Showing Further the Control Features

through two worm spindles, each carrying a pair of right-and-left-hand worms meshing with sectors X. The upper worm spindle extends to the right and connects through gearing with the governor shaft, while the lower worm spindle extends to the left carrying the handwheel Y_1 and connecting through links and a rack (see Fig. 6) with the main control handle Y.

When the pointer of the main control handle is in the central, or "stop," position (see Fig. 1) the bell-crank levers W (Fig. 5) are separated so as not to be actuated by the cam U. Through the arrangement of links shown in Fig. 6, this position of the bell cranks is held ordinarily through the starting period. When the control handle is turned past the first notch to the running position, the lower worm spindle is rotated and, by means of the sectors and slides, brings the bell-crank levers closer together, so that they are actuated by the cam U, and the fuel pumps are set in operation. The governor, now acting through the upper worm spindle, is able to control the position of the bell cranks and vary the stroke of the pumps to suit the load. The small handwheel Y_1 permits manual control of the fuel without altering the position of the main control wheel Y. By this means the engineer is enabled to control the speed of the engine at will, and the governor will maintain control at this speed. This feature is especially useful in marine work when running through a heavy head sea with the engine racing.

In addition to the fuel control through varying the stroke of the pumps, the lift of the fuel atomizers may be altered at will from the control wheel while the engine is running. Referring to Fig. 3, the lower ends of the atomizer push-rods may be swung outward through the arc on the upper side of the rockers, which in turn are actuated by the cams on the main camshaft. It will be seen that when the push-rods are at the extreme right the rockers can be actuated without imparting any motion to the atomizer spindles. When they are moved to the extreme left the atomizers will have their greatest travel. Intermediate positions of the push-rods on the rockers will correspond with definite openings of the atomizers. These push-rods are shifted by means of the bell cranks shown, which in turn are operated through vertical rods connected with the horizontal bar Z (Figs. 1 and 6), also connected with the control handle. The operation is obvious.

A four-cylinder, 240-i.hp. Southwark-Harris engine has just been installed in the yacht "Southwark," owned by C. P. Vauclain, of Philadelphia. The "Southwark" is 98 ft. overall, 16-ft. beam and 7-ft. draft, and on her first trial trip made a speed of about 10 miles per hour against the tide and a head wind, with the engine turning up at 225 r.p.m. Extensive tests are now being made and the results will be available at an early date.

The principal dimensions, horsepower, weight, etc., of the sizes listed are given in the following table:

Increased the Capacity of the Plant—B. M. Babcock informs us that in his letter under the foregoing caption, May 18 issue, the beginning of last paragraph on page 685 should read: "The grate surface was extended from 6 ft. in length to 8 ft., giving 56 instead of 42 sq.ft. of grate surface," instead of, "the grate surface was extended from 42 in. in length to 56 in."

Priming a Centrifugal Pump*

By E. M. Ivens

SYNOPSIS—Several letters on the troubles experienced in priming centrifugal pumps have appeared recently in Power. *Interested, and drawing on his wealth of experience in this practice, Mr. Ivens presents the following, which shows several ways of overcoming priming troubles. It is a timely, practical and interesting article.*

The several letters that have appeared in Power on the subject of priming centrifugal pumps indicate that much interest centers in that topic.

It is more or less well known that before a centrifugal pump of the suction type can pick up its water, the air contained in the space between the top of the impeller blade or blades and the surface of the water in the suction basin must be expelled. With the removal of this air there occurs, inside and outside of the pump and piping, a difference of hydrostatic pressure which causes the water to rise in the suction pipe and submerge the rotating parts, and immediately, discharge of water begins. The height to which water may be so lifted obviously depends upon the barometric conditions at the time. At sea level the theoretical lift is equivalent to 14.7 lb. of pressure (approximately 34 ft.), but owing to the impracticability of obtaining and maintaining a perfect vacuum, it is impossible to operate a pump having so high a lift. Pump manufacturers seem to have agreed that 25 ft. (dynamic) is the practical limit and advise that less than this be employed if possible.

There are but two principles that may be followed in priming a centrifugal pump and its piping. One is to actually withdraw the air, using vacuum-forming ap-

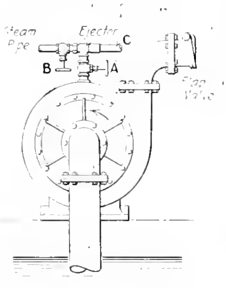

Fig. 1. Steam Ejector for Priming Pump

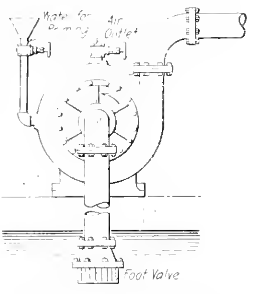

Fig. 2. Displacing Air by Filling Pump with Water

paratus of some kind, and the other is to displace the air with the liquid to be pumped. Fig. 1 illustrates an elementary installation wherein the former method of priming is employed, and Fig. 2, the latter.

In Fig. 1 the air is exhausted by means of the well-known steam ejector placed on top of the pump casing. As shown, the system is closed to the atmosphere by means of the flap valve placed at the end of the discharge pipe. Plainly, this method can be employed only when steam is available, and even then it is objectionable in that the flap valve is with difficulty made air-tight. The method is exceptionally tedious and expensive when relatively high lifts and long suction and discharge pipes are necessary.

In Fig. 2 water is admitted from some outside source, usually an overhead tank provided for the purpose, through the funnel shown and is held by means of the foot-valve attached to the lower end of the suction

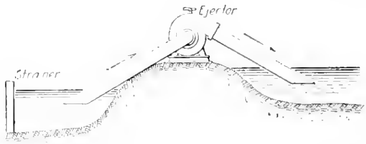

Fig. 3. Typical Location of Pump for Drainage or Irrigation Systems

pipe. An air vent is provided at the top of the volute to prevent "locking." It frequently happens that obstructions find their way through the strainer and lodge on the seat, preventing a complete closure of the valve and making priming temporarily impossible. Expensive shutdowns often occur and considerable annoyance is experienced with foot-valves, when water is drawn from rivers, lakes or other open bodies of water, as is done in rice irrigation and land reclamation.

Centrifugal-pump installations are seldom as simple as those just described. More often, long and angular suction lines are necessary and various other conditions peculiar to the requirements have to be met, such as method of drive, angle of suction and discharge nozzles, stability of water level in the suction basin and the nature of the pumping head.

The writer is fortunate in that he has had the opportunity to design and install a number of pumping plants having a wide range of capacities and pumping heads. With the experience gained it has been found possible to overcome the typical priming difficulties previously mentioned and thus preclude the possibility of annoyance due to loss of vacuum, and at the same time meet the conditions imposed by the nature of the duty. Following are three descriptions of priming methods that have given satisfaction and may be applied to advantage in many places. These will be recognized as embodying the principles already given, but somewhat modified to meet the requirements of each installation.

Fig. 3 illustrates an installation of a low-lift, large-capacity pump such as used in drainage projects. As may be noted, both suction and discharge ends are water-sealed and consequently the use of the troublesome foot and flap valves is dispensed with. A steam ejector is fitted to the top of the pump casing for priming. In the event that steam is not available, a vacuum pump, independently operated, may be substituted. This method of installation possesses other advantages not pertinent here.

*"Power," Mar. 2, p. 291; Apr. 6, p. 481; Apr. 20, p. 550; May 4, p. 615; June 8, p. 778.

Fig. 4 shows a row of motor-driven turbine pumps installed in the water-works plant of a small Louisiana town. The four larger pumps have each a capacity of 250 gal. of water per min. against 100 lb. pressure and are reserved for fire purposes only. The smaller pump is for constant service and has a capacity of 100 gal. per min. against 45-lb. pressure. Current for the motors is supplied by two oil-engine-driven alternators.

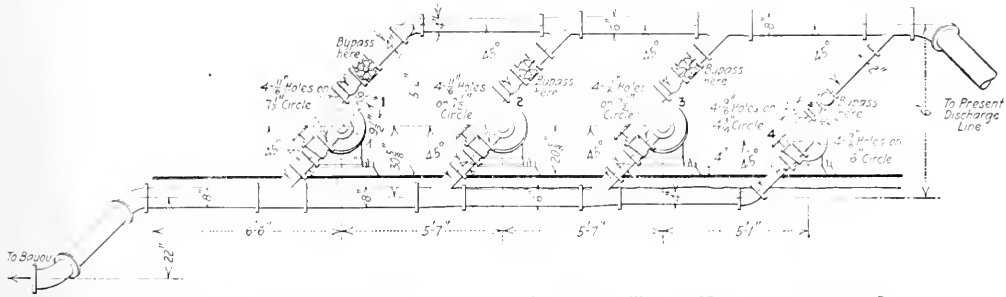

Fig. 4. Layout of Pumping Plant for Small Louisiana Town; Note the Suction Lift

The arrangement of valves and piping is such that any one or all pumps may be placed in service at any time. The suction line is 8 in. diameter, 125 ft. long, and the static suction lift is 12 ft.

These pumps are primed by the method of displacement. Located in the suction line and in the manner shown in Fig. 5, is a surface priming valve designed by the writer. This valve is a combination check and flap valve having all parts made readily accessible by suitably located hand holes. Fig. 6 shows the exterior of the valve and Fig. 7 a vertical cross-sectional view.

The operation of priming and the action of the valve are as follows: Water is admitted from the standpipe

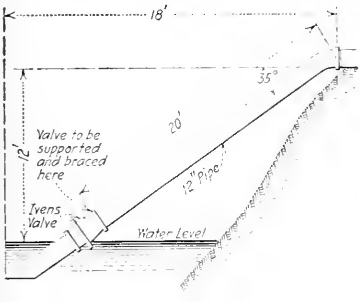

Fig. 5. Application of Valve Shown in Fig. 7

to the pumps through the bypasses indicated in Fig. 4, and the air is vented off through pet-cocks provided on the tops of the pump casings. When water appears at the pet-cocks, the system is filled from the discharge nozzles to the surface valve. Between the valve seat and the water surface there remains an unfilled space or air pocket. Before the column can be started this air must be disposed of, and this is done by the action of the small check valve shown at *A*, Fig. 7, and in the manner later explained.

The motor is now started, and when the full-load speed is reached there appears a tendency to force the contained water out of the discharge, and a surging results. This relieves the pressure above the small check valve, it is opened by the air pressure beneath and air rushes in from the pocket, breaking the partial vacuum created. The column pressure then closes the check valve, and the air admitted by its raising seeks the high point, which is the discharge nozzle of the pump. Continued operation of the motor is accompanied by continued making and breaking of vacuum due to surging, until finally the air pocket disappears. The large flap is then opened by the rising column and occupies the recess provided in the valve body. A free passage is offered to the column, and the only resistance encountered is that caused by part of the weight of the flap.

As shown in Fig. 7, cleaning of the valve seat may be easily accomplished through the handholes and a thorough examination or renewal of all moving parts made by removing the large cover plate to which the flap is attached.

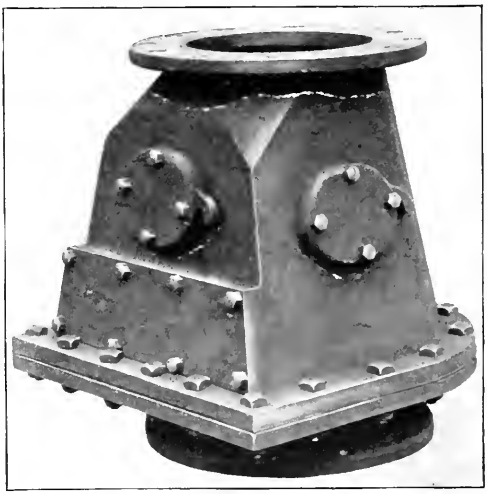

Fig. 6. The Ivens Priming Valve

The writer has used this valve with gratifying results on medium-lift pumps where it was necessary (owing to fluctuating suction lift) to attach the valve direct to the suction elbow, or Y connection, on the pump and some 20 ft. above the water level. Several rice-irrigation plants located on the Mississippi River are using the valve in this way.

A rather interesting system of automatic priming suggested by the writer is employed by a large sawmill in Louisiana. A diagrammatic illustration of the installation is shown in Fig. 8. The equipment consists of a 750-gal., two-stage turbine pump, direct-connected to a 100-hp., 2200-volt, three-phase, 60-cycle, 1740-r.p.m. motor, and a 6x4½-in. vacuum pump, gear-driven by a 5-hp., 220-volt, three-phase, 60-cycle motor. The plant is located on the Mississippi River about a mile and a half from the electric generator which furnishes the current for the motors.

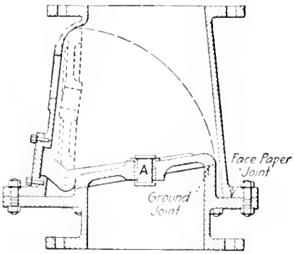

FIG. 7. SECTION OF IVENS PRIMING VALVE

The suction of the vacuum pump is connected to a chamber and thence to the discharge nozzle of the pump, as shown. The chamber is made of 6-in. pipe and contains a cedar float suspended by a rod attached to a check valve above. The weight of the float and rod is sufficient to hold the check open under 25-in. vacuum when the chamber is empty. If, by any chance, water should enter the chamber, the buoyancy of the float permits the check to close immediately. This prevents water being drawn into the cylinder of the vacuum pump.

The motor operating the vacuum pump is equipped with a pressure-control switch, the pressure pipe of which is connected to the discharge nozzle of the centrifugal pump. Operation is as follows:

Both motors are started simultaneously and the vacuum pump rapidly withdraws the air, priming the system. When a pressure of 10 lb. is reached in the water-discharge piping, the pressure switch actuates and the vacuum pump is stopped. If, at any time, the pump should lose its column, the vacuum pump starts automatically and the process of priming is repeated.

This installation has no regular attendant, and difficulty has never been experienced since first starting.

It is quite true, as Mr. Palmer says (POWER, Apr. 6 issue), that considerable trouble has been experienced in priming centrifugal pumps, but often the operator is to blame and frequently the fault lies in the method of installing the equipment. In answer to trouble calls the writer on two occasions traveled several hundred miles, to find the pump rotating in the wrong direction. On a number of other occasions the trouble was caused by leaky suction pipes or air locking due to the accumulation of air at high points in the suction piping. One unpleasant experience was caused by the designer's disregard of frictional loses, and an attempt was being made to operate several pumps with a suction lift far in excess of that theoretically possible. In every instance the operator first stated that the pumps were defective and then, after his difficulty had been overcome for him, it was "priming trouble."

Characteristics of Radiation Pyrometers

The Bureau of Standards will have ready for distribution shortly a paper entitled "Characteristics of Radiation Pyrometers." A careful study of this type of temperature-measuring instrument was considered urgent on account of the extensive use of radiation pyrometers in the technical industries. These instruments are widely used in the temperature control of the various processes involved in iron and steel manufacture, alloy-foundry work, glass, ceramics, and brick manufacture, smelting, gas works, steam generation, lamp manufacture, etc.

Many of the instruments examined show different temperature readings for different focusing or sighting distances. Errors thus occasioned may amount to several hundred degrees. The effect of dirt upon the lenses and mirrors is of serious importance. The question as to whether the pyrometer absorbs all the heat radiation falling upon it is discussed, and the theory of the instrument and the connection of its behavior with the theoretical radiation laws are given.

The bureau receives a large number of these instruments for test and standardization from various technical industries throughout the country. Heretofore, this testing required about three days for a single instrument, on account of the difficulty in heating a furnace to an exactly uniform temperature. A new method has been developed which permits a satisfactory standardization of a radiation pyrometer within one hour. Many suggestions are given for minimizing the errors to which the pyrometer is subject, and it is shown that this type of instrument, suitably designed, adequately calibrated and correctly used, is a trustworthy pyrometer having many advantages over other types of temperature-measuring devices, both for scientific and technical use.

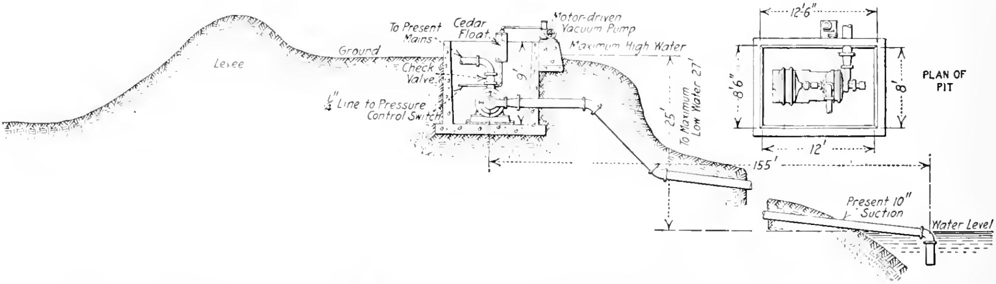

FIG. 8. PUMPING PLANT HAVING MOTOR-DRIVEN AIR COMPRESSOR WHICH AUTOMATICALLY KEEPS PUMP PRIMED

Firebrick for Boiler Settings*

By William A. Heisel†

SYNOPSIS—An unusually complete, interesting and highly valuable article on an important subject about which little has been written.

Chemically pure fireclay consists of silica and alumina and combined water. Pure fireclay is called "kaolinite" and consists of about 40 per cent. of alumina, 46 per cent. of silica and 14 per cent. of combined water. It acquires in its travels various impurities, such as iron, lime, magnesia, alkalies, soda and potash, together with more or less organic material.

In this country the most important fireclays are found in Kentucky, Pennsylvania and Missouri.

Physical and Chemical Properties of Fireclays

Flint clays are more nearly chemically pure than plastic clays, because of the difference in their formation. The flint clays have practically no plasticity, while the plastic clays vary from slightly to highly plastic.

The colors of plastic fireclays range between the two extremes of white and black, with such intermediate colors as gray, brown and olive. Flint clays do not show a marked color difference, being either white, gray or mottled black. The color of clay is not always a safe guide in its selection for quality, for in some cases it indicates the amount of contained impurities in both the flint and the plastic clays.

Impurities in Fireclays

The impurities in fireclays occur in various forms—the iron, for instance, as pyrites (sulphite of iron), sometimes in large particles widely distributed, and at other times in small particles uniformly distributed. Again, the iron occurs as carbonate of iron, usually in large, hard lumps. The lime occurs as gypsum and as limestone. When magnesia occurs, it is usually associated with lime in limestone. The alkalies enter in the form of mica or feldspar.

The amount of contained impurities in the finished product, firebrick, is not always a reliable indication of the temperature at which the brick will soften, as is clearly shown by the curves representing the result of 44 different tests.

Method of Manufacture

The impossibility, on account of excessive shrinkage and consequent liability to warpage, of using all raw clays makes necessary the calcining, or burning, of some of them, preferably the flint clay, to obtain a high-grade product. The amount to be used of this calcined, or burned, clay is determined by the physical and chemical qualities the manufacturer is striving to obtain for the character of work. As flint clays and calcined clays have no plasticity, a bonding material is necessary, this being supplied by a plastic clay. The amount of the latter used for bonding varies from 15 to 50 per cent. In some classes of work, practically all plastic clay is used.

Firebricks are used in innumerable ways—in the various metallurgical furnaces, in the manufacture of lime, cement and glass, and in the settings of steam boilers.

The last practice, particularly in later years, has demanded a higher grade of brick than was satisfactory under the former milder working conditions. The more general use of mechanical stokers, their greater degree of perfection and the more thorough knowledge by the operators of the theory of combustion, have developed conditions which have made high-grade firebricks much sought for. The development in the manufacture of firebricks has not kept pace with the comparatively more marvelous increase in the severity of service in boiler and stoker installations.

Boiler-Furnace Conditions

With the present modern equipment much improved combustion occurs, much higher temperatures prevail and higher ratings are obtained than were possible with the less intelligently designed and operated installations and boiler and stoker equipment of former years. Whereas some years ago a 50-per cent. overload on a boiler was about the maximum to be expected, it is now not uncommon to see in the larger plants stoker-fired installations operated at 100 to 150 per cent. over their commercial rating.

While not much thought was given to the selection of firebrick in previous years for boiler work, and a brick of mediocre refractoriness would show reasonable life, the best today is none too good under the present extremely severe operating conditions. It is not to be inferred that much progress and improvement have not been made in the manufacture of fireclay brick, as a superior article is today being made by most manufacturers, and continued advancement may be expected.

It would seem from present-day experiences that the capacity of most stoker-fired boilers is limited only by the ability of the firebricks to withstand particularly the extreme temperatures generated. As an example of high temperatures: In some stoker-fired furnaces a quantity of platinum was melted in a graphite crucible, the melting point of platinum being 3191 deg. F. This temperature approaches closely the melting point of pure fireclay, which is 3326 deg. F.

Refractories with High Melting Points

Efforts have been made to substitute materials with melting points higher than the commercial fireclay brick, but because of the inability of these materials to withstand certain other conditions, such as sudden heating and cooling, pressure at high temperatures, the action of certain gases of combustion, and the chemical action of certain fused ash, these substitutions have failed to realize the theoretical expectations. The other refractories that have been given a trial in boiler work are silica, bauxite, chrome and magnesite.

Silica bricks, made from silica rock, or ganister as it is sometimes called, and bonded with about 2 per cent. of lime, have the particular objection for use in boiler-furnace work, especially in arches, of being unable to

---

*Paper before the Ohio Society of Mechanical, Electrical and Steam Engineers.

†With the Charles Taylor Sons Co., Cincinnati, Ohio.

withstand sudden changes of temperature without spalling. The lime used as a bond in silica bricks combines with the silica and makes a product that is hard and dense after burning. Although silica bricks are highly refractory and should stand high temperatures, it would not be practicable to maintain, in boiler furnaces, conditions that would be favorable to their long life and general use. In furnace side-walls silica bricks, because they are an acid material, would be readily attacked by the usually basic ash, the ash of nearly all coals being high in ferrous oxide (oxide of iron) which is basic in relation to silica.

Silica bricks would stand the service well with an oil or gas flame, as far as chemical action is concerned, but here again the sudden change in temperature following the sudden turning on or shutting off of the burners would cause a rapid deterioration through spalling. With coal the furnace temperature is not so suddenly reduced, as the fuel bed acts as a reservoir of heat.

A silica brick in comparison with a fireclay brick has a permanent expansion; that is to say, upon repeated heatings its size increases up to a certain point, the rate of increase varying with the different makes of silica bricks. For example, upon the first heating it increases, say, to about 0.04 in., upon the second heating to about 0.03 in., and upon the third to about 0.02 in.—a total of 0.09 in. If, then, it had reached its limit, further heating would increase the size only temporarily, the brick reducing to its final size upon being cooled. The tendency of the firebrick is to become slightly smaller, if anything, upon repeated heatings.

Springs in Arches Unsuccessful

Silica bricks have been used in the arches of heating furnaces in metallurgical operations, and the expansion of the silica arch taken care of by sets of springs placed on the sides of the furnaces at each end of the arches. This is a costly and an annoying arrangement, so we are told, and so far as known is not sufficiently satisfactory to meet with general adoption.

Chrome and magnesite bricks, used in basic openhearth furnaces and other places where the temperature and chemical action is severe, would seem to be ideal for use in boiler side-walls, but because of their inability to withstand much pressure at high temperatures and the heating and cooling effects, these materials are out of the question.

On bauxite bricks experiments are being made to determine their value as a refractory in boiler settings. It has been difficult thus far to make a product of bauxite which will give uniformly good results, by reason of the wide variation in the chemical composition and physical properties of the raw material and the difficulty met with in attempting to control the crude ore. On account of the value of bauxite to the aluminum manufacturer the fields of the best ore are owned by the aluminum industry, and what is available to the brick manufacturer is of inferior quality. Also, more than the usual methods must be employed in reducing the great shrinkage in bauxite, which requires calcining at high temperatures. Bauxite brick, too, is likely to spall.

From the discovered deficiencies of these special refractories—namely, silica, magnesite, chrome and bauxite—for boiler furnace and arch practice, it would appear that the manufacturer who is striving to develop an extraordinarily refractory product for this class of service must confine himself in his experiments to find the proper combination of fireclays.

Selection and Use of Materials

Much trouble with firebrick settings is due to improper selection and ignorance in the use of the materials, and also in many cases to lack of care in constructing and laying up the work. In arches, particularly where the service is hard, care should be taken that all bricks in the same row are of the same thickness and shape, as it is difficult to secure high-grade brick of the same thickness and uniformity. This fact is apparently recognized by the United States Government, which makes liberal allowances for variation in the size of firebrick in its specifications. In a maximum of 9 in. in length it allows a minimum of 8¾ in., although this wide variation should not occur in any one lot of brick and is a variation that the manufacturer would not be proud of.

A conscientious mason will carefully select his brick, culling out those of irregular shape, and will try the selected brick dry over the arch-form with a straight-edge. Then he dips them in a creamy solution of fireclay and rubs them in place. Bricks of uneven thickness should be cut and rubbed. If this care is not exercised large fireclay joints will be required and the life of the arch seriously shortened.

Wedges should be used as often as is necessary to keep the bottoms of the bricks in even contact with the arch form, and the key-brick course should make a true fit from top to bottom. The key brick should be driven from 1 to about 1½ inches, depending upon the hardness of the brick and the width of the arch.

Fireclay Mortar and its Relation to the Life of Firebrick

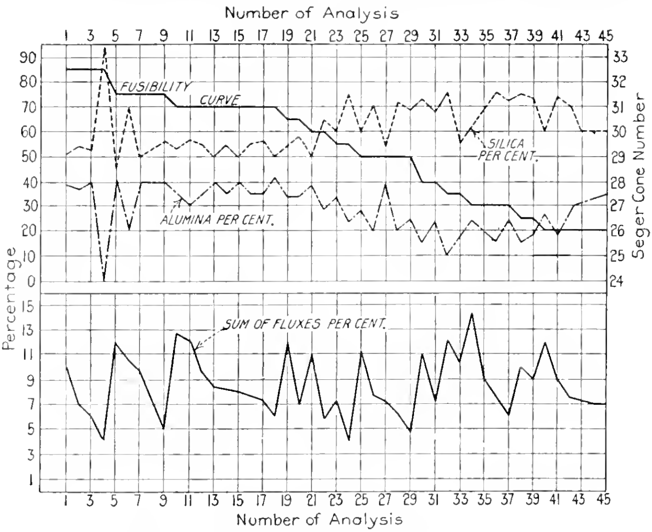
All firebrick, whether fireclay or special refractories, should be laid in mortar of nearly the same composition as the brick itself to prevent a fluxing action, such as would be caused if, for instance, siliceous mortar were used with magnesite brick. In the case of fireclay bricks, a good grade of fireclay should be used, the refractoriness of which is practically equal to that of the bricks themselves. This precaution is sometimes not taken, with the result that the fireclay begins to melt at a lower temperature than the bricks will stand, and in melting dissolves the bricks adjoining it, much the same as a piece of copper is melted at a temperature lower than its natural melting point when placed in a pot of melted babbitt metal. Inferior clay used in an arch may therefore result in the softening of the bricks and the collapsing of the arch.

Foreign materials, such as salt and lime, added to fireclay to make it soften and fuse the brick together is, in the manufacturer's opinion, a practice not to be recommended, as both of these materials are active fluxes and readily attack the bricks, especially at high temperatures.

In mixing fireclay to be used as a mortar, best results can be obtained by using a certain amount of fire sand; that is, pulverized calcined clay or bricks. This prevents shrinkage of the raw clay and the crumbling out of the joints. Regarding the benefits derived from boiling fireclay, there is a difference of opinion. Some boil the clay, feeling that it takes out the shrinkage, although there is not enough heat in the boiling process to take out any appreciable shrinkage; but boiling results in a complete mixture, making it free from lumps and putting it in shape to make a tight job.

Laboratory Tests Compared with Practical Tests

In selecting bricks to be used in furnace practice, the manufacturer is often asked for an analysis of the brick he intends to furnish in order that the user may judge as to its quality. The analysis alone of a brick does not afford the best way to judge its suitability for the work intended, as the analysis merely shows its composition without giving any information as to its physical properties, which are usually more important than the chemical composition. The analysis does not reveal the way in which the impurities occur—an important item in considering the temperature to which the bricks may be subjected without danger of failure. The curves show clearly that the melting point cannot be judged by the analysis alone. On these curves showing the fusibility of 44 different firebricks, the percentage of silica, alumina and total fluxes present in each brick, it will be noted that brick No. 5 melted at Cone No. 31½, or 3200 deg. F., and had 42 per cent. of alumina, 47 per cent. of silica, the sum of fluxes being 12 per cent.; brick No. 21 melted at Cone 30, or 3046 deg. F., and had 50 per cent. of silica, 38 per cent. of alumina, the sum of fluxes being 11 per cent. It would seem from the similarity of these analyses that these two bricks would melt at the same temperature, but owing to the difference in the physical structure one is more refractory than the other.



Results of Analysis of Forty-Four Firebrick

To secure a sample for determining in a laboratory the melting point of a firebrick, the usual method is to knock a corner, about one inch high, off a brick, the bottom of the test piece so secured forming a triangle, each side of which measures approximately one-half inch. This piece, together with three small cones, each having a different known melting point, is then placed in an electric furnace for observation as the temperature of the furnace increases. When the sample piece of firebrick, in the form of a small pyramid, loses its shape, it is considered melted, and the highest pyrometric cone which is melted alongside of the test piece indicates the melting point of the brick. For example, if three pyrometric cones were used, each having a different melting point, say 3218, 3254 and 3290 deg. F., and the 3254 deg. cone was left unaffected, while the 3218 cone was melted at the time the brick sample started to melt, we would know that between 3218 and 3254 deg. F. was the melting point of the sample. This way of determining the melting point has the advantage over other methods using pyrometers, inasmuch as these cones take into account the time element; time should be considered in determining the softening temperature of any fireclay product, as a brick which melts at a high temperature, say in one day, can be melted at a much lower temperature by holding the heat for a longer time.

The melting point is sometimes determined by means of an optical pyrometer. This is also a good method, if all tests are carried out in the same length of time, so as to be comparative.

The temperature at which a piece of firebrick melts in an electric testing furnace is often higher than this same brick will stand in a boiler or commercial heating furnace, as in such furnaces there are conditions, such as the action of the slag and furnace gases, which are not present in the small electric furnace test. On the other hand, in the electric furnace the brick is surrounded by a high soaking-in heat, no chance being afforded for radiation, as is the case with bricks in furnace walls in some types of furnace arches. The service due to heat alone is not as severe on firebricks placed in walls exposed to the atmosphere as in partition or division walls between furnaces, where the heat i. acting on both sides of the wall. That this is true is demonstrated by the longer life that arches exposed to the air on one side will show over those subjected to fire on both sides. Although brickwork will show longer life where there is such cooling action, this gain is usually had at the expense of lost heat energy.

United States Government Tests

Another way to determine the softening point is by means of the government load test. This consists in placing a brick on end, loaded 50 lb. per sq.in. of cross-section, and in having it successfully stand a temperature of 2400 deg. F. for one hour without showing any deformation, checking, spalling, or contraction greater than ½ inch in length. In making this test the heat is brought up so that 2400 deg. F. is reached in four hours, and this temperature is maintained for another hour. Another government test consists of breaking up a brick and subjecting the pieces to a temperature of 3200 deg. F., which it must stand without softening. Under the load test, if the brick contains many impurities, its fluxing action will occur at this or a lower temperature and cause the brick ^ soften, thereby allowing it to compress under the total weight of 562 lb. This load test is better than the melting- or softening-point test, as it shows more clearly the temperature at which the brick commences to soften, and this is the temperature which the user of firebrick, especially firebrick for boiler practice, is interested in. It is also a more comparative test than the melting-point test, as the time element is always the same and it is merely a case of measuring the length of the brick before and after testing to determine the contraction; whereas in the melting-point determination the question always arises at just what point the brick is considered melted, that is, whether it is melted when the tip and sharp corners of the pyramid become rounded or whether it is melted when the piece of brick is seen to distinctly flow, the difference in temperature between these two points being considerable, as the viscosity of most brick is high.

Conductivity of Brick Important

The conductivity of firebrick is a property seldom mentioned in considering brick for boilers; but tests have shown that a hard-burned, dense brick possesses a higher conductivity than a soft, open-grain one. The chemical analysis does not provide information as to the rate at which a fireclay brick will conduct heat, this property depending upon physical makeup.

Some Causes of Failure

A not unfrequent cause of trouble in arches is spalling, which is a popping-off of large pieces of the bricks. This sometimes results from arch bricks becoming frozen or wet through a leaky boiler tube, header cap, drum seam or water used in washing out or in turbining the boiler tubes. With this condition unnoticed or unknown to the operators, a hot fire is started before the bricks have been slowly dried, with the result that some, if not all, of the bricks crack and pop off. Once this action is started in any part, the balance of the arch is usually doomed to early destruction. This is because the adjoining bricks are exposed on more than one side to the action of hot gases, more area is receiving heat and more heat is being absorbed by these bricks than they have capacity to take care of by conduction and by final radiation to the atmosphere or a cooler zone of the furnace.

Why Spalling Happens

Spalling, again, may be caused by the natural inability of the brick to withstand the high temperatures of large volumes of slowly moving or confined gases. The ends of the brick are absorbing heat faster than they can conduct it to a comparatively cooler zone, consequently the clay in the exposed ends becomes vitrified, the elasticity of that portion is lost, and when further heating and cooling take place the difference in the rate of expansion and contraction between the two parts of the brick causes a separation, the vitrified section dropping off unless held temporarily by the compression of the arch.

Spalling is also the result of strains due to inrushes of comparatively cold air striking the incandescent bricks and suddenly contracting them. These cold blasts occur when fire-doors are held open too long, or when hand- or stoker-fired grates are improperly operated and large holes in the fuel bed permit a strong draft to pull the cooler outside air into the furnace.

A test sometimes resorted to by prospective buyers to determine the value of a brick for archwork, is one wherein the sample is placed in the furnace, brought up to a red heat, and suddenly dropped into a pail of water. If it does not crack, it is assumed that it will not spall in service. This is no indication of the ability of a firebrick to withstand the heating and cooling strains in an arch, as the conditions are not the same. In heating a brick in an open fire it expands uniformly in all directions, and when thus suddenly cooled the contraction is likewise equal in all directions, whereas a brick in an arch is exposed to high temperature on one side and to comparatively cool gases on the other. When the bricks in an arch are suddenly cooled by a draft of cold air, the upper ends contract at a different rate from the remaining portion.

It is found that a close-grained, hard-burned brick is usually more susceptible to this action than a soft, open-grained, or porous, brick, which is more elastic and better able to adjust itself to this expansion and contraction. The theoretical explanation of this is that in a close-grained, or fine-ground, hard-burned brick, the molecules are more closely associated and heat is more rapidly transmitted from one molecule to the other. Open-grained bricks for this reason act, we might say, more as insulating material, tending to repel the heat instead of absorbing it. When making this comparison we have in mind only such bricks as are made of highly refractory clays, as no matter how carefully a brick may be constructed, if it has not clays of such refractoriness as will resist the action of the temperatures applied, it will be useless for the work.

Another trouble with arches is caused by the improper setting of the skewbacks, through a failure to pack them tight against the buckstays at the sides of the furnace, or using with them, as filling-out pieces, firebrick which come up tight to the buckstays and are set snugly together without fireclay joints.

Allowance for Expansion and Contraction

Arches should be designed and constructed so that they will meet no interference when expanding or contracting. They should not be tied into front-wall brickwork or carry the weight of any other part of the setting. One also should strive to secure as nearly as possible the same conditions both under and above the arch for its entire length. In other words, if an arch within a boiler setting is made a continuation of the dutch-oven arch outside the setting, there is liability of the arch breaking. The extension furnace arch has its upper side exposed to the cooler atmosphere, while the inner arch is in contact with the hot gases of combustion on both sides. The rate of expansion of these two differently located parts of the arch, it is evident, will be different.

Spring of Arch

Arches with too much spring frequently buckle and break their backs when they rise by expansion. A rise or spring of 2 in. to the foot of furnace width is the commonly adopted practice. This gives a reasonable spring to the flatter arch and acts as a resistance to expansion, keeping the arch tight.

Rounding off the last, or end, bricks in an arch frequently lessens or remedies the trouble caused by the spalling off of these ends, and due to the gases making a short, right-angled turn and throwing an intense heat into the corner of these bricks, which have two of the faces exposed.

Different Brick for Different Parts of Furnace

In considering firebricks for different parts of a furnace, it must be borne in mind that the conditions in side walls are different from those in an arch and that a brick which often gives excellent service in arch practice does not always give correspondingly good results in the side walls of the same furnace. It is therefore well in some cases to use two kinds of brick rather than to try to make one kind do for both places.

Arch practice requires a brick that is not only sufficiently refractory to withstand high temperatures, but one that will withstand these temperatures under much compression, that will not spall and that has a minimum amount of shrinkage and expansion.

In the United States Government tests made on various bricks throughout the country, many bricks were found which would hold up under a temperature test of 3000 and 3200 deg. F. without softening, but only a few, we understand, stood the heat test under pressure.

Furnace side walls are not so much affected by spalling as they frequently are through the chemical action of the fused ash and distilled gases of some coals. Generally speaking, where coal is used as fuel, furnace side walls require a brick less porous and soft than would be used in an arch, in order to stand abrasion from the fire tools and the cutting action of the clinkers when being disturbed or removed.

Arch Blocks

Blocks for arches and side walls are sometimes used and in many cases give better results than standard 9-in. brick. They have the advantage of reducing the number of joints and parts to lay, and the radial arch blocks turn true to the given circle. These blocks are usually made on special orders of a certain combination of clays, are tried for fit, and by some manufacturers machined down, where necessary, on a carborundum wheel to secure level sides and to insure a good fit. On account of the greater mass of contained material, these blocks must be carefully and slowly dried on a cool floor and painstakingly burned.

Turbo-Reduction Gear

The planetary type of gear shown in Figs. 1 and 2 is a recent development of the Turbo-Gear Co., Baltimore, Md. It is designed to be used as a speed-reducing or speed-increasing gear and will run either right- or left-hand. The driving and driven shafts rotate in the same direction.

The gear consists of a large internal double-helical gear made of an openhearth steel forging. A double-helical pinion cut integral with the high-speed shaft is made of chrome-vanadium. The intermediate double-helical gears are made of manganese-bronze and are mounted on hardened and ground forged-steel shafts which are secured to the cast-steel slow-speed member by means of a taper fit and Woodruff keys.

The slow-speed member to which is secured the slow-speed shaft is mounted on two heavy-duty ball bearings, one on each side of the gears, and supported directly by the heavy housing. The slow-speed member, the shaft carrying the intermediate gears and the high-speed shaft and pinion are independent of each other for support and each is supported directly by the housing.

The housing is made of cast iron, horizontally split to afford accessibility to all internal parts. It is heavy and well ribbed to provide a rigid support for the gear members in order to secure quiet operation. Caps protect the high- and low-speed bearings from dust.

The high-speed shaft has a central passage through which the oil is pumped, and a continuous stream is sprayed on the gears through radial passages in the

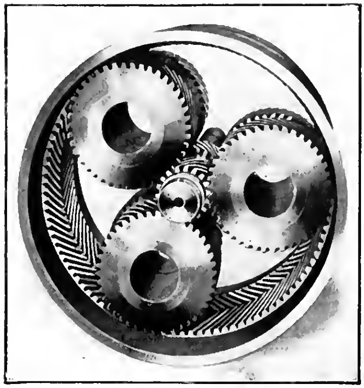


Fig. 1. Turbo-Reduction Gear

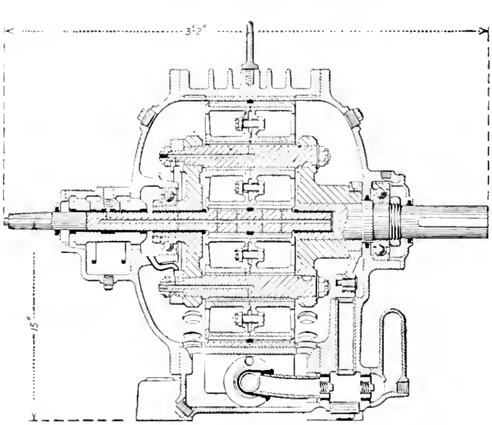

Fig. 2. Section through the Turbo-Reduction Gear

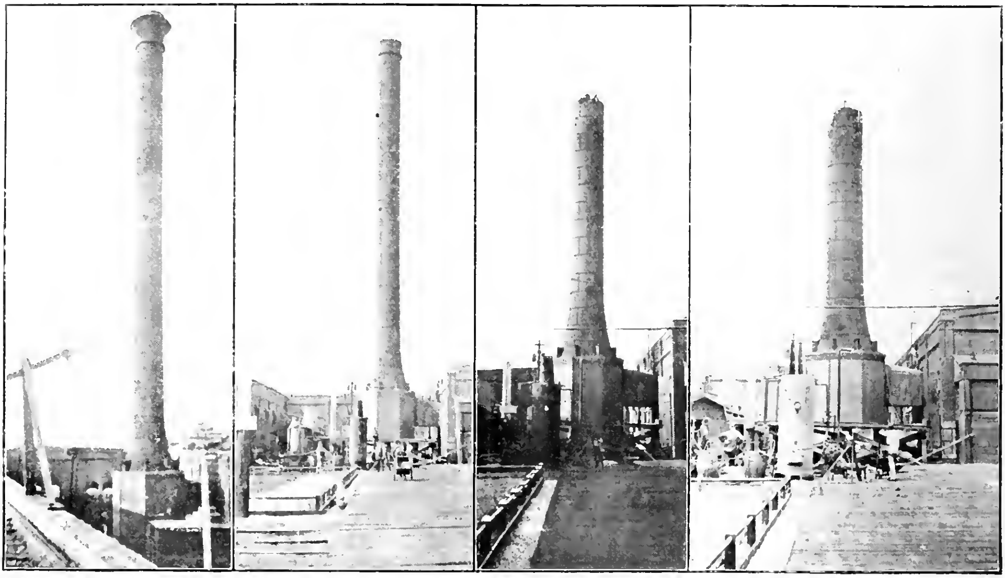
pinion. The high-speed bearings, besides having forced-feed lubrication, are provided with oil rings and an oil reservoir for emergency use. The superfluous oil from the high-speed bearings is collected by a centrifugal oil ring and forced through the hollow shafts carrying the intermediate gears, flushing their bearings. The oil, after lubricating the bearings and gears, is immediately drained to the main oil reservoir in the base of the housing; here it is strained, cooled, returned to the pump and used over again.

Cutting Down a Steel Stack

On Apr. 20, 1915, the St. Louis & San Francisco R.R. began removing the smoke-stack at its North Springfield shops. This stack was 146 ft. high, 8 ft. in diameter and composed of sheets $\frac{7}{16}$ to $\frac{5}{16}$ in. thick. Seventeen rings were removed, the height of each being 56 in.



Removing a Steel Stack with the Oxyacetylene Torch

Oxyacetylene was used in cutting down this stack, says E. W. Allen in the *American Machinist*, at a cost of $283.73 for gas and labor. On account of the condition of the stack, it would have cost approximately $500, if any other method had been employed and would have taken 17½ days to remove it. By using oxyacetylene it was removed with a saving of about $216, and the work completed in six days.

Ingersoll-Rand High Efficiency Air Compressor

The constant demand for higher efficiency and greater economy and the increasing tendency towards the use of higher steam pressures have led to the development by the Ingersoll-Rand Co., 11 Broadway, New York City, of an improved small steam-driven, high-speed air compressor.

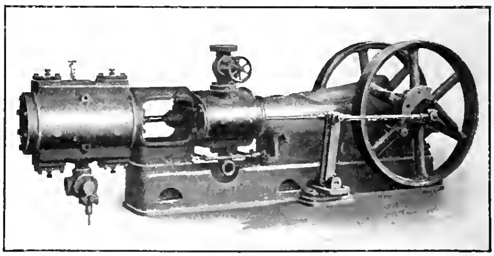
The machine is designed along the same lines as the company's former small steam-driven type, but embodies many improvements which give it a higher efficiency in the air end and a considerably lower steam consumption in the steam end. These improvements are as follows:

The adoption of the Ingersoll-Togler air valves, which allow of high speeds, give high compression efficiency, are almost silent in operation and are independent of any operating mechanism.

Balanced-piston steam valves, designed after the most advanced European practice, permit of high speeds, high steam pressures and the use of superheated steam, at the same time giving a higher efficiency under ordinary low-pressure steam conditions.

An automatic cutoff control gives high steam economy under conditions of varying load or varying steam pressures. This control is regulated by a centrifugal flywheel governor which acts to shorten or lengthen the stroke of the piston valve, thus changing the cutoff.

All wearing parts are copiously and automatically oiled by means of automatic splash lubrication, and inclosed construction and removable covers make for cleanliness with great accessibility.



Steam-Driven Air Compressor

The machine is designed and constructed with special attention to rigidity without excess weight. The bearing surfaces are large and special provision has been made for ready adjustment of all parts, without loss of time.

The automatic cutoff control is supplemented by an air unloader, which assures economy while possessing a high degree of automatism, which is essential in a small compressor designed for severe duty, and generally subject to considerable neglect.

Editorials

Fruits of the Locomotive Boiler Inspection Law

The most cheering part of the paper on "Fruits of the Locomotive Boiler Inspection Law," read before the Western Railway Club by Frank McManamy and published elsewhere in this issue, is that the number of serious locomotive-boiler accidents is decreasing, not because of the application of appurtenances simple or automatic, not because money is being invested in this and that contrivance, but just because the law promotes more thorough maintenance and greater carefulness of operation. Yes, of course, this could have been done without the law. But it was not. And therein lies the chief force of any good boiler-inspection law.

"No railroad man," says Mr. McManamy, "with knowledge of conditions and practices prior to the passage of the law can question the fact that, generally speaking, inspections are now more carefully and more regularly, and repairs more promptly, made, and the question of repairs is less apt to be determined by the number of loads in the yard awaiting movement."

There is just as much morality and altruism in railroad men as in any other class. And it is with due appreciation of these virtues that we remark that the improved conditions mentioned by Mr. McManamy exist because the potential offenders know that they are being watched more closely now than before the passage of the law. The same is true in stationary practice.

Most of us are good anyway, but if we know we are being watched we are better. We admit this to ourselves, but seldom to others.

This looseness or carelessness often manifests itself in acts or conditions that cannot be said to be due to exigencies of the service, or to sacrifice of safety for convenience, or to the erroneous idea of saving money by putting off the day of spending it in needed repairs to parts in dangerous condition. This kind of laxity is detestable, because it is void of reason and inexcusable.

For example, during the last fiscal year the department records show that eighteen persons were injured by studs blowing out of fireboxes or wrapper sheets. Doubtless most of them gave long and ample warning, by leaking, that they needed renewing. It is also true that, usually, they can be renewed more cheaply before blowing out than after. But no, they are tinkered with. They are calked or neglected altogether until finally they blow out.

For this sort of psychological phenomenon no boiler law can of itself do any good. The attitude of mind that allows this condition to continue can be cured only by education, whether it comes by persuasion and reason or is got by the offender-victim being nearly killed before he learns his lesson.

That some opponents of boiler-inspection laws still offer the argument that all boiler explosions are crown-sheet failures, therefore man failures and not preventable through law, is evident from one of Mr. McManamy's statements. Of course such a contention is mere froth. In the locomotive-inspection service during 1914, as compared with 1912, crown-sheet failures decreased forty-eight per cent. and the number killed, sixty-four per cent.

From Mr. McManamy's paper it appears that on some locomotives the location, relative to the highest point of the crown-sheet, of the bottom fittings for gage-glasses constitutes a menace.

It is difficult enough, owing to grades, curves and stops, to keep the crown-sheets of locomotives covered at all times, even where the glasses are conveniently and properly located, and to put them elsewhere is nothing short of criminal. On a busy division particularly, an engineer has so much to watch along the right-of-way that simply a glance from his seat should enable him to see the water level. But we learn that on some types of locomotives the engineer must leave his seat to see the water level, and on others must step back out of reach of the throttle, brake valve and reverse lever to try the gage-cocks. The strongest condemnation of these conditions is too mild.

Happily, the aim of all is to reduce the hazards and attain better conditions generally. And the law is responsible for the movement.

Clean New Steam Lines

In our issue of June 8, on page 785, we printed a letter from E. E. Strong, president of the Strong, Carlisle & Hammond Company, calling attention to the importance of seeing that new steam lines are clear of grease, white lead, iron filings and dirt of all kinds before they are put in use, so that foreign matter may be kept out of separators, reducing valves, steam traps, and all other devices.

The necessity of doing this seems so self-evident that it hardly would appear that comment on the subject was called for, but inasmuch as a man of Mr. Strong's experience has found that carelessness in this particular is common, we feel the importance of calling attention to it on this page, in an effort to do as Mr. Strong suggested—start a campaign of education along the lines of showing the importance of clearing steam lines before they are put in use.

There is a saying somewhat to this effect, although not in exactly the same words, that "the man who would not put dirt in the works of his watch would nevertheless put things into his stomach which are equally bad for that organ." The author of this remark might have gone further and added that the man who takes great pains to keep the brasswork on his engine polished, and other things about his plant neat, will sometimes do just such careless things as to connect up a steam line with lengths of pipe that have lain where they could accumulate dirt and rust in the interior, or that possibly are fouled with chips from threading, without first blowing these lines out with steam before connecting to them anything so susceptible to injury from foreign particles as a separator or a reducing valve or even a steam trap.

Surely this is one of the big little things about a steam plant that the engineer in charge should give his personal attention to, whether the work is being done by outside help or by his own force, so that no pipe connections may be made in such a way that there is any risk of foreign matter getting into the system.

License Committees Take Notice

When the framers of the present New Jersey license law had completed their task, with the assistance of an attorney, no one of the many who looked over the bill could find fault with it. When the license bureau began its work, however, a defect showed itself.

The law states that "provisions of this act shall not be construed to include or apply to" marine engineers, engineers in plants under the jurisdiction of the United States, nor locomotive engineers. They were and are willing to be examined and pay for licenses, but the attorney-general says that they cannot lawfully be granted licenses. They are now aggrieved and protest vigorously.

The import is far more serious than appears on the surface. The wording of the law is such that an engineer holding a license to run a dinky tugboat may operate the largest and most complex stationary plant in the state and be immune from any action that the license bureau may see fit to take.

This is important, and license committees should take a lesson from New Jersey's error.

The Firebrick Problem

Obtaining the investment and operating advantages possible with high boiler ratings has confronted the engineer with high-temperature problems that, while serious, are being admirably met. Procuring the most suitable firebrick for given conditions is only one of these problems, but it is so far the one furthest from a satisfactory solution.

The engineer may, after tests and experience, select the most suitable of available bricks, but it is the manufacturer's function to produce bricks that will meet the extremely high temperatures associated with modern boiler-room practice. When a boiler is operating at from two hundred to three hundred and fifty per cent. of rating, the furnace is filled with a dazzling white gas and the temperature approaches three thousand degrees Fahrenheit. This is within a few hundred degrees of the temperature at which pure fireclay will melt.

With the widely fluctuating furnace temperature, the bricks are subjected to severe expansion and contraction. Arches frequently have extremely high temperatures on one side and comparatively cool gases on the other; side walls are affected by the chemical action of the fusing ash; and poor clay, when between joints, soon drops out, exposing the brick to a soaking-in heat. And so it goes, the sources of trouble being numerous, and greatly increased if the masonwork is not of the best.

Notwithstanding the seriousness of the firebrick problem, it is a fact that little really useful information relative to it has been published. The article elsewhere in this issue is one of the best general ones that has come to our attention. It is replete with information that any engineer can use, whether he operates at a high or a low rating, or a large or a small boiler plant.

But it is not enough. There are many plants where the firebrick problem has been, and is now being, investigated and the need for immediate dissemination of results is urgent. Those who have investigated extensively and discovered and compiled truly useful and applicable information should give others the benefit by making it available for publication.

Does the Amended Massachusetts Law Discriminate?

We have just received a communication which brands as discriminative the Massachusetts license law as amended. As told editorially in our issue of June fifteenth, the law was amended to allow plants operating the major part of the time by water to be in charge of an engineer holding a special license. The writer of the letter wishes to know why plants having waterwheels should be so favored, while the same liberties are not extended to plants run by electric motors, driven by purchased current the major part of the time.

If the danger is no greater in one case than in the other, then there is no reason why the plant operated most of the time by electric motors, but only part of the time by its own high-pressure-steam-driven machinery, should not be allowed to be operated by a man holding a special license. Where none of the engines and boilers in such a plant is not of greater capacity than one-hundred and fifty horsepower, a special license will cover the plant. But if any of the engines or boilers are of greater capacity a first-class engineer must be in charge, though the plant is driven most of the time by purchased current.

Technically, it is easy to show that the amended law is discriminative in favor of water power, but plants operating on purchased current most of the time and running their own engines and boilers some of the time are few. The condition rarely exists, because when an industrial plant uses purchased current it uses it exclusively or only on overloads, which are carried by new equipment just as soon as the latter can be advantageously installed. Of course, breakdown service is available in some plants, but, as its name implies, it is only for emergencies.

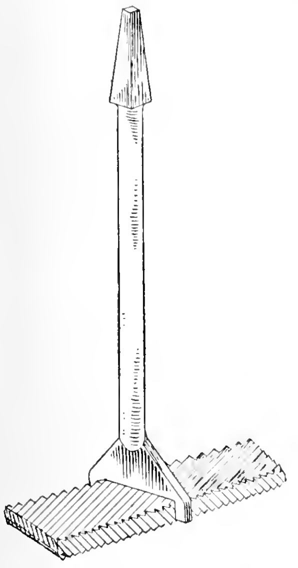
It is not at all likely that serious trouble will follow the discovery of this technical discrimination, because there are few, if any, such plants in existence to be discriminated against. In plants such as our correspondent has in mind, the owner will find it good business to keep a thoroughly competent man in charge, regardless of what the law allows him to do. The law will allow you to take your watch to a blacksmith for repair, or get your hair cut by a gardener who trims the hedge, but you would not take advantage of either opportunity.

Efforts are being made before the New York Constitutional Convention to have the Public Service Commissions made constitutional bodies surrounded with all the safeguards afforded the courts. There are few departments in the state government wherein personal integrity and moral courage count for more, and any step that will help to render the public service commissions free from personal or political influence is commendable.

Correspondence

To Smooth a Valve Seat

A 1-in. globe valve, although nearly new, gave trouble by leaking. It was in a rather dark corner, so for a long time it was not noticed that the valve seat had become roughened from some cause. When discovered, the first thought was that a new valve would be necessary, as we had no tools at hand for dressing the seat, but a piece of flat file short enough to be turned around while lying flat on the seat did the work. A contrivance for rotating the file was made from the shank of an old wood bit, flattened and shaped as shown in the illustration. With this tool in a common bit brace, the valve seat was quickly made as smooth as when new.



VALVE SEAT SMOOTHING TOOL

G. E. MILES.

Engineer Killed in Peculiar Turbine Accident

About the middle of last month a turbine connected to a 250-kw. generator in a cold-storage plant in New York City wrecked itself and instantly killed the engineer in charge. The cause of the accident is not definitely known nor the circumstances leading up to it, as the engineer was alone in the room at the time. From indications, however, it is believed that the bearing-cap on the end of the shaft next to the rotor had become loosened and that the engineer was tightening or adjusting it at the time. The shaft was 1⅝ in. diameter and ran at 9000 r.p.m. It was impossible to tell from the wreckage whether it was the shaft or the bearing which gave way first, as both were badly broken up.

The duty of this set was particularly severe, as there was no duplicate machine and it was kept in constant operation, except a stop of half an hour on Sundays, so that most of the adjustments which were made had to be done while the machine was in service. This accident demonstrates anew the extreme risk to man and machinery of making even minor adjustments not intended to be made while the machine is in motion, and especially so when operated at such high speed.

WILLIAM SOUTHARD.

New York City.

Notes on Alternating- and Direct-Current Motors

In the May 4 issue under the caption, "Interior Wiring for Lighting and Power Service," Mr. Cook makes some statements that are not quite up to the latest practice. First, in reference to the voltage employed by alternating-current motors, he states that in some cases for very large motors 2200 volts is used. Now 2200 volts is commonly used and 6600 and 7500 volts are occasionally used for large motors. Probably the most notable 6600-volt induction-motor installation is the three 6000-hp. machine group in the rail-mill department of the steel works of the U. S. Steel Corporation, at Gary, Ind. A description of these motors was published in POWER in the issue of Apr. 5, 1910. In a recent steel-mill installation 6600-volt induction motors have been used throughout; the machines ranging in size from 350 to 3000 hp. and aggregating approximately 12,000 hp.

Another important installation is the 300-hp., 7500-volt induction motors used to drive the exciters in the new power house of the United Electric Light & Power Co., New York City.

If we include synchronous condensers and frequency changers in this category, it will be found that the voltage is even higher, as there are a number of 11,000- and 13,200-volt synchronous motors in operation in this country; probably the highest-voltage machine of this type being the 16,500-volt, 6000-kv.-a. synchronous condenser used for power-factor correction by the Southern California Edison Co., of Los Angeles. What in all likelihood is the largest frequency changing set in service today is that installed to interconnect the Boston Elevated and Boston Edison systems. This set consists of a 13,200-volt, 25-cycle unit rated at 9000 kv.-a., and a 13,800-volt unit rated at 9000 kv.-a.,

Secondly, with direct-current systems it is possible to obtain motors that will allow a speed change of 3 to 1. One of the latest productions of the electrical industry is an adjustable-speed reversible direct-current motor for metal planers and slotters, having a speed range of 250 to 1000 r.p.m. by field control; these machines have been standardized up to 50 hp. Motors for continuous service, with a speed range of 1 to 4, have been built in sizes up to 125 hp., and 225-hp., 500-volt machines with a speed range of 225 to 675 r.p.m., or 1 to 3. Moreover, 115-230-volt machines may be had with a speed range of 1 to 6 in sizes up to 25 hp. continuous-service rating, or 15 hp. intermittent-service rating.

Thirdly, Mr. Cook appears to use the terms "adjustable-speed" and "variable-speed" alternating-current motors synonymously, whereas they mean two different types. The variable-speed machine is one in which the speed is constant for constant load, but varies with the load, accelerating with light loads and dropping again when the load comes on, as in a direct-current motor with armature control or a phase-wound rotor polyphase induction motor with rheostatic control. Adjustable-speed machines are those in which the speed remains approximately constant at any adjustment, irrespective of the load. One of the best examples of this type is the direct-current shunt motor with field control. Until recent years only direct-current motors were available for strictly adjustable-speed drives, which is also true today for small motors where wide ranges of speed are required. However, during the past eight or ten years schemes have been developed for adjusting the speed of alternating-current motors, so that now the adjustable-speed polyphase induction motor in many cases compares favorably with the direct-current machine, especially in large units for rolling-mill drives, mine fans, etc., and in some cases it shows an advantage over the direct-current machine. For example, in 1913 a 600-hp., 2200-volt adjustable-speed polyphase induction-motor set for driving a rolling-mill was installed, having six different synchronous speed adjustments between the limits of 300 and 500 r.p.m. This set consists of two machines arranged so that they can be connected in cascade. The primary motor has a phase-wound rotor with its stator wound for 14 and 16 poles; the secondary motor is a squirrel-cage machine having its stator winding arranged so that it can be grouped for 4- or 8-pole connections. It is worthy of note that this set was chosen in preference to a direct-current machine, and that it has proved very satisfactory in service.

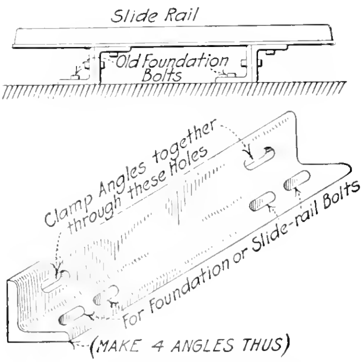
Realigning a Belt-Driven Generator

The illustration shows a method I used in realigning a belt-driven exciter so the belt would not slip off under heavy load.

The material required consists of four pieces of angle iron selected in proportion to the size of the machine. The combination of lateral and transverse slots gives freedom of motion to square up the machine. For ordinary aligning four symmetrical angles will do. However, should a machine have to be shifted endwise considerably, slots can be cut in the foundation angle bars.



Material for Mounting Generator

Hood over Dash Pot

We had considerable trouble in keeping the latch blocks and plates in good condition and the cutoff equalized on a Brown twin-engine. It was impossible to maintain an equal cutoff or equal distribution of the load between the two sides.

The valve-stem stuffing-boxes being very shallow, it is difficult to prevent some leakage, and most of the time there is more or less water dripping into the dashpots. A sort of drip cup is provided under the stuffing-boxes, intended to catch and carry off the leakage, but it is of little value. It is desirable to keep water away from the valve gear because it washes off the oil, but there is no room to put a shield where it will do the most good. I therefore arranged a sheet-metal hood over each dashpot, as shown in the illustration. Previous to this we were tinkering with latch blocks and plates and adjustments continually, but now the engine runs for months without requiring more than slight adjustments to the valve gear.

Reversed Field Coils

The terminals of some field coils are so located that if the coil has been turned over or turned end for end while installing, the appearance of the terminals makes the mistake evident. There are coils, however, which may be inverted without the appearance of the terminals suggesting any irregular condition. The terminals of such coils are located in the centers of opposite sides or of opposite ends, and the coil appears the same irrespective of the manner in which it may have been installed. Any such mistake which results in the current circulating in the wrong direction will reverse the polarity of the coil, and if the number of reversed coils is a sufficiently large proportion of the total number, the machine will be unable to build up its field. At all events, the voltage obtainable will be reduced and commutation will be impaired.

An inspector was called to locate the trouble in a generator that was unable to build up its field; even when the machine was separately excited from another, the value of the voltage obtainable was very small. The machine had been in a flood and had been disassembled for cleaning. The operator stated that he had marked the field spools when removing them and that he had replaced them just as they had been marked. He evidently either had marked the spools incorrectly or had failed to observe the marks carefully while reassembling, because on raising the brushes, exciting the field from another machine and testing the polarity with a nail, all the bottom poles were found to be of the same polarity.

The terminals of the field coils were in the centers of opposite ends of the coils and two alternate coils had been installed end for end, thereby reversing two coils out of five and making five consecutive similar poles. An inspection of the direction arrows stamped on the flanges of the field spools confirmed the supposition.

Where the marks on the flanges are not plain or where there is any doubt as to how a coil should be placed, the best plan is to temporarily place and connect the coil and test the polarity with a nail or compass. Where a compass is used by an inexperienced person, it is best that the test be made with the armature withdrawn; otherwise, the poles induced in the armature core by the polepieces may cause misleading results.

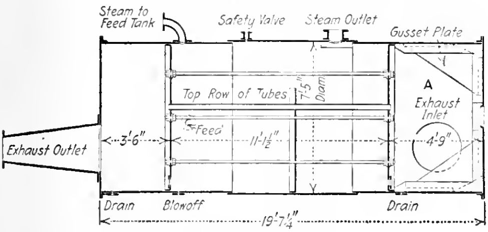
Exhaust-Gas Heated Boiler

In one of the power houses of a large engineering works where gas made from bituminous coal supplied the motive power, the heat from the engine exhaust was utilized to generate the steam supplied to the gas producers. The plant was run with the ammonia-recovery process, thus requiring 1 to 1.25 lb. of steam for every pound of coal



Section through Boiler

used. Three 1000-hp. engines and exhaust boilers were to be installed, although only one unit was at first put in.

The exhaust pipe was 30 in. in diameter and had two gate valves arranged so that the gases could be led either to the boiler, from which they entered a large masonry chamber, or silencer, built in the ground, or they could travel directly to the silencer.

The sketch shows the boiler, which evaporates 2.5 lb. of water at 100 lb. per sq.in. per brake horsepower delivered by the engine. It was of horizontal cylindrical construction, 19 ft. 7¼ in. in length and 7 ft. 5 in. least internal diameter, the sides being ½-in. plate and the ends of ⅝-in. plate; the tube-sheets were ¾ in. There were 182 tubes, 3¼-in. outside diameter at 4½-in. pitch, giving over 1700 sq.ft. of heating surface. The tube sheets were stayed by seven 1½-in. stays, and midway the tubes were supported by a plate cut out at intervals around the circumference to permit of freer circulation of the water.

The exhaust gases entered the firebrick-lined compartment shown and, after passing through the tubes, entered a 3½-ft. compartment, also supplied with a manhole and drain, and then through a 30x18-in. reducer to the silencer. The working level of the water was about 4 in. above the top row of tubes.

The boiler was fitted with the usual safety valve, manhole, steam and water gages, a 3-in. steam connection for heating the feed-water tank, a 3-in. feed inlet, a blowoff valve and mudholes, and was connected to the gas producers by an 8-in. steam line. Below the steam opening in the boiler was a ⅛-in. copper plate clearing the opening by 2¾ in., for preventing priming. The heating surface of the tubes was 1723 sq.ft.

An Emergency Gasket

The lead gasket illustrated and described by F. W. Reynolds in the issue of May 25, on page 725, has been used with fair success under different conditions for many years. A light piece of lead pipe is often employed for the same purpose. Such a gasket may be improved by drawing into the pipe a piece of asbestos rope to act as an equalizing cushion.

Wrong Stator Connections

If the stator coils of a three-phase induction motor are delta-connected, each will be subjected to the full line voltage; if Y-connected, however, each pair of line wires will include two stator coils in series, in which case the voltage per coil will be approximately 0.58 of the line voltage. Moreover, in a Y-connected stator the current of the line and of each coil is the same, whereas with the delta connection the line current divides between two paths. The operating characteristics of the motor will vary accordingly as one or the other of these connections is used, because the resistances and reactances involved differ in the two cases.

For several years a three-phase induction motor had successfully driven the compressor used for storing with compressed air the whistle-blowing reservoir of a fire-alarm system. Owing to continuous neglect of the automatic governor, abnormal pressures obtained at times, with the final result that the stator burned out. It was rewound, after which, firemen in the outlying districts began to miss fires and invariably gave the excuse that they had not heard the whistle. Repeated trials proved the excuse to be well-grounded; the whistle was inaudible in districts where it could be plainly heard, even if an opposing wind were blowing, before the stator was rewound.

Investigation disclosed that the motor was heating abnormally and that it could store against only 60 lb. pressure, whereas it formerly had been able to store at 100 lb. without any distress. Checking of the rotor speed showed the slip at 60 lb. to be 240 r.p.m. On a normal motor the slip would not have exceeded 60 r.p.m. The end shield was then removed and the connections inspected, and it was found that the coils which were bought for the rewinding were greater in number and had smaller wire than those of the original winding. The repairman had installed the new coils in the same manner as he had found the old ones, and in the absence of instructions he was justified in doing so. The original coils were Y-connected and the new ones were also, but they should have been delta-connected.

J. A. HORTON.

Schenectady, N. Y.

A Mistaken Notion

I observed an engineer carefully pointing a pine plug to drive in as a substitute for a pump-cylinder cock that was lost. Inquiry developed that he believed the steam would have less chance to blow the pointed plug out than if the end was blunt.

Since then I have heard others pull off the same line of argument. It is true, of course, that if steam or water is issuing with considerable force a pointed plug may be more easily entered, but that is "another story." I hope I will not be classed as a "plug fitter" by reason of the foregoing observations.

Cambridge, Ohio.

Indicator Showed Leaking Piston

Diagrams taken from a 9x16x24-in. Corliss engine with the low-pressure cylinder disconnected for experimental work showed a peculiar back-pressure line. The

FIG. 1. DIAGRAM INDICATES LEAKAGE

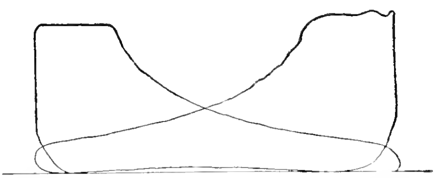

FIG. 2. CONDITION AFTER INCREASING TENSION

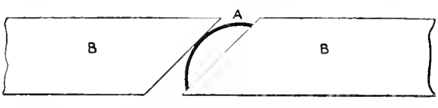

FIG. 3. STEEL SPRING TO GIVE TENSION TO RING

hump in the exhaust line, shown in Fig. 1, would appear on the head end for a day or so, then show up on the crank end for a few days, and then back to the head end again, owing to some change in the position of the piston ring.

A piece of heavy clock-spring was filed and peened to fit, as shown at *A*, Fig. 3, and just long enough not to bind when the ring was compressed. The joint was open about $\frac{3}{16}$ of an inch when compressed to the cylinder size, allowing sufficient clearance for the spring. Before inserting the piston in the cylinder the joint of the ring was turned to the top of the piston to prevent spring *A* working loose and cutting the cylinder. Other diagrams were taken after this change, with results as shown in Fig. 2.

Storm Demolished Two Stacks

On the night of May 27, a storm blew down the two 30-in. x 75-ft. smoke-stacks of the Moberly artificial ice plant at Moberly, Mo. Only one boiler was in use at the time, and, strangely, the $1\frac{1}{4}$-in. water-column pipe was torn out from that boiler, blowing all the water out. The stack fell in such a way that it did not damage the building or equipment except as stated.

Moberly, Mo.

Inquiries of General Interest

Weight of Spanish Libra—What is the relation between the weight of the Spanish pound used in Latin-American countries and the avoirdupois pound of the United States?

P. P. C.

The Spanish "pound," or more properly "libra," is equal to 1.0161 United States avoirdupois pounds, or 1 lb., 0.2676 oz.

Capacity of Pump—What is the capacity, in gallons per minute, of a duplex steam pump with water cylinders 6 in. diameter, when running at a piston speed of 90 ft. per min.?

E. P.

Without allowing for reduction by presence of the piston rod, the piston displacement in each water cylinder would be

$$(6 \times 6 \times 0.7854) \times 90 \times 12 = 30{,}536.35 \text{ cu.in. per min.}$$

and, without allowance for slippage, the combined pumpage of two water cylinders would be

$$(2 \times 30{,}536) \div 231 \text{ cu.in. per gal.} = 264.4 \text{ gal. per min.}$$

and, allowing 5 per cent. slippage, the delivery would be

$$264.4 \times 0.95 = 251.18 \text{ gal. per min.}$$

Factor of Evaporation with Superheated Steam—What would be the factor of evaporation in the generation of steam at 135 lb. gage pressure with 100 deg. of superheat, from feed water at 200 deg. F.?

R. J. F.

A gage pressure of 135 lb. per sq.in. would be equivalent to about 150 lb. absolute, and by reference to Marks and Davis' Steam Tables it is found that a pound of steam at 150 lb. absolute, when superheated 100 deg. F., contains 1249.6 B.t.u. above 32 deg. As the latent heat of steam at 212 deg. F. is 970.4, then, as compared with evaporation from and at 212 deg. F., the factor of evaporation would be

$$\frac{1249.6 - (200 - 32)}{970.4} = 1.1146$$

Testing Flow of Steam—How can a test be made of the weight of steam used by a small steam pump?

W. L. B.

If one of the several types of steam meters is not available, a close approximation to the rate of flow can be determined for a stated pump speed and other operating conditions by placing a gaging stop valve in the steam line to the pump and ascertaining the flow that takes place through such a valve under the same conditions of valve opening and pressure on each side of the valve as when the pump is in operation. For the purpose, place a pressure gage on each side of the valve and, with the gaging valve partly closed, observe the indication of each pressure gage while the pump is in operation. Then, with the pump shut down, determine, by increase of weight, the rate at which the steam condenses when discharging without loss into about three-fourths of a barrel of water, having the same opening of the gaging valve and same readings of the pressure gages as when the pump was in use. The pressure on the discharge side of the stop valve can be regulated by throttling the escape of steam to the condensing water.

Relative Economy with Different Initial Pressures—What would be the relative economy of employing steam at an initial pressure of 75 lb. and at 100-lb. gage pressure per sq.in., if in each instance the clearance is 5 per cent., cutoff at ¼ of the stroke, the average back-pressure 4 lb. gage and the boiler-feed water 200 deg. F.?

G. K.

By referring to a table of mean pressures per pound of initial pressure with different clearances and points of cutoff (such as given on page 115 of Low's "Steam Engine Indicator"), it may be seen that with cutoff at ¼ stroke and 5 per cent. clearance, the mean pressure per pound initial absolute would be 0.6258 lb. Therefore, with an initial pressure of 75 lb. gage, which is equal to about 75 + 15, or 90, lb. absolute, and back-pressure of 4 lb. gage, or 4 + 15 = 19 lb. absolute, the mean effective pressure would be

$$(90 \times 0.6258) - 19 = 37.322,$$

and with an initial pressure of 100 lb. gage, or 115 lb. absolute, and the same average back-pressure, the mean effective pressure would be

$$(115 \times 0.6258) - 19 = 52.967 \text{ lb.}$$

As the density of steam at 90 lb. absolute is 0.2044 lb. per cu.ft., and of steam at 115 lb. absolute is 0.2577 lb. per cu.ft., then for the same cutoff and same diagram factors the relative weight of steam required per pound m.e.p. would be as

$$\frac{0.2044}{37.322} \text{ to } \frac{0.2577}{52.967}, \text{ or as } 1.1256 \text{ to } 1.$$

For comparison of cost, it may be assumed that in each instance steam is generated from a feed-water temperature of 200 deg. F. A pound (wt.) of steam at 90 lb. per sq.in. absolute contains 1184.4 B.t.u. above 32 deg. F., hence each pound raised from feed water at 200 deg. F. would require

$$1184.4 - (200 - 32) = 1016.4 \text{ B.t.u.}$$

while a pound (wt.) of steam at 115 lb. per sq.in. absolute contains 1188.8 B.t.u. above 32 deg. F., and each pound raised from the same temperature of feed water would require

$$1188.8 - (200 - 32) = 1020.8 \text{ B.t.u.}$$

Therefore, the cost of steam required per lb. m.e.p. or per hp., employing 75 lb. boiler pressure, would be to the cost employing steam at 100 lb. boiler pressure as

$$1.1256 \times 1016.4 \text{ to } 1 \times 1020.8, \text{ or as } 1.1207 \text{ to } 1.$$

Action of Bourdon Gage Tube—What causes the tube of an ordinary Bourdon spring pressure gage to become straighter for an increase of pressure?

J. R.

As the tube is curved and flattened at right angles to the plane of curvature, when inflated there is a tendency for it to assume a circular form of cross-section, giving rise to tensile stress in the tube material which forms the outside of the curve and compressive stress in the material forming the inside of the curve.

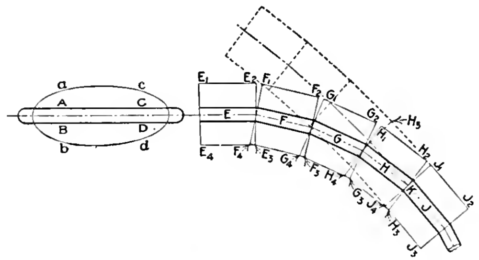

Diagram Illustrating Action of Gage Tube

The action is the same as though the curved tube was composed, as shown in the figure, of a number of straight tubes of cross-section like ACDB joined together in polygonal form EFGHJ. Such sections, when independently inflated to the oval form of cross-section acdb, would be represented by the trapezoids $E_1E_2E_3E_4$, $F_1F_2F_3F_4$, etc. But, as shown by the figure, when the sections are thus separately inflated, they would separate along the outer, or convex, side as at H_2KJ_1 and would be compressed together along the inner, or concave, side of the tube as indicated by the overlapping J_4KH_3. Hence, after inflation of the sections, when a section like H remains continuous with an adjacent section like J, the latter being held stationary, then for H_2 to remain in contact with J_1 and for H_3 to remain at J_4, the inflated section H would have to assume the position $H_5J_1J_4$. Like movement of the consecutive sections would result in a change in their alignment to that indicated by the dotted lines, and the action of straightening out from inflation would be similar if the original sections were short enough to form a continuous curve of flattened tubing, such as used in the Bourdon spring pressure gage.

[Correspondents sending us inquiries should sign their communications with full names and post office addresses. This is necessary to guarantee the good faith of the communications and for the inquiries to receive attention.—EDITOR.]

Testing Central-Station Heating Mains

During the last heating season, engineers of the Merchants' Heat & Light Co., Indianapolis, Ind., have been making tests to determine whether any part of the central hot-water heating system in that city needed renewal. The tests were also designed to discover the location of any overloaded section of the piping system. The procedure of the tests was as follows: Observers were stationed at the plant, at the end of the main trunk line about 800 ft. from the plant, and at the end of laterals about 3000 ft. from the trunk line. With these watchers in readiness and with constant pressure maintained on the system, the fires under the circulating boilers were dropped simultaneously at a prearranged time. Immediately afterward the fires were forced skillfully to bring the water temperature back to normal. The various observers took simultaneous time and temperature readings, noted the fall in temperature as the cooler water passed their respective stations and also the time that elapsed before the temperature was restored to normal. With these data and with the distance between stations known, a few simple calculations gave the speed of the water in the mains and the line losses in deg. F. occurring between the power plant and the point of reading. The results were plotted with time as ordinates and temperature as abscissas. The curve produced clearly showed the passage of the cooler water by a dip in an otherwise comparatively straight line. Near the station the readings showed the dip to be very pronounced. Further out on the system it became more shallow. These dips gave an indication of the relative line losses in the main and laterals, while the velocity of the water was taken as the most definite indication of the loaded conditions of the pipe, high velocity indicating heavy loading, low velocity, light loading. Considering velocities of 4 ft. per sec. in mains and 3 ft. per sec. in laterals as the maxima allowable, the test data show conclusively that almost the entire system is in good operating condition, although the lines were laid fourteen years ago, and according to some theories of depreciation, should now be ready for replacement.

Readings were also taken on all lines to determine the difference between the flow and the return pressure. These data will be of value in considering future loading of the lines, because in general customers should not be added to a line with a differential pressure of less than 1 lb. per sq.in.—"Electrical World."

Encouraging Water-Power Development in Washington

Through its Extension Division, the University of Washington, Seattle, has adopted an interesting plan to encourage the active development of local water power, affording free expert advice for proper and effective installations at available properties. In this, the primary purpose is to assist individual owners of water sites who might be unable at the moment to employ experienced engineering talent, as well as small rural communities similarly situated, inspiring active interest in the possibilities presented.

The inauguration of this department has led to considerable activity along coöperative lines. Owners have been supplied with information applicable to service, in a consistent, economical and profitable way. In some cases recommendations to employ consulting engineers have been made, it being the particular province of the university to suggest the most feasible plan, with all essential data, rather than carry the proposed project to completion.

In explanation of this new public consulting department, the university calls to notice that hundreds of small water powers are still undeveloped in the state. Many farms and country homes are so situated that electric power for lighting and cooking could be secured at a very reasonable cost, while in some cases, heating by electricity is possible at an economical figure. Investigations show that a large proportion of the small water powers are worthy of the utmost development. Owners do not always know the value of their sites and on such uncertainty cannot afford to employ an engineer capable of giving the necessary advice; on the other hand the engineer cannot afford to give his services free.

As regards the working of the plan, the University of Washington, being a state institution, is in a position to lend assistance by sending an expert to report on the advisability of development. If no extended surveys are required, this engineer will suggest a proper method of procedure and probably make some little sketch to be followed in the construction. Should surveys be necessary and the expense is justified, it will be so reported and the owner asked to secure some private engineer to make them, provided the owner wishes it done at his expense. No charge is made for the information or technical advice given out by the university engineer, excepting his necessary traveling expenses, which must be borne by the person asking his services.

Convention of American Boiler Manufacturers

The twenty-seventh annual convention of the American Boiler Manufacturers' Association, held at the Hotel Lawrence, Erie, Penn., was called to order by the president, W. C. Connelly, on June 21, with 108 manufacturers' representatives present. The report of the committee on uniform boiler laws recited the efforts which had culminated in the A. S. M. E. code. Thomas E. Durban, chairman of the committee, said that the industrial commissions of Pennsylvania and Wisconsin had already adopted the code. He was assured that California, Chicago and St. Louis would adopt, and that the conservative Master Boiler Builders' Association had already approved the code. N. A. Baumhart, chairman of the Ohio Board of Boiler Rules, told the convention that the Ohio rules would be amended to include the A. S. M. E. code. John A. Stevens, chairman of the A. S. M. E. committee that formulated the code, urged its promulgation on behalf of the consulting engineer.

C. H. Wirmel, formerly head of the Ohio Boiler Inspection Department and chairman of the N. A. S. E. committee on legislation, invited the attendance of those interested in the general adoption of the code at the N. A. S. E. convention to be held at Columbus, Ohio, in September. John T. McCabe, boiler inspector of Detroit, approved the code, but held that the city or state could only prescribe absolute essentials, and even then the burden of proof rests on the inspector. He also announced that he would pass A. S. M. E. boilers wherever made. Dr. C. L. Huston stated that "two dollars per ton" was not the only difference between furnace and flange steel. The firebox plates, which are stressed by unequal temperatures, required more rigid inspection. The steel used should be openhearth selected from the middle of the run, and there should be closer supervision of the entire process. Mr. Lynch, representing the Association of Steel Manufacturers, testified to its approval of the code, which was a credit to Messrs. Stevens and Durban. H. P. Goodling, speaking for the portable-engine interests, said the principal objections to the enforcement of the code would be the inspection and license requirements. The attempt to adopt such measures in Florida had been frustrated because the small operators were afraid they would have to employ licensed men. Michael Fogarty, a delegate to the New York Constitutional Convention, said that a boiler law must be passed before the code could be adopted. At his request the convention adopted a resolution indorsing a proposed constitutional amendment. A copy of the resolution was sent to the Hon. Herbert Parsons, chairman of the committee on industrial relations of the New York Constitutional Convention. T. W. Herendeen, secretary of the National Boiler and Radiator Manufacturers' Association, expressed his association's approval of the code and pledged coöperation in securing its general adoption. G. S. Barnum, of the Bigelow Boiler Works, told of a rumor that a law or rule might be passed admitting code boilers to Massachusetts. T. M. Rees, of Pittsburgh, belatedly protested against the adoption of the code. He especially objected to its condemnation of lever safety valves and lap joints, quoting "Power" to show butt-strap joints were not immune from cracks. The convention voted to refer his objections to the committee on A. S. M. E. boiler code. C. V. Kellogg, president of the National Tubular Boiler Makers' Association, told of its activities and expressed sympathy with the A. S. M. E.'s efforts to promulgate the boiler code.

President Connelly recommended for consideration: The adoption of uniform specifications covering material guarantees, workmanship and methods of payment; ways and means to secure universal adoption of the A. S. M. E. code; the securing of laws whereby boilers approved by authorities in one state should be recognized as good in all states; the action of water-tube boiler manufacturers in guaranteeing boilers for 200-per cent. capacity, thus cutting the market for boilers in half.

The convention decided to form an administrative council consisting of one member each from the American Boiler Manufacturers' Association and from other allied organizations. This council will conduct a campaign for the adoption of the boiler code, the campaign expenses to be prorated among the interests represented, to the amount of $12,000 a year. A model inspection and license law was referred to this council to be modified and adapted to conditions in various parts of the country. H. D. Mackinnon presented a report of the committee on uniform cost system. The convention adopted suitable resolutions on the deaths of Past-President E. D. Meier and Past-Treasurer Joseph F. Wrangler. The following officers were elected: President, W. C. Connelly (reëlected); first vice-president, C. V. Kellogg; second vice-president, G. F. Barnum; third vice-president, E. C. Fisher; fourth vice-president, Isaac Harter, Jr.; fifth vice-president, Charles F. Hooper; secretary, J. D. Farasey; treasurer, H. N. Covell; representative on administrative council, E. R. Fish. Past-Presidents Richard Hammond and Henry J. Hartley were elected honorary members. Fifteen firms joined the association during the past year, making 87 companies and 15 associate members enrolled. Six of the fifty charter members were present at the convention. The convention passed a vote thanking the Erie City Iron Works, Union Iron Works, Burke Electric Co., and the visitors that had contributed to the discussion and the committee work. The business sessions concluded with a banquet at the Hotel Lawrence on the evening of June 22.

Future Developments in Heating and Ventilation*

By A. H. Barker

SYNOPSIS—The author discusses the general nature of unsolved heating and ventilation problems and outlines some interesting experimental work now being conducted at the University College.

The twin sciences of heating and ventilating have more unexplored problems and greater difficulties attending their solution than almost any other branch of engineering. This is due to the immense complexity of the two sciences, the difficulty of defining in exact terms the results to be expected and the fact that the criterion of success has of necessity been the feelings of individuals rather than the readings of scientific instruments. In addition, the immense power of adaptability of the human organism tends to make actual variations of conditions appear unimportant in practice. In this branch the first obstacle is the great difficulty of finding the facts.

Consider, for instance, the first problem for an engineer endeavoring, without previous experience, to arrange a satisfactory scheme for ventilating a building. He would begin with the assumption that the artificial ventilation of a building consists of forcing in a calculated volume of air. If he were familiar with fans and the laws of the flow of air in ducts, he might think the task easily accomplished. But after he had once tried to satisfy the occupants of the building, he would find the distribution of air currents a problem of great difficulty even in a small building. Although each of these currents obeys rigidly accurate laws of nature, as a whole they are so complex that their expression as terms of exact science is almost impossible. Complaints of the ventilation of almost every public room are heard, but should the ventilating engineer be held responsible when no one can specify what is wrong or what is needed to put it right?

The arrangement of a satisfactory heating system is no less complex. Heat is delivered into the room by convection currents of heated air and by radiant energy. These forms of heat are quite different from each other, yet they can be instantaneously transformed from one to the other and back again. Their measurement, again, is not a problem to be easily solved. The mere act of measuring the amount of radiant energy turns all or part of it into convected heat.

The most baffling difficulty, however, in the attempt to reduce this subject to an ordered science is that the object of both heating and ventilating, though primarily physiological, is also to some extent psychological. The primary object is to keep the inhabited rooms healthful; to keep them comfortable is of almost equal importance. The effect of any given condition on the human body is, if possible, more complicated than the laws which govern air currents and heat flow. The author believes that in the interests of health the temperature maintained should he as low as can be endured without real discomfort. Yet others will say that the room should be so warm that the occupants feel comfortable without any effort. No one can tell us within 300 per cent. how much fresh air per head per hour is the minimum consistent with health. A room filled with air absolutely pure, so far as chemical analysis can detect, may feel very stuffy. For instance, in the House of Commons the air is, chemically speaking, as pure as in any room in the world. No less than 13,000 cu.ft. of air is supplied per head per hour, yet it produces the effects associated with defective ventilation—lassitude, sleepiness, and infection. A room may, on the contrary, feel fresh and sweet when, judged by chemical standards, the air is very bad. The author has analyzed air containing 25 volumes per 10,000 of CO_2, which felt as fresh as a spring morning, although 10 volumes is regarded as the extreme allowable impurity.

The future of heating and ventilating depends, on the scientific side, upon the further analysis of the conditions that produce the feeling of comfort and other effects. This half of the problem is for the psychologist. The attempt to specify healthful and comfortable conditions involves experiments, that in essence are attempts to calibrate human beings.

The practical side of the problem depends on the controlling of these conditions and on the further development of construction and transmission apparatus. We must first be able to express exactly each of the chemical and physical conditions which make up the sum total of the room condition. The criterion of successful design must not be the self-contradictory feeling of people, but must be the exact reading of radiometers, hygrometers, airmeters, apparatus for the analysis of air, dust counters, thermometers and other instruments.

The practical problem is to introduce heat in quantity and form to make the building comfortable. As heat can be introduced by convection currents and by radiation, there will be at least two corresponding temperature conditions in a room. The expression "temperature of a room" commonly means the reading of a correct thermometer in the room. This thermometer does not indicate the temperature of the surrounding air, for it is largely influenced by the amount of radiant energy impinging on the bulb and having no connection with the air temperature. The problem is not solved when the heat causes a thermometer in a room to read a certain figure. Of course, in designing a large system a great deal of calculation is required to obtain a uniform and proportional flow to all parts of the apparatus. Even when this is done a large number of persons undoubtedly cannot endure apparatus heat in any shape.

To get to the bottom of the problem the temperature of the air itself and the temperature corresponding to the radiant conditions should be studied. To make a systematic beginning we must also develop experimental means for recognizing and measuring air and radiant temperatures, and quantities of convected heat and radiant energy. It is necessary to determine experimentally the relation between the thermometer rating, the air temperature and the radiant temperature. The term "radiant temperature" signifies the temperature registered by a thermometer if there were no air in the room at all—a sort of mean of the temperature of the surrounding walls.

Separate instruments have been devised at the University College for registering the air and radiant temperatures. The first shows the mean temperature of all exposed surfaces, such as the walls of the room and the furniture, affecting the bulb of the thermometer. The principle of the instrument is to surround a delicate thermometer with air at the same temperature as that of the room, and also to envelop it with a surface whose temperature can be adjusted to any degree and held absolutely uniform. The instrument for finding the temperature of air is constructed on the principle that a thermometer surrounded both by air and by double-walled surfaces at the same temperature as the air in the room will read exactly the temperature of the room air. If the radiant and air temperatures are made identical, both will be the same as the thermometer reading.

*From a paper read before the Society of Engineers (Inc.), in England, and abstracted in "The Mechanical Engineer."

The author claims to have proved with these instruments that the stuffy feeling often associated with heating systems is caused largely by too high air, and too low radiant temperatures. The freshness of a building depends on keeping the air temperature relatively low and the radiant temperature high. This explains why a room warmed by an open fire often feels much more comfortable than one heated by a radiator. The temperature and humidity of the air are the important points, and not its chemical freshness, freedom from CO_2 or from other organic products.

In this connection it is important to separate the heat communicated to a room as radiant energy from that communicated by warming the air. In an apparatus contrived for this purpose, a canopy collects all the warm convection currents proceeding from the heater. A delicate electrical method is applied for testing the quantity and temperature of the heat. The heater is surrounded by radiant-heat meters, such as radiometers and thermopiles

The effect on the human organism of dust in the air must be determined, but as there are millions of particles per cubic inch, special methods are required for counting them. In the "Aitken" dust counter a minute sample is measured and diluted largely with a known quantity of pure and dustless air. The particles of dust in a fraction of this enlarged volume are deposited on a glass plate underneath a microscope and actually counted. By multiplying by the total number in a cubic inch, the original sample can be calculated.

In no respect has the science of heating and ventilation been more backward than in the knowledge of laws governing the movements of air. The flow of air is brought about by the operation of very trifling momentary and constantly varying causes. So, no doubt, is the flow of electricity in relatively large quantities at low voltages. The ventilating engineer is also concerned with a comparatively large flow of air at low differences of potential. The electrician would find difficulty in investigating the current through a cube of copper measuring three feet in every direction. Local circuits would be set up by any accidental distribution of electromotive force, such as those set up by the movements of a magnet in the neighborhood. This exactly corresponds to the problem with which the engineer is confronted in ventilating a building. Air is introduced, for instance, into a room at a certain point. At other points in the room, sometimes near, sometimes remote, from the point at which the air is introduced, currents of air which the occupants of the room call "drafts," are experienced. It is held up as a reproach to the ventilating engineer that these exist, and so no doubt it is. Yet the laws of pneumatics are quite as definite as those of electricity. The difficulty is in gaging and controlling the working conditions. In developing experimentally the laws of pneumatics on a basis somewhat similar to those of electricity, standard units must be evolved comparable with those of electrical science.

We are experimentally testing the validity in all kinds of pneumatic flow of a fundamental formula similar to Ohm's law. The law may be stated as $H = RQ^2$. The unit of aëromotive force H is naturally a foot of air column, or that difference of pneumatic pressure against which it would require one foot-pound of work to force one pound of air. The unit of flow Q is one cubic foot of air per second. Since the corresponding unit of resistance is closely equal to the resistance of a hole 6 in. diameter in a thin flat plate, a pressure equal to one foot of air column will cause a flow of one cubic foot per second through the hole. If we can compare all pneumatic resistances with this unit, we will understand the flow of air better than when working with the present complicated formulas. The fundamental difference between the laws of pneumatic and of electrical flow is that in the former the aëromotive force is nearly proportional to the square of the flow, whereas with electricity the electromotive force is exactly proportional to its first power. These differences are not sufficient to exclude the application of similar experimental methods. A large apparatus, the pneumatic analogue of the Wheatstone bridge, is used for the determination of pneumatic resistances, and sundry methods of battery resistance have been applied to determine the internal resistance of a fan. If we can specify the proper resistance in pneumatic units for a boiler flue and chimney, we can deal rationally with the much vexed chimney problem. This problem has been treated only in the most incomplete and perfunctory manner. We can determine, by the application of these rules, the actual resistance of a boiler flue, and can tell exactly the maximum capacity of a plant in heat units or in pounds of steam, even without lighting the fire in the boiler. To thus determine the resistance of boiler flues and chimney shaft, it is only necessary to have a fan discharge to the boiler through a chamber in which a constant low pressure of air can be maintained. The resistance between the fan and the boiler inlet is then varied, the current measured, and the pneumatic resistance can be at once established.

It is easy to show that the total resistance of a boiler plant consisting of three Lancashire boilers, 28 ft. by 7 ft. 6 in., with a chimney 100 ft. tall, should be about 0.00172 unit of resistance. It is even possible to determine this resistance without a fan or an anemometer, but with a very accurate micrometer pressure gage. By measuring accurately the pressure in the inlet chambers due to the pull of the chimney, the flow of air through the flues at any given moment can be determined by calculation. The resistance of the boiler flues and chimney in pneumatic units can then be easily found.

Enough has been said to show engineers that there is more in this subject than the collection of rough rules of thumb found in the current literature. At present, heating and ventilation resemble mechanical science at the time of Newton, or electrical science at the time of Faraday. It would be very much to the advantage of mankind if engineers would take more seriously a subject worthy of a high place in practical science.

Results of the Locomotive Boiler Inspection Law*

By Frank McManamy†

The following table shows the inspection work performed each year since the passage of the law three years and eight months ago, and the decrease in the percentage of locomotives reported defective indicates in a measure the improvement in conditions:

	1914	1913	1912
Number of locomotives inspected.....	92,716	90,346	74,234
Number found defective............	49,137	54,522	48,768
Percentage found defective.........	52.9	60.3	65.7
Number ordered out of service......	3,365	4,676	3,377

It does not, however, fully show the improved conditions resulting from the operation of the law, because, as pointed out in our 1913 report, attention was first concentrated on the more serious defects, so that the number of fatalities might be reduced; therefore, the improvement is more accurately indicated by the reduction in the number of casualties, as shown by the following table:

	1914	1913	1912
Number of accidents..................	555	820	856
Decrease from previous year, per cent...	32.3	4.2	...
Decrease from 1912, per cent...........	35.1	...	...
Number killed	23	36	91
Decrease from previous year, per cent...	36.1	60.4	...
Decrease from 1912, per cent..........	74.7	...	...
Number injured	614	911	1005
Decrease from previous year, per cent...	32.6	9.3	...
Decrease from 1912, per cent..........	38.9	...	...

The data cited are taken from the records up to July 1, 1914. A check of the first six months of the present year, that is, from July 1, 1914, to Jan. 1, 1915, in comparison with the corresponding period in the preceding years, shows the following results:

During the period ended Jan. 1, 1914, there was a total of 349 accidents that resulted in injury, with 15 killed and 385 injured thereby. During the period ended Jan. 1, 1915, there was a total of 253 accidents that resulted in injury, with 6 killed and 271 injured thereby, or a decrease of 27.5 per cent. in the number of accidents, 60 per cent. in the number of killed and 30 per cent. in the number injured by the failure of locomotive boilers and their appurtenances.

*From a paper before the Western Railway Club, Chicago.

†Chief, boiler inspection department, Interstate Commerce Commission.

Going back further and making a comparison with the corresponding period for 1912, we find that during the six months period ended Jan. 1, 1913, there were 470 accidents that resulted in injury, with 24 killed and 512 injured thereby. In other words, the number killed by failure of locomotive boilers and their appurtenances during the first half of our fiscal year beginning on July 1, 1912, was 12½ per cent. greater than for the corresponding periods in the two following fiscal years, with almost as great a decrease in the number injured and the number of accidents. Or, to state the whole matter briefly, in three years the number killed by failure of locomotive boilers and their appurtenances has been reduced from about 100 per annum to less than one-fourth that number, and the number injured from more than 1000 per annum to less than one-half that number, with a corresponding decrease in the number of accidents.

WHY LAW HAS REDUCED BOILER ACCIDENTS

These are the direct results of the operation of the Locomotive Boiler Inspection law and indicate the manner in which it is fulfilling the purpose for which it was enacted—to promote safety. The question will no doubt arise as to just what the law has done to produce such results; and in reply I will say that they are due to a number of reasons, among which are more careful inspection, more prompt repairs and attention to minor defects, investigation and classification of every accident that resulted in injury, with a view to determining the cause and remedying it, and giving publicity to the information collected.

FEDERAL INSPECTION PROMOTES BETTER MAINTENANCE OF BOILERS

No railroad man with a trace of honesty and a knowledge of conditions and practices prior to the passage of the law can question the fact that, generally speaking, inspections are now more carefully and more regularly, and repairs more promptly, made, and that the question of repairs is less apt to be determined by the number of loads in the yard awaiting movement, although unfortunately that is still occasionally considered to be the deciding factor; an illustration being a recent request by a master mechanic to operate a locomotive with 43 broken stay-bolts a distance of 312 miles, because they needed the power.

FIREBOX STUDS NEGLECTED

The importance of giving attention to minor defects can be shown by an illustration: During the last fiscal year 18 persons were injured from studs blowing out of firebox or wrapper sheets. In almost every instance they gave warning of their defective condition by leaking before they blew out; and they can be renewed with less expense to the company at that time than after they blow out and cause injury. It should be done, and the practice of repairing leaking studs by calking, or permitting them to continue in service without repairs, should be discontinued.

Investigating every accident to determine the cause, and classifying it so that the number and causes of the various accidents can be readily seen, has been an important factor in shortening the accident list. This information is given publicity in our annual report for the purpose of directing attention to the causes of accidents so that they may be avoided.

FEWER CROWN-SHEET FAILURES

I have recently had occasion to read carefully statements made before Congressional committees at the time the boiler-inspection law was pending, to the effect that all boiler explosions were really crown-sheet failures due to low water, therefore, were man failures which could not be prevented by Federal supervision; and still more recently have listened to a repetition of these statements from a source which would indicate that they represented the consensus of opinion of railroad officials. To correct this misapprehension, attention is directed to the records of such accidents since July 1, 1911.

During the year 1914, as compared with 1912, accidents which are usually termed boiler explosions which resulted in injury have decreased 44 per cent. or from 97 in 1912 to 54 in 1914, and the number of killed and injured has decreased 64 per cent., or from 290 to 104. During the same period crown-sheet faiures due to low water decreased 48 per cent., or from 92 to 48.

I am directing attention especially to this class of accidents, first to show that such casualties as these, which were said to be unpreventable, have been materially reduced, and also because our investigations have shown that by proper application and maintenance of boiler appurtenances they can be still further reduced. I refer to the location, manner of application and maintenance of such appurtenances as injectors, gage-cocks and water glasses.

INCONVENIENT LOCATIONS OF GAGE GLASSES A MENACE

Rule 42 provides that "every boiler shall be equipped with at least one water glass and three gage-cocks. The lowest gage-cocks and the lowest reading of the water glass shall be not less than 3 in. above the highest point of the crown-sheet." While it may be a compliance with the letter of the law to locate these appurtenances where they can be most easily applied, regardless of their convenience to the enginemen, it is manifestly not a compliance with the intent of the law and is not conducive to safety, as an improper or inconvenient location may seriously interfere with their proper use. As an illustration of an improper location, a certain type of locomotive has the water glass directly behind the engineer and out of sight of the fireman. As these locomotives are used in passenger service on a busy division, where it is at times necessary for the engineer to read a signal each 20 sec. or less, it is certain that under such conditions the reading of the water glass will not be as frequent as it would if placed in a more convenient location.

In other instances glasses are found so obscured by other boiler appurtenances or by improper shields that it is difficult, and under certain conditions impossible, to see the water level. A recent investigation of a crown-sheet failure showed that the cab arrangement was such that the water glass and gage-cocks were 9 in. above the engineer's head and that ne regularly carried a small keg to climb upon to try the gage-cocks. Can it be seriously questioned that such conditions cause accidents, particularly when operating in a busy terminal?

Using a shield that obstructs the view of the water glass is also too common. In some instances it has been found that the shield almost entirely obscures the water glass. On deckless locomotives we frequently find the water glass located behind the wind sheet or back wall of the cab, in such a position that only by leaving his usual position and peering intently into the space between the boiler head and wind sheet can the engineer see the water level. On the same type of locomotives we find gage-cocks so located that to try them the enginer must step back out of reach of the throttle, brake valve and reverse lever. The inevitable result is that when busy switching, or when trying to get a tonnage train over a hill on a slippery rail, gage-cocks located out of reach are not used as often as they otherwise would be.

VITAL IMPORTANCE OF CORRECT LOCATION OF BOTTOM GAGE-GLASS FITTING

The manner of application is also important, both as to water glasses and gage-cocks; and in reference to this I will quote a paragraph from a paper I read before this club in 1913:

> Another matter that has not always received the consideration that it should is the location of the bottom water-glass fitting. The opening of the boiler for this fitting should always be above the highest point of the crown-sheet, yet on a large percentage of locomotives they appear to have been located without much regard to the height of the crown-sheet, the proper height of the lowest reading of the glass being obtained by the use of nipples of various lengths. When this opening to the boiler is made below the highest point of the crown-sheet, if the top water-glass cock is closed or the opening restricted, water will show in the glass when there is none on the crown-sheet, and we have records which show that this has been the cause of more than one crown-sheet failure; therefore, I desire to urge the importance not only of having the fitting so applied that the glass cannot under any circumstances show water when the crown is bare, and this means that the fitting should be so designed and located that the proper reading of the glass can be obtained and the opening to the boiler kept above the crown-sheet.

I am referring to this again for the reason that investigations conducted since that time have shown positively that the combination of conditions shown in that paragraph is one cause of crown-sheet failures, one of which occurred quite recently.

GAGE-COCKS AND THEIR DRIPPERS

We also find that the manner in which gage-cocks and gage-cock drippers are applied indicates that the purpose for which they were applied did not receive sufficient consideration. While the application of a dripper is important to prevent the discharge from the gage-cocks scalding anyone in the cab, it should not be so close to the cocks that the nipples extend down into the dripper, preventing enginemen from seeing the discharge, as dripper pipes occasionally become obstructed and fill with water, in which event the sound of water and steam are identical.

This is not offered as an excuse for crown-sheet failures due to low water, because we believe there are no excuses; but our investigations have shown that these conditions are sometimes the cause of such accidents; therefore, sufficient care and foresight should be exercised to so apply all these appurtenances that they will to the best advantage serve the purpose for which they are required.

FREQUENT FAILURES OF INJECTOR STEAM PIPES

Failure of injector steam pipes continues to be one of the most frequent causes of serious accidents, and is the only one which shows an increase during the present fiscal year over the corresponding period for the previous year.

Of 16 injector steam-pipe failures five were due to nuts breaking, one to threads stripping, one to a nut being too large, five to collar or sleeve breaking and four to defective brazing. Each of the accidents due to the nut breaking or stripping resulted from attempting to tighten the joint without shutting off the pressure, for which the remedy is obvious, although perhaps somewhat difficult to apply.

BRAZED JOINTS DANGEROUS UNLESS REINFORCED

The other nine failures, four of which were due to poor brazing and five to collar or sleeve breaking, could, I believe, have been prevented by extending the pipe through the collar or sleeve and flanging or beading it, thus reinforcing the collar and reducing the strain on it, as the end of the pipe itself will be solidly held in the joint; therefore, it will carry the load. If properly applied in this way, brazing is not necessary, although it can be done if desired. This method of application is at least as cheap as brazing, and defective or improper workmanship can be discovered by inspection, which is impossible with the brazed connection.

The discussion on the location of the bottom fittings of gage-glasses was to the effect that that fitting should always be placed above the highest point of the crown-sheet, notwithstanding the complaint of some engineers that such location prevents a timely warning of foaming.

Fuel-Oil for Locomotive Use*

From 1907 to 1914 the use of fuel oil by railroads increased 112 per cent., until a total of 31,000 miles, distributed over 50 railways, was operated with this fuel. For a time during the years 1912 and 1913 there appeared to be a tendency to discontinue the use of oil, on account of the great demand for the distilled products of crude oil used for other purposes, leaving a diminished supply of fuel oil and residuum. Opening up of new fields, more efficient methods of distillation, the production of gasoline from natural gas, etc., have again increased the fuel oil supply, and its use is again extending.

In the combustion of fuel oil, where a steam spray is used for vaporization, we are confronted with the fact that in the process of atomization the particles of oil are started on their way to the flues even before they are partly burned. The first result of these particles coming into the heated portion of the furnace is to separate the carbon from the hydrogen, the former thus being left as a fine dust floating in the furnace in such a manner as to be easily carried to the flues unconsumed, to be deposited as an insulating layer of soot, or to be carried out of the stack in the form of black smoke. If these fine particles of carbon were attached, as in a bed of coals, a supply of air could easily complete their combustion. With liquid fuel, therefore, the diffusion must be simultaneous with ignition, with the resultant long flame. The surface tension of oil, especially when the particles are finely divided, is such as to make the drops assume a spherical form of extreme rigidity and therefore expose the least possible area to the oxygen. We are thus brought to realize that large furnace volume is essential to the burning of fuel oil. While the relative dimensions are of minor import to the volume, it is evident that a flame passage of sufficient length to prevent unconsumed particles passing to the flues must be provided. It was the realization of the limited volume of the locomotive furnace that brought about the change from back- to front-end burner arrangement a few years ago, in an attempt to lengthen the flame path.

While it is generally conceded that lack of oxygen is responsible for smoke, the restricted furnace volume and the attending lack of time for the proper mixture of the gases in the more highly heated portion of the furnace is the most common cause for black smoke from an oil-burning locomotive. One of the difficulties met with in the use of oil in the locomotive is the frequent necessity for the removal of soot from the flues, by means of sanding out. This, of course, is attended with several disadvantages, not the least of which is the resultant loss of fuel.

Special attention is brought to this point in connection with locomotive oil-burner furnace design because of the general tendency to restrict the furnace volume by carrying draft pan and brickwork too high in the firebox, covering up valuable heating surface and bringing about the continual necessity for forcing the fire at the expense of the remaining exposed surfaces.

*Abstract of paper read by G. M. Bean before the International Railway Fuel Association, Chicago, May 17-20, 1915.

One of the principal requirements in the burning of oil is to expose the fuel to the furnace heat so that the greatest possible area is presented to the oxygen. A study of the atomization of oil is therefore of some importance, and it will be readily seen that the stretching of the surface of fuel oil is a study of capillary action and that it is not hard to determine the work necessary. Oil in bulk has little surface, but when broken up into fine particles it has the combined surface of the spherical areas of the drops thus formed, and the work of atomization is the work of stretching the surface of exposure.

Theoretically, it should be possible to atomize oil to a definite fineness of spray by means of a mechanical device much more economically than by means of the steam jet.

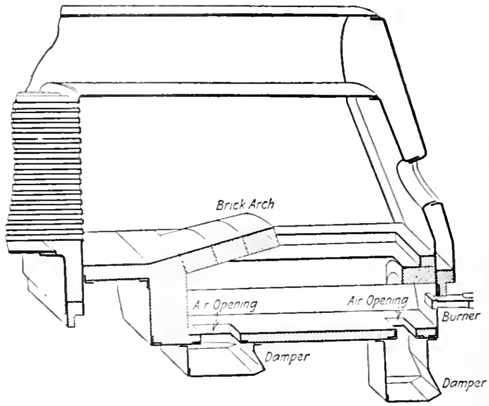

FIG. 1. BURNER AT BACK OF FURNACE

Many attempts have been made along this line, with almost as many failures. The simplicity and flexibility of the steam-jet burner make that method difficult to improve, and the fact that the type of burner now in use on the majority of locomotives is practically the same as the one first introduced in this country would lead to the belief that when improvement is made in the oil-burning locomotive furnace, it will not be made in the burner. One of the simplest of all burners and now standard on the Santa Fé Ry. has been in continuous use on that line since oil was first introduced as fuel, and has never failed, in itself, to show up well in connection with any furnace design. In other words, where failures in design or arrangement were met with, it was always traced to other features being wrong, rather than the burner. The type of burner therefore seems of minor importance, so long as it is simple, substantial, not easily stopped up and easily cleaned.

Locomotive furnaces are not considered ideal for the use of fuel oil, and for this reason as much as any other there have been as many different furnace arrangements as there have been localities in which oil fuel has been used.

At the first inception of the idea in this country it was natural that the designs used in Russia should be followed. The burner was placed under the rear of the firebox, Fig. 1, and directed forward with an upward incline, so that the flame shot under a low, short brick arch, with the result that combustion became so intense in this limited space as to cause the flame to pass from under the arch with such velocity as to impinge on the door-sheet, side-sheets and crown-sheet, with detrimental results. Bad water conditions throughout the Southwest aggravated this to such an extent that the life of fireboxes was only about eighteen months or two years, and the replacing of them soon became a severe burden. The back-end burner arrangement also required an excessive quantity of firebrick, which not only gave trouble by continually burning out, but also served to cover up valuable heating surface, restrict the furnace volume and throw an increased load on the remaining heating surface.

While the back-end burner arrangement is still in use to some extent throughout Texas, it has entirely disappeared from every other section. The burner is now placed in the front end of the draft pan, Fig. 2, and directed toward the rear in such a manner that the draft is forced to reverse the direction of the flame before it passes to the flues. The furnace is open, the brickwork is kept low and the maximum of heating surface is exposed. The correct drafting of this arrangement is still a somewhat debatable subject, but the general idea seems to favor the admission of the principal volume of air through openings in the vicinity of the flash-wall, which is built up under the door, it being the plan to admit this air through numerous small openings, preferably circular in shape and distributed well over the rear third of the draft pan in such a manner that the air is brought in contact with the flame from several directions and not in too concentrated a volume. A small amount is also admitted around or under the burner, so as to prevent it from overheating and to keep the flame from dragging on the floor of the pan. This arrangement results in a uniform distribution of heat and the consequent lengthened life of the fireboxes and flues, until it can safely be said that for service under like conditions, a firebox on a locomotive burning oil will last longer than one in a coal burner if consideration is given to the extra work possible to be obtained from the oil burner.

Oil requires from 20 to 30 per cent. more air per pound of fuel than the average bituminous coal. There is a tendency to restrict the air openings in draft pans of oil burners, and it is generally the rule that with locomotives of the same class in both oil- and coal-burner service, the oil burner will have the smaller nozzle, indicating the necessity for maintaining a higher front-end vacuum to draw in the necessary amount of air to make the engine steam properly. This is attended with the added difficulty that the high velocity of the entering air produces a more concentrated column or stream, which is difficult to break up, requiring a heavy atomizer, the use of which has its disadvantages.

There is a question whether the open furnace created by the front-end burner arrangement is all that can be desired, for it is true that the gases will follow the path of least resistance and the velocity at the center of the combustion space will be much higher than at the sides, this indicating the necessity of some sort of a baffle to increase the velocity of flow at the top and sides where the gases wipe the heat-absorbing firebox sheets. It is also apparent that when the flame path is surrounded by heat-absorbing surfaces to hasten the process of diffusion and shorten flame length, the subjecting of the gases to the presence of incandescent baffles is desirable.

Aside from the two furnaces outlined there is in service on one of the Southwestern railways, as well as on some Mexican railways, the arrangement shown in Fig. 3. This differs from the others in that it has a burner in both the front and the rear of the draft pan, directed toward each other, the line of flame of the front burner being slightly higher than that of the rear. This furnace also has the advantage of the low brickwork and large exposed heating surface. In fact, the opposing burners do away with the necessity for a high flash-wall under the door.

Fig. 2. Front-End Burner Furnace

In the two last-named types it is the practice to keep the brick low on the sides and expose all possible heating surface. Firebrick for this service must be of good quality, as the firebox temperatures range from 2500 to 2750 deg. F., which, with the fluxing action of the salt and alkalies carried in the oil, are severe on the furnace and cause it to give out readily, making frequent renewals necessary. The proper maintenance of brickwork is essential to good results, and the possibility of the brickwork falling down in the path of the flame must be avoided, as it usually results in an engine failure.

The oil supply is carried in tanks built to fill the coal space of the tender and piped from there through suitable connections to the burner. It is generally necessary to provide means for heating the oil so as to insure a proper flow, as gravity is depended upon for the necessary pressure. This heating is also an aid in atomizing, and various means are provided for the purpose. The original practice was to turn steam directly into the oil, but aside from an emergency feature, this has been generally abandoned, as the accumulation of condensation gave trouble in disposal, as well as by getting into the oil line and interfering with the burner operation. The draining of the condensation from the tank was always accompanied by some loss of oil, and the direct heating often resulted in overheating the entire contents of the tank, with the attending loss. An improvement was to place steam coils in the space and heat indirectly. This had some advantages, but it also caused trouble by overheating and by the pipes leaking at the joints. It is probable that the box heater is the most desirable arrangement. It is indirect in its action, only heats a sufficient volume to insure a supply at the burner and is not liable to cause trouble by allowing water to get into the oil storage.

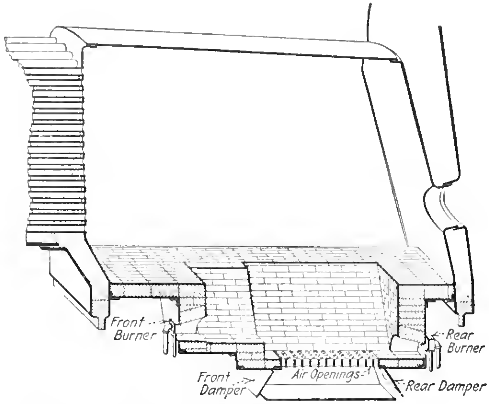

Fig. 3. Burner and Brick Arrangement in the Hammel Furnace

The oil-storage tanks are provided with suitable gages or measuring devices to give a check on their contents at all times. Means are also provided for cutting off the supply of oil to the burner in case of accident, such as a wreck or a break between the engine and tender. The supply of oil is regulated by means of a suitable valve placed near the burner and operated through connections by the fireman. In some climates it is necessary to provide an auxiliary heater in the pipe line to reheat the oil before it goes to the burner. Such a heater should be used only when necessary, as extensive heating tends to carbonize the fuel in the oil-supply line and the burner.

Emphasis should be placed on the fact that the oil fireman is an important factor in the success of the operation of oil-burning locomotives. He must intelligently follow every movement of the engineer that demands regulation of the fire. He has two gages to guide him—the top of the stack and the steam gage. That is, the proper steam pressure must be maintained with the least possible smoke. A thin gray color at the top of the stack is usually indicative of proper combustion.

Given a modern locomotive with a furnace designed along the lines indicated, with equipment in proper adjustment and an intelligent engine crew, the result should be of as high an order as is so far attainable with steam-operated motive power.

New York State N. A. S. E. Convention

The twentieth annual convention of the New York State Association; N. A. S. E., was held June 11 and 12 at Auburn. Upward of fifty delegates were in attendance at the business sessions, which were held in Woodmen's Hall. The first floor of this building was arranged for the use of exhibitors. The convention was called to order Friday morning by F. J. De-Witt, chairman of the local committee. He introduced City-

Att[illegible] William S. Elder, who welcomed the delegates in the absence [illegible] Mayor Charles W. Fraster. State-President Frederick [illegible] responded to this address of welcome. The next [illegible] was Charles G. Adams, secretary of the Auburn Chamber of Commerce, who gave a description of the manufacturing resources of the city. National Vice-President Walter [illegible] of Buffalo dwelt briefly on the aims and principles of the association. He was followed by Past-National-President Reynolds, of New Jersey, who outlined the aims and plans of "The National Engineer." State-President Felderman then called the business meeting to order and announced the various committee appointments.

A feature of the convention was a luncheon given to the delegates and guests at the Osbourne House, through the courtesy of the McIntosh & Seymour Corporation. Afterward, special cars conveyed the party to an inspection of the company's plant. The entertainment program also included an illustrated lecture on oil and steam engines, given under the auspices of the McIntosh & Seymour Corporation, an inspection of the Auburn prison, a trip to the plant of the Empire Gas & Electric Co., and auto rides for the ladies to points of interest in the city.

A pleasant surprise to State-President Felderman was the presentation of a handsome clock. A silver service tray was given to his wife. Past-National-President Reynolds made the presentation addresses. A memorial service for members who had passed away during the past year was conducted by Vernon N. Yergin, pastor of Calvary Presbyterian Church. At the closing session Niagara Falls was chosen for the June, 1916, meeting. The state officers unanimously elected were: William H. Aydelotte, of Niagara Falls, president; William Downey, New York City, vice-president; William Roberts, Yonkers, secretary; William Downes, New York City, treasurer; Joseph C. Butrich, conductor; George Ely, doorkeeper; and David Larkin, chaplain. William Bedard was chosen to succeed himself as state deputy.

The exhibitors were as follows:

Albany Lubricating Co.
Amer. Steam Gage & Valve Co.
Anderson Co., V. D.
Auburn Woolen Co.
Burg & Hill
Clapp Mfg. Co.
Columbian Rope Co.
Crandall Packing Co.
Cross, Orrin C.
Cuddy & Geherin
Dearborn Chemical Co.
Dunn McCarthy Co.
Eccles Co., Richard
Engineering Supply Co.
Garlock Packing Co.
Garrett Coal Co.
Henry & Allen
Herron Hardware Co.
Home Rubber Co
International Harvester Co.
Interstate Machine Co.
Johns-Manville Co., H. W.
Keystone Lubricating Co.
Lunkenheimer Co.
McIntosh & Seymour Corp.
McLeod & Henry Co.
"National Engineer"
New Birdsall Co.
Otis Elevator Co.
Peerless Rubber Mfg. Co.
"Power"
Quaker City Rubber Co.
Roebling Sons Co., John A.
Smith & Pearson
Wadsworth, David & Son
Woodruff & Murphy.

DELEGATES TO NEW YORK STATE N. A. S. E. CONVENTION, IN FRONT OF AUBURN STATE PRISON

Co-operators

To conserve and continue the work done by Frederick W. Taylor, the initial steps have been taken to found an organization to be known as the Frederick W. Taylor Coöperators. In harmony with Mrs. Frederick W. Taylor's request, James M. Dodge, Carl G. Barth, Morris L. Cooke and H. K. Hathaway have taken the initiative and have issued a preliminary letter stating the purpose of the organization. This is to gather books, data and other material that would be of use in a biography or for a memorial to Mr. Taylor, and to provide for the continuation and extension of the Taylor System of Management.

Rear Admiral Isherwood Dead at 92

Benjamin Franklin Isherwood, engineer-in-chief of the United States Navy during the Civil War and one of the founders of the experimental theory of the steam engine, died at his late residence in New York on June 19, in his 93d year. Born Oct. 6, 1822, in New York City, he was a great-grandson of a distinguished French military engineer, Captain Du Clos, an officer on General Lafayette's staff in the American Revolution. His early schooling was received at the Albany Academy, where he studied natural philosophy under Joseph Henry, after which he entered the employ of the Utica & Schenectady R.R., and later went to work on the construction of the Croton aqueduct, on its completion entering the service of the Erie R.R.

His entry into governmental service was under the Lighthouse Board, where he seems to have performed work of responsibility, for he was sent to France to superintend the construction of some lighthouse lenses from designs by himself. The steam-engineering corps of the Navy was meanwhile being organized by Charles H. Haswell, and Isherwood was one of its earliest appointees, being made first-assistant engineer, and in 1848 was promoted to chief engineer. Meantime the Mexican War had been fought and he had been an active participant on shipboard; in fact, he was in every naval action. He served on the "Princeton," the first American screw steam vessel, and later on the "Spitfire." After the war he cruised for three years in the "San Jacinto," attached to the Asiatic squadron.

Late Rear Admiral Isherwood

One of the earlier performances that brought Isherwood professionally into notice was the design of alterations for the engines of the "Allegheny," 1851-52. He arranged the cylinders with a back-acting motion in a manner which anticipated the type of engine afterward bearing his name. The device showed his mechanical ingenuity, although the vessel as a whole was not a success, and the experience taught him in future designing to provide engine frames strong enough to allow for weakness in the hull, a point which was especially important when so many old vessels, many of which were of light construction, had to be equipped during the Civil War.

At the outbreak of the Civil War, Isherwood, although some distance from the top of the list, was appointed to the responsible position of engineer-in-chief of the war navy. His appointment was dated Mar. 26, 1861. Not only did he evince a dependable zeal for the Federal Government—which, at a time when so many officers were going over to the Confederacy or wavering in their allegiance, was no small recommendation—but his professional qualifications were of an exceptionally high order. For many years past he had given his attention to systematic experimental research in steam engineering, where he had done splendid work and was probably the leader in America. The result of some of these researches had been given to the public, notably in 1859, in a book entitled "Engineering Precedents," which embodied his studies on the indicated power of engines, frictional losses, power expended in actual propulsion of vessels, etc. It is interesting to note that this book had the first published indicator diagrams reproduced from actual engines.

The task confronting Isherwood upon his appointment was that of evoking a new and large navy out of nothing, or next to nothing, in a short period. At the beginning of the war the Government had only 69 vessels of all classes, 34 of them being sailing ships. By the end of the year 1861 it had improvised a navy amounting to 211 vessels, with 2301 guns and 20,000 men, which by the close of the war had grown to 600 vessels of all classes.

One of the reasons for Isherwood's success was his strong common sense, which was shown particularly in the design of the machinery built during the Civil War. Although the adoption of a low ratio of expansion, and hence high mean pressure, gave him small engines, the machinery was very heavy. Designers working 30 or 40 years later, with improved materials, have criticized this machinery, forgetting one point with which Isherwood was supreme—this machinery was designed for war vessels, and it was absolutely essential that it should not break down. The enormous expansion of the Navy led to the employment of large numbers of patriotic but comparatively unskilled engineers. To have intrusted delicate machinery to such men would have been to run the risk of disaster. For the same reason, such expansion as was obtained depended only on the ordinary Stephenson link, there being no separate and complicated cutoff gears. But almost incredible was his ability to find time for the continuation of elaborate scientific investigations, to profit by his unrivaled opportunity for practical experiments, and even during those busy years to publish in huge volumes the results of his researches.

In 1863, when swift cruisers were coming into use, speed qualities received especial attention. About this time the rivalry in design between Isherwood and Ericsson was carried out in the construction of twin 4200-ton ships—the "Madawaska," with engines of Ericsson's design, and the "Wampanoag," fitted with Isherwood engines. The latter had a pair of 100-in. cylinders with 4-ft. stroke and wooden gears, to make 2.04 revolutions of the screw for each double stroke of the piston.

Here, again, we note an illustration of Isherwood's sound common sense. The machinery, which for the time was extremely powerful, was to go into a relatively light wooden hull, and to have used direct-driven engines would have racked the hull. Ericsson's engines were of the same size, but directly connected to the shaft. In the trials the "Wampanoag" made a wonderful record for those days, attaining an average speed of over 16 knots in a winter's sea, and during several periods of a six-hour run over 17 knots were obtained. The "Madawaska" also was capable of high speed, but she could not stand the racking. This did not disprove Ericsson's essential correctness in having, long ago, come out as an advocate of direct, ungeared connections, but the abnormal narrowness of the vessel created a special condition to which the design of her machinery was not adapted. Not for 21 years was the "Wampanoag's" speed again reached in the Navy.

In the early personnel struggles, Isherwood was a champion of his corps. He contended that naval engineers required not only technical training, but theoretical education, and should possess official rank, which has since become established. It is largely to him that we may credit the Congressional Act of 1864 providing for the education of midshipmen as naval constructors or steam engineers.

After serving as engineer-in-chief for eight years, covering the stressful period of the war, Isherwood was succeeded, in 1869, by James W. King. The remainder of his term in the service was largely taken up with special duties. His experiments with screw propellers at Mare Island are scarcely less famous than the expansion tests and those on the economy of compound engines.

By operation of law he retired in 1884 with the relative rank of commodore (since raised to rear-admiral). More than a quarter of a century of life was still in store for him, however. He made his home in New York City, interested and active in research, scientific and literary work, and indulging in extensive tours abroad. The published output of his life in books and papers has been considerable. His "Experimental Researches in Steam Engineering," compiled in Civil-War times, has become a classic, and, as the late Dr. Thurston pointed out, "his conclusions, once ridiculed, are now the basis of the modern engineer's practice."

OBITUARY

BEN B. LAMPREY

Ben B. Lamprey died June 14, at the age of 68, in Westfield, Mass. He was born in Moultonborough, N. H., and in his younger days conducted a hotel and ran a steamboat line at Lake Winnepesaukee. He was the inventor of the Lamprey arch plate and of other devices for low-pressure steam boilers, and was the owner of the Lamprey Boiler, Furnace & Protective Co., of Boston.

PERSONALS

M. A. Hudson, formerly vice-president and general manager of the J. E. Lonergan Co., Philadelphia, Penn., has become general manager of the Central Western branch, United Roofing & Manufacturing Co., with headquarters in the Marquette Building, Chicago.

J. N. Oswald, formerly a member of the engineering department of the Pittsburgh Ry. Co., has been appointed mechanical engineer with the Vacuum Oil Co., Pittsburgh. He was the first erecting engineer of the Nagle Corliss Engine Works, of Erie, Penn., and was for 11 years at the head of the power department of the Gould Coupler Co., Depew, N. Y. Mr. Oswald is president of Pittsburgh No. 3, N. A. S. E.

Osborn Monnett, after a creditable service of four years as chief smoke inspector of the City of Chicago, has become associated with the Institute of Thermal Research of the American Radiator Co., Chicago. In this connection he will offer his services to smoke commissions and smoke inspectors throughout the United States and in every way possible coöperate with those interested in the movement to standardize smoke ordinances and to abate the smoke evil in the heating field. Mr. Monnett was an associate editor of "Power" before taking the Chicago position.

ENGINEERING AFFAIRS

The Canadian Association of Stationary Engineers will hold its annual convention July 20-22, at Hamilton, Ont. It is expected that the attendance of delegates and the display of exhibits will be larger than ever before. The local committee, with the assistance of the officers of the Exhibitors' Association, has arranged an enjoyable entertainment program.

The New England States Association of the National Association of Stationary Engineers will hold its annual convention in Holyoke, Mass., July 7-10. The Nonotuck Hotel has been selected as the headquarters. The meetings of the delegates will be held in the large hall of the Temperance Building, and the City Hall has been secured for the exhibits. An enjoyable program of entertainment has been arranged by the local engineers' committee and by a committee of the supplymen.

TRADE CATALOGS

International Nickel Co., 43 Exchange Place, New York. Catalog. Monel metal. 12 pp., 4x8½ in.

General Electric Co., Schenectady, N. Y. Bulletin No. 42,552. Motor generator sets. Illustrated, 28 pp., 8x10½ in.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Bulletin 34-X. Class A-G "Giant" gas and gasoline engines. Illustrated, 8 pp., 6x9 in.

Fisher Governor Co., Marshalltown, Iowa. Bulletin Catalog. Pump governors, reducing valves, pressure regulators, etc. Illustrated, 6½x9½ in.

Ingersoll-Rand Co., 11 Broadway, New York. Form No. 3031. Ingersoll-Rogler Class FR-1 air compressors. Illustrated, 24 pp., 6x9 in. Form No. 4034. Leyner-Ingersoll water drill. Illustrated, 4 pp., 6x9 in.

A. S. Cameron Steam Pump Works, 11 Broadway, New York. Bulletin No. 104. Station and sinking pumps. Illustrated, 36 pp., 6x9 in. Bulletin No. 150. Double suction volute centrifugal pumps. Illustrated, 16 pp., 6x9 in. Bulletin No. 151. Turbine centrifugal pumps. Illustrated, 20 pp., 6x9 in. Bulletin No. 152. Single suction volute centrifugal pumps. Illustrated, 8 pp., 6x9 in. Bulletin No. 153. Centrifugal pumps for house service. Illustrated, 8 pp., 6x9 in. Bulletin No. 300. Triplex pumps. Illustrated, 4 pp., 6x9 in.

NEW EQUIPMENT

ATLANTIC COAST STATES

Bids will be received until 2:30 p.m., June 29, by E. S. Elwood, Secy., State Hospital Comn., Capitol, Albany, N. Y., for the construction and equipment of a power house and electrical work at the Middletown State Homeopathic Hospital, Middletown, N. Y.

The Board of Education, Paterson, N. J., has engaged Lewis E. Eaton, Consult. Engr., to prepare plans for a light and power plant for the High School. An appropriation of $5000 has been made for the work.

SOUTHERN STATES

An election will be held June 29 in Orangeburg, S. C., to vote for a bond issue of $15,000, the proceeds of which will be used for the improvement of the municipal electric-light plant. Edward Howes is City Engr.

The City Council of Cordele, Ga., will engage an engineer to prepare plans and estimates for the construction and operation of a municipal electric-light plant in Cordele.

At a recent election the citizens of Toccoa, Ga., voted in favor of issuing $35,000 in bonds to be used for the installation of a municipal electric-light plant.

CENTRAL STATES

The Falls Rubber Co., Cuyahoga Falls, Ohio, is having plans prepared for a one-story brick and steel power house for its plant. Ernest McGeorge, Leader-News Bldg., Cleveland, is Engr.

It is reported that the Ohio Public Utilities Commission has authorized the Dayton Power & Light Co., Dayton, Ohio, to issue $172,000 in additional capital stock, the proceeds of which will be used to increase the output of the plant from 20,000 to 30,000 hp.

The City Council of Wellsville, Ohio, will soon advertise for bids for the sale of $60,000 in bonds, the proceeds of which will be used for the construction of a municipal electric-light plant.

It is reported that bids will be received until July 12 by the Wernette-Bradfield-Meade Co., Arch. and Engr., Grand Rapids, Mich., for the construction of a power plant for the Imperial Furniture Co., Grand Rapids.

It is reported that the City of Petoskey, Mich., is preparing to rebuild the municipal electric-light plant. J. W. Lovelace is Mgr. and Supt.

The Town of Three Rivers, Mich., is reported to have $50,000 in bonds available for the construction of a municipal electric-light and water-works plant. George Champe, Toledo, Ohio, is Consult. Engr.

WEST OF THE MISSISSIPPI

It is reported that the Des Moines Electric Co., Des Moines, Iowa, contemplates the construction of a 44,000-volt transmission line to Knoxville, Iowa, to furnish energy to the Knoxville Electric Co.

(Official)—Bids will be received until July 1 by the City Council of Davenport, Neb., for the installation of an electric-light plant to cost about $5000. Charles F. Sturtevant, Holdrege, Neb., is Consult. Engr. Noted June 22.

The City Council of Holdrege, Neb., has extended the franchise of the Holdrege Lighting Co. for a period of 25 years. The company has agreed to reduce its rates for lighting and will make various improvements in its plant.

The Union Light, Heat & Power Co., Fargo, N. D., is enlarging and improving its power station, and will install new equipment, including two 1500-kw. steam turbines, two water-tube boilers, a three-unit motor generator set of 600 hp., boiler feed pump, exciters, switchboard, etc. M. L. Hibbard is Mgr.

(Official)—Bids will be received until 2 p.m., July 15, by John A. Ryan, Secy., Bd. of Pub. Wks., Chillicothe, Mo., for installing in the municipal electric-light plant the following equipment: One 375-kw., three-phase, 60-cycle, 2300-volt generator, direct-connected to a steam engine or steam turbine to operate condenser, with separate exciter, switchboard panel and instruments, power circuit panel, etc.; one 500-g.p.m. motor-driven centrifugal pump, for use with condenser, and one 12-in. barometric condenser, one 12-in. horizontal oil separator, and the necessary pipe, valve fittings, etc., required to install the pump and condenser. Harper & Stiles, Grand Ave. Temple, Kansas City, is Consult. Engr.

The Missouri Public Utilities Co., Cape Girardeau, Mo., has been granted a franchise to construct a transmission line from its power station at Charleston, Mo., to East Prairie, a distance of 12 miles, to furnish electrical service to the latter place.

It is reported that H. W. Wright and Thomas Peterson, both of Peoria, Ill., are considering plans for the installation of an electric-light and power plant in Fulton, Mo. Energy for the operation of the plant will be obtained from the Keokuk Electric Co., Keokuk, Iowa.

Henry S. Grimes has made application to the City Council of Lowry City, Mo., for a franchise to install an electric-light plant in Lowry City.

It is reported that the City of Brownsville, Tex., is considering the sale of the municipal electric-light plant to a company which will also take over the street-railway company and combine the two properties. J. W. Davis is City Engr.
